

24 **Abstract.** The increase of secondary species through cloud processing potentially increases
25 aerosol iron (Fe) bioavailability. In this study, a ground-based counterflow virtual impactor
26 coupled with a real-time single-particle aerosol mass spectrometer was used to characterize the
27 formation of secondary species in Fe-containing cloud residues (dried cloud droplets) at a
28 mountain site in southern China for nearly one month during the autumn of 2016. Fe-rich, Fe-
29 dust, Fe-elemental carbon (Fe-EC), and Fe-vanadium (Fe-V) cloud residual types were obtained
30 in this study. The Fe-rich particles, related to combustion sources, contributed 84% to the Fe-
31 containing cloud residues, and the Fe-dust particles represented 12%. The remaining 4%
32 consisted of the Fe-EC and Fe-V particles. It was found that extremely high amounts of sulfate
33 had already accumulated on the Fe-containing particles before cloud events, leading to no
34 distinct changes in sulfate during cloud events. Cloud processing contributed to the
35 enhancement of nitrate, chloride, and oxalate in the Fe-containing cloud residues. However, the
36 in-cloud formation of nitrate and chloride in the Fe-rich type was less obvious relative to the
37 Fe-dust type. The enhancement of oxalate in the Fe-rich cloud residues was produced via
38 aqueous oxidation of oxalate precursors (e.g., glyoxylate). Moreover, Fe chemistry involved in
39 the Fenton reaction further promoted the conversion of the oxalate precursors to oxalate during
40 cloud events, although the photolysis of Fe-oxalate complexes also existed in the Fe-rich cloud
41 residues. This work emphasizes the role of combustion Fe sources in participating in cloud
42 processing and has important implications for evaluating Fe bioavailability from combustion
43 sources during cloud processing.

45 processing, southern China

46 **1 Introduction**

47 Iron (Fe) is frequently detected in atmospheric aerosols. Aerosol Fe has an adverse effect on
48 human health, causing issues such as DNA strand breakage and cell damage (See et al., 2007;
49 Abbaspour et al., 2014). Some researchers also reported that aerosol Fe solubility might be an
50 important criterion for toxicity in lung fluid (Costa and Dreher, 1997). Bioavailable Fe derived
51 from atmospheric aerosol deposition can limit the photosynthetic activity of marine
52 phytoplankton in high-nutrient low-chlorophyll waters, indirectly affects oceanic carbon uptake
53 and storage, and has feedback effects on climate (Jickells et al., 2005). Fe-containing aerosol
54 particles contained various species, such as calcium (Ca), silicon (Si), aluminum (Al),
55 vanadium (V), elemental carbon (EC), secondary inorganic and organic species (Zhang et al.,
56 2014; Bi et al., 2016; Dall'Osto et al., 2016). The presence and coexistence of various species
57 could further modify the effects of aerosol Fe on human health, ecology, and climate
58 (Mahowald et al., 2005; Abbaspour et al., 2014).

59 Aerosol Fe sources mainly include mineral dust and combustion emissions (e.g., biomass
60 burning, coal combustion, and iron/steel industrial activities) (Jickells et al., 2005; Sedwick et
61 al., 2007). Abundant Ca, Si, and Al often exist in aerosol Fe from mineral dust sources (Sullivan
62 et al. 2007), while aerosol Fe from combustion sources usually contains EC and other metals,
63 as well as minor amounts of Ca (Li et al., 2013; Dall'Osto et al., 2016). The chemical properties
64 of aerosol Fe depend on its emission sources and could also be modified by the formation of
65 secondary species during atmospheric processes (Zhang et al., 2014; Dall'Osto et al., 2016; Lin
66 et al., 2017). Aerosol Fe in East Asian outflows was often observed to be internally mixed with
67 sulfate, mostly due to the large amount of SO₂ from coal in China (Furutani et al., 2011; Moffet

68 et al., 2012; Li et al., 2013). Sullivan et al. (2007) proposed that the enrichment of sulfate in the
69 Asian mineral dust was possibly due to the Fe-catalyzed oxidation of SO₂ to sulfate. In
70 European urban areas, Dall'Osto et al. (2016) found that aerosol Fe was internally mixed with
71 nitrate rather than sulfate, and was most likely associated with urban traffic activities. The
72 frequent measurement of oxalate in the aerosol Fe was produced via photochemical and/or
73 aqueous oxidation over East Asia (Sullivan and Prather 2007; Yang et al., 2009; Cheng et al.,
74 2017).

75 The above observations about atmospheric processes of aerosol Fe were mainly performed
76 in environments with low relative humidity. Cloud processing accompanied by high amounts
77 of water played a vital role in the formation of secondary species (e.g., sulfate, nitrate, chloride,
78 ammonium, and oxalate) through the partitioning of gas-into-aqueous phases or
79 heterogeneous/multiphase processes (Sellegrri et al. 2003; Lim et al., 2010; Chang et al., 2011;
80 Harris et al., 2013). For example, one model study had estimated that up to 80% of the total
81 production of sulfate globally originated from aqueous reactions (Tsai et al., 2010). The
82 presence of Fe in cloud droplets also allowed the conversion of SO₂ to sulfate via Fe-catalyzed
83 autoxidation reactions (Harris et al., 2013). Furthermore, Fe chemistry involved in Fenton or
84 Fenton-like reactions in cloud droplets yielded OH-radicals that can induce the conversion of
85 glyoxylic acid to low volatility organic aerosols (e.g., oxalate) (Ervens et al., 2011). Variable
86 alkaline species or organic precursors from different aerosol Fe types might affect the in-cloud
87 formation of secondary species. However, research on the effects of cloud processing on the
88 formation of secondary species in various aerosol Fe types remains poorly understood.

89 In this study, we used technology combining a ground-based counterflow virtual impactor

90 (GCVI) coupled with a real-time single-particle aerosol mass spectrometer (SPAMS) to obtain
91 information on the characteristics and potential sources of Fe-containing cloud residues at a
92 mountain site in southern China. Additionally, Fe-containing interstitial (non-activated particles)
93 and cloud-free particles were also analyzed. The impact of cloud processing on the formation
94 of sulfate, nitrate, chloride, ammonium, oxalate precursors, and oxalate in various Fe-
95 containing particle types were addressed.

96

97 **2 Experimental section**

98 **2.1 Sampling site**

99 The sampling site was situated in the Nanling Background Station (112°53'56" E, 24°41'56"
100 N, 1690 m a.s.l.) in southern China. The measured area was in an acid precipitation region
101 (Annual Environment Report of China in 2016, <http://www.mep.gov.cn/hjzl/>). Due to the site
102 being surrounded by a national park forest (273 km²), it was minimally affected by local
103 anthropogenic activities. However, it might be subjected to polluted air masses from the
104 southern Pearl River Delta city groups or from northern China (Lin et al. 2017). A detailed
105 description of the sampling site can be found elsewhere (Lin et al. 2017).

106

107 **2.2 Instrumentation**

108 Cloud droplets with an aerodynamics diameter greater than 8 µm were collected using a GCVI
109 inlet system (GCVI Model 1205, Brechtel Manufacturing Inc.). The collected cloud droplets
110 were dried using an evaporation chamber (airflow temperature at 40 °C) in the GCVI until only
111 dry residual particles (cloud residues) remained. To reliably guarantee the presence of cloud

112 events, an upper-limit visibility threshold of 5 km and a lower-limit RH threshold of 95% were
113 set in the GCVI software (Bi et al., 2016; Lin et al., 2017). During precipitation periods, the
114 GCVI automatically shut down to protect against interference from raindrops. The particle
115 transmission efficiency of the cut size (8 μm) was 50% (Shingler et al., 2012). Due to the cloud
116 droplets being concentrated in the GCVI inlet, an enrichment factor was estimated to be 5.25
117 based on theoretical calculations (Shingler et al., 2012). More detailed information about the
118 GCVI has been described in Bi et al. (2016). The number concentration of particles collected
119 by the GCVI was below 1 cm^3 during cloud-free periods, suggesting that instances of particle
120 breakthrough and small particle contamination were absent (Shingler et al., 2012). In addition,
121 interstitial particles or cloud-free particles were sampled using an inlet with a cut-off
122 aerodynamic diameter of 2.5 μm during cloudy or cloud-free episodes. The measurement
123 campaign was conducted from 9 October to 4 November, 2016. The time for cloud events was
124 approximately 300 hours in the whole period. The measurement period of cloud residues,
125 interstitial particles, and cloud-free particles are shown in Figure S1.

126 The sampled cloud residues, interstitial particles, and cloud-free particles were subsequently
127 measured by a single particle aerosol mass spectrometer (SPAMS) (Hexin Analytical
128 Instrument Co., Ltd., Guangzhou, China) to obtain their size-resolved chemical composition.
129 Bipolar mass spectra of individual aerosol particles were obtained by the SPAMS. The
130 analytical method of the SPAMS has been described in Li et al. (2011). Briefly, the aerosol
131 particles are focused into a narrow particle beam and accelerated to a region where the vacuum
132 aerodynamic (d_{va}) size of the aerosol particles is measured using two continuous diode Nd:YAG
133 laser beams (532 nm). Based on the light scattered by the particles, a pulsed high power laser

134 (266 nm) can be precisely triggered to evaporate and ionize the particles. Production of positive
135 and negative fragment is subsequently recorded using a dual-polarity time-of-flight mass
136 spectrometer. A specific mass-to-charge ratio (m/z) in the mass spectral corresponding to the
137 most probable ions is dependent on previous field and lab studies, and the peak area of a given
138 m/z on each particle is relevant to the amount of the corresponded species (Bhave et al., 2002;
139 Pratt et al., 2011). Polystyrene latex spheres (Nanosphere Size Standards, Duke Scientific Corp.,
140 Palo Alto) of 0.2-2.0 μm in diameter were used to calibrate the sizes of the detected particles at
141 the sampling site.

142

143 **2.3 Screening of the Fe-containing aerosols**

144 During the sampling period, 154,862 cloud residues, 15,420 interstitial particles, and 168,427
145 cloud-free particles with d_{va} ranged between 0.2 and 2.0 μm were chemically analyzed with
146 bipolar ion mass spectra. The Fe-containing aerosols typically had a positive ion peak at m/z
147 56. Because the Fe ion peak at m/z 56 may be contaminated with other species in the atmosphere,
148 such as $[\text{CaO}]^+$, $[\text{KOH}]^+$, and $[\text{C}_3\text{H}_4\text{O}]^+$, the natural isotopic composition of Fe ion peaks at
149 both m/z 54 and 56 were selected for the Fe screening process to minimize the interference
150 from other species (Furutani et al., 2011; Zhang et al., 2014). A peak area ratio $^{56}\text{Fe}/^{54}\text{Fe} > 10$
151 was also applied to strengthen the screening through excluding more ambiguous assignments
152 (Zhang et al., 2014; Dall'Osto et al., 2016). Thus, 5,682 cloud droplet residues, 395 interstitial
153 particles, and 5,086 cloud-free particles were found to be internally mixed with Fe, representing
154 3.7% of the total cloud residues, 2.6% of the total interstitial particles, and 3.0% of the total
155 cloud-free particles, respectively. Because the low number of the collected Fe-containing cloud

156 residues limited the statistical analysis, the differences between single cloud events were not
157 analyzed. Instead, an average analysis covering all the cloud events was presented.

158 The Fe-containing aerosols, including cloud residues, interstitial particles, and cloud-free
159 particles, were initially grouped into 106 clusters using an adaptive resonance theory-based
160 neural network algorithm (ART-2a) with a vigilance factor of 0.8, learning rate of 0.05, and 20
161 iterations (Song et al., 1999). Then, by manually combining similar clusters, four primary types
162 of Fe-containing aerosols were obtained, including Fe-rich, Fe internally mixed with mineral
163 dust species (Fe-dust), Fe internally mixed with EC (Fe-EC), and Fe internally mixed with V
164 (Fe-V).

165

166 **3 Result and discussion**

167 **3.1 Characteristics and potential sources of the Fe-containing particle types**

168 The averaged mass spectra of the four Fe-containing types are shown in Figure 1. One common
169 feature was that the four Fe-containing particle types were internally mixed with secondary
170 inorganic ions such as sulfate (m/z -97[HSO_4^-]) and/or nitrate (m/z -46[NO_2^-] or -62[NO_3^-]).
171 This suggests that the Fe-containing aerosols experienced atmospheric aging processes during
172 long-range transport.

173 The Fe-rich type exhibited the highest peak at m/z 56 Fe as well as sulfate and nitrate, which
174 was the largest fraction of Fe-containing particles, and contributed approximately 80% to the
175 cloud residues, interstitial particles, and cloud-free particles (Figure 2). The crustal elements
176 were rarely detected in the Fe-rich type, suggesting a nonmineral dust source. The Fe-rich type
177 was unlikely to be caused by biomass burning sources due to the weak potassium (m/z 39[K^+])

178 peak (Bi et al. 2011). Lithium (m/z 7[Li]⁺) was found to account for 7% of the Fe-rich type,
179 implying a partial contribution from fly ash as suggested by Furutani et al. (2011). Zhang et al.
180 (2014) considered that the Fe-rich particles were mostly produced by the iron/steel industry
181 from Shanghai in eastern China. In this study, a steel production site with an annual yield of 6.5
182 million tons was located approximately 60 km east of the sampling site. The Fe-rich type
183 detected here was most likely from industrial activities.

184 The Fe-dust type was mainly composed of mineral dust peaks including [Al]⁺ (m/z 27), [Ca]⁺
185 (m/z 40), [SiO₃]⁻ (m/z -76), and [PO₃]⁻ (m/z -79) (Figure 1), which accounted for 12-15% of the
186 cloud residues, interstitial particles, and cloud-free particles (Figure 2). However, no clear
187 enhancement of the Fe-dust aerosols was detected in the micron size (Figure S2). The micron
188 Fe-dust aerosols might have already been deposited over long-distance transport. Additionally,
189 the Fe-dust type may have occupied a larger size that could not be detected by the SPAMS.

190 The Fe-EC type was characterized by EC cluster ions (e.g., m/z ±12[C]^{+/-}, ±24[C₂]^{+/-}, ±
191 [36C₃]^{+/-}, ±48[C₄]^{+/-}, ±[60C₅]^{+/-}) as well as strong sulfate (Figure 1). The internal mixture
192 of Fe-containing particles with EC was also observed in the Asian outflow atmosphere, mainly
193 due to the contribution from fossil fuel combustion in China (Furutani et al., 2011). The Fe-V
194 type showed the intense [Fe]⁺ and [V]⁺ (m/z 51) or vanadium oxide (m/z 67[VO]⁺) peaks
195 (Figure 1). The Fe-V type was possibly related to residual fuel oil combustion sources, such as
196 ships and refineries (Furutani et al., 2011; Zhang et al., 2014; Dall'Osto et al., 2016). The Fe-
197 EC and Fe-V types were minor contributors (below 5%) in this study (Figure 2).

198

199 **3.2 The impact of cloud processing on secondary inorganic species in the Fe-containing**

200 **cloud residues**

201 Sulfate, nitrate, chloride, and ammonium were the most common secondary inorganic species
202 produced by aqueous reactions. Comparisons of these secondary inorganic species between Fe-
203 containing cloud residues, interstitial particles and cloud-free particles showed the impact of
204 cloud processing or aqueous phases on the formation of these species associated with Fe-
205 containing particles. Comparisons during daytime (local time 0800-1900) and nighttime (local
206 time 2000-0700) were also performed to investigate the irradiation effect. However, due to the
207 low number of particles detected, the Fe-EC and Fe-V particle types were not analyzed in this
208 section. Note that variation in the meteorological conditions may influence the comparisons.

209 The number fractions (NFs) of sulfate in the Fe-containing cloud residues (93%) and
210 interstitial particles (92%) were lower than those in the cloud-free particles (96%), as shown in
211 Figure 3. The sulfate peak area, proportional to mass, in the Fe-containing cloud residues and
212 interstitial particles were 0.96 and 0.85 times than that in the cloud-free particles. The NFs of
213 sulfate in the non-Fe cloud residues and interstitial particles were also not observed to enhance
214 relative to the non-Fe cloud-free particles (87-88% versus 92%). Several field studies also failed
215 to find the increased NF or mass fraction of sulfate in cloud residues or interstitial particles
216 (Drewnick et al., 2007; Twohy and Anderson, 2008; Schneider et al., 2017). The cause for these
217 observations remained unknown. In this study, an extremely high NF of sulfate was measured
218 in the Fe-containing cloud-free particles, which makes it hard to find the minor changes after
219 the particles experienced cloud events. It was worth noting that the Fe-containing particles
220 might experience one or more cloud processes prior to arrival at the observed site, wherein
221 sulfate may have accumulated on the Fe-containing particles. Low SO₂ level (below 5 ppb) in

222 the observed site may also limit the formation of sulfate. Thus, we speculated that the
223 contribution from the in-cloud formation of sulfate was relatively small compared to the total
224 amount of sulfate in the Fe-containing cloud-free particles in this study.

225 The NFs of nitrate in the Fe-containing cloud residues (86%) and interstitial particles (89%)
226 were enhanced in comparison to the cloud-free particles (76%) (Figure 3). The enhancement of
227 nitrate during cloud processing can be attributed to the partitioning from gaseous HNO_3 into
228 the aqueous phase and/or the heterogeneous reaction of N_2O_5 (Hayden et al., 2008; Chang et al.,
229 2011; Schneider et al., 2017). Photochemical reactions probably played a vital role in nitrate
230 formation (Pathak et al., 2009), leading to the increased NF of nitrate in the Fe-containing
231 cloud-free particles during daytime (Figure 4b). However, in the case of the Fe-containing cloud
232 residues, there was no distinct change in NF of nitrate between daytime and nighttime (Figure
233 4b), reflecting that the in-cloud formation of nitrate was less affected by photochemical
234 reactions. The higher NF of nitrate in the Fe-dust cloud residues was compared with the Fe-rich
235 cloud residues, despite a similar NF of nitrate observed in the two Fe-containing cloud-free
236 particle types (Figure 4b). This can be explained by the fact that gaseous HNO_3 would be
237 neutralized upon reaction with alkaline-rich (e.g., Ca) particles in the Fe-dust cloud residues
238 during cloud processing (Matsuki et al., 2010).

239 Higher NFs of chloride were found in the Fe-containing cloud residues and interstitial
240 particles compared to the cloud-free particles (16-13% versus 6%) (Figure 3). Sellegri et al.
241 (2003) observed that 80% of chloride in the aqueous phase originated from volatile gaseous
242 chloride (i.e., HCl) during cloud processing. The enhancement of chloride during cloud
243 processing was unlikely to have resulted from the invasion of sea salt particles, because the

244 related sea salt peaks (e.g., m/z 81 or $83[\text{Na}_2\text{Cl}]^+$) were barely detected in the Fe-containing
245 cloud residues. Only 115 sea salt particles were obtained in the Non-Fe cloud residues,
246 suggesting less gaseous HCl was released from aged sea salt particles during cloud processing.
247 There was no change in the NF of chloride in the Fe-containing cloud residues during either
248 daytime or nighttime, although enhanced chloride levels were found in the Fe-containing cloud-
249 free particles during daytime (Figure 4c). This result suggests that the amount of in-cloud
250 chloride formation could overwhelm the simultaneous irradiation effect. A significant feature
251 was also found in that the NF of chloride in the Fe-dust cloud residues was much higher than
252 that in the Fe-rich cloud residues (45% versus 12%) (Figure 4c). Relative to sulfate and nitrate,
253 chloride showed a highly internally mixed state with Ca particles (Figure S3), indicating that
254 the Ca-rich particles in the Fe-dust cloud residues were responsible for the in-cloud formation
255 of chloride. Despite lower amounts of Ca particles in the Fe-rich cloud residues, the enhanced
256 NF of chloride was obvious (Figure 4c). This was likely attributed to the uptake of volatile
257 gaseous chloride (i.e., HCl) over simple physical sorption due to the high water solubility of
258 gaseous HCl (Sellegri et al., 2003).

259 The NFs of ammonium in the Fe-containing cloud residues (35%) and interstitial particles
260 (34%) were slightly higher than that in the cloud-free particles (30%) (Figure 3). Nearly 100%
261 of ammonium was found to be internally mixed with sulfate and/or nitrate in the Fe-rich cloud
262 residues. The increased NF of ammonium in the Fe-rich cloud residues was expected to take up
263 gaseous NH_3 to neutralize the secondary acids. Analogously, most ammonium in the Fe-dust
264 cloud residues was also internally mixed with sulfate and/or nitrate. The secondary acids
265 accumulated on the Fe-Dust cloud residues might be a sink for NH_3 (Sullivan et al., 2007; Nie

266 et al., 2012). However, enhancement of ammonium in the Fe-dust cloud residues was only
267 measured during nighttime (Figure 4d). Compared to nighttime, the increased ammonium in
268 the Fe-dust cloud-free particles was the combined result of the enhancement of nitrate and
269 chloride during daytime (Figure 4d). This process might lead to a minor change in the NF of
270 ammonium between the Fe-dust cloud residues and cloud-free particles during daytime.

271

272 **3.3 The impact of cloud processing on oxalate precursors and oxalate in the Fe-containing** 273 **cloud residues**

274 The aqueous oxidation pathway of organic precursors was an important contributor to the in-
275 cloud formation of oxalate (Sorooshian et al., 2007; Zhang et al., 2017). Acetate (at m/z -59
276 $[\text{C}_2\text{H}_3\text{O}_2]^-$), methylglyoxal (m/z -71 $[\text{C}_3\text{H}_3\text{O}_2]^-$), glyoxylate (m/z -73 $[\text{C}_2\text{HO}_3]^-$), pyruvate (m/z
277 -87 $[\text{C}_3\text{H}_3\text{O}_3]^-$), malonate (m/z -103 $[\text{C}_3\text{H}_3\text{O}_4]^-$), and succinate (m/z -117 $[\text{C}_4\text{H}_5\text{O}_4]^-$) had been
278 suggested as the main precursors for the formation of oxalate in the atmospheric aqueous phase
279 (Ervens et al., 2004; Lim et al., 2005; Sorooshian et al., 2006). Increased NFs of these
280 precursors were clearly identified in the Fe-containing cloud residues (38%) and interstitial
281 particles (35%) compared to cloud-free particles (26%) (Figure 3). These findings indicate the
282 contribution of cloud processing to the formation of oxalate precursors. Photochemical
283 reactions were another major pathway to form oxalate precursors (Kawamura and Bikkina,
284 2016). Although enhancement of the oxalate precursors was observed in the Fe-containing
285 cloud-free particles during daytime, no variation in NF of the oxalate precursors was found in
286 the Fe-containing cloud residues during either daytime or nighttime (Figure 4e). Therefore, the
287 in-cloud formation of the oxalate precursors is less likely to be influenced by photochemical

288 reactions. Interestingly, these precursors presented in 62% of the Fe-dust cloud residues, which
289 was much higher than 35% of the Fe-rich cloud residues (Figure 4e). A similar trend was also
290 found during the cloud-free periods (43% versus 23%) (Figure 4e). These findings suggest that
291 the oxalate precursors would readily enrich in the Fe-dust particles.

292 The NFs of oxalate in the Fe-containing cloud residues (45%) and interstitial particles (38%)
293 were higher than that in the cloud-free particles (25%) (Figure 3). Only slightly enhanced NFs
294 of oxalate without its precursors were found for the Fe-containing cloud residues (15%) and
295 interstitial particles (13%) in comparison to the cloud-free particles (10%) (Figure S4). This
296 possibly resulted from gaseous oxalic acid partitioning into cloud droplets (Sellegri et al., 2003).
297 It should be mentioned here that such an enhancement of oxalate may be related to other
298 precursors (e.g., glutarate) that were not considered in this study. On the other hand, oxalate
299 that was internally mixed with its precursors accounted for 30% and 25% of the Fe-containing
300 cloud residues and interstitial particles, respectively, which were higher than the amount in the
301 cloud-free particles (16%) (Figure S4). Similarly, the oxalate peak area was enhanced in the Fe-
302 containing cloud residues and interstitial particles when it was internally mixed with its
303 precursors (Figure S5). These results indicate that the presence of oxalate precursors would
304 enhance the in-cloud formation of oxalate, mostly via the aqueous oxidation of oxalate
305 precursors (Ervens et al., 2004; Sorooshian et al., 2006). Compared with the Fe-rich cloud
306 residues, the higher NF of oxalate in the Fe-dust cloud residues (Figure 4f) might be related to
307 the plentiful precursors in the Fe-dust cloud residues (Figure 4e). Interestingly, a lower NF of
308 oxalate in the Fe-containing cloud residues was measured during daytime relative to nighttime,
309 indicating the photolysis of Fe-oxalate complexes (Figure 4f). This phenomenon differed

310 greatly from the in-cloud formation of nitrate, chloride, and oxalate precursors in that their NF
311 had no obvious change during both daytime and nighttime. The lower NF of oxalate in the Fe-
312 containing cloud residues during daytime also implies that the photolysis of Fe-oxalate
313 complexes could overwhelm the in-cloud formation of oxalate during the day.

314 The Fenton reaction ($\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{OH}^- + \bullet\text{OH}$) would yield OH-radicals, which
315 promote the conversion of the precursors to oxalate during cloud processing (Lim et al., 2010).
316 Obviously, the higher NF of oxalate in the Fe-containing cloud residues was compared with the
317 non-Fe cloud residues (45% versus 7%) (Figure S6). Moreover, a peak area ratio of oxalate to
318 its precursors was enhanced in the Fe-containing cloud residues relative to non-Fe cloud
319 residues (Figure 5a). These findings supported the role of the Fenton reaction in the conversion
320 of the precursors to oxalate during cloud processing. Sorooshian et al. (2007) observed that
321 oxalate was more efficiently produced from aqueous oxidation of glyoxylate with higher cloud
322 liquid water content, corresponding to higher cloud droplet pH values. Relative to Fe-
323 containing interstitial particles, an increased peak area ratio of oxalate to its precursors in the
324 cloud residues (Figure 5a) might be due to their higher liquid water content. Moreover, in the
325 presence of ammonium, the peak area ratio of oxalate to its precursors was also enhanced in the
326 Fe-containing cloud residues (Figure S7). The enhanced peak area ratio of oxalate to its
327 precursors in the Fe-dust cloud residues at night (Figure 5b) was likely due to the enhancement
328 of ammonium. Furthermore, nearly 90% of oxalate was found to be internally mixed with
329 ammonium in the Fe-dust cloud residues during nighttime. Ortiz-Montalvo et al. (2013)
330 considered that the formation of ammonium oxalate would substantially reduce the vapor
331 pressure of oxalate, enhancing the yield of oxalate during cloud processing. During the daytime,

332 the decreased peak area ratio of oxalate to its precursors mostly resulted from the degradation
333 of oxalate associated with photolysis of Fe-oxalate complexes.

334

335 **3.4 Mixing state of the Fe-containing cloud residues**

336 Figure 6 displays the number fraction of various species in the four Fe-containing cloud residual
337 types. Abundant sulfate was found in the Fe-rich (94%), Fe-dust (85%), Fe-EC (92%) and Fe-
338 V (98%) cloud residues. Substantial sulfate in the Fe-containing particles was also observed
339 over East Asia (Furutani et al., 2011; Moffet et al., 2012; Li et al., 2013). Despite no
340 significantly increased sulfate in Fe-containing particles during cloud processing, the
341 substantial sulfate observed here was expected due to the likely high levels of SO₂ encountered
342 during long-distance transport. High amounts (82-92%) of nitrate were observed in the Fe-
343 containing cloud residues except for the Fe-EC type (59%). However, a relatively high NF of
344 ammonium was obtained in the Fe-EC cloud residues (62%) compared to the other Fe-
345 containing cloud residual types (33-41%). This implies that ammonium in the Fe-EC particles
346 was likely in the form of ammonium sulfate, rather than ammonium nitrate. It should be noted
347 here that the evaporation chamber of the GCVI may lead to a depletion of ammonium nitrate
348 in the Fe-EC cloud residues (Hayden et al., 2008). The higher NF of chloride was found in the
349 Fe-dust cloud residues (45%) relative to the other Fe-containing cloud residual types (12-14%).
350 As discussed above, the Ca-rich particles in the Fe-dust type contributed considerably to the in-
351 cloud formation of chloride. Oxalate accounted for 45-51% of the Fe-rich, Fe-V, and Fe-dust
352 cloud residues, which was much higher than the oxalate found in Fe-EC cloud residues (19%).
353 The less abundant oxalate in the Fe-EC cloud residues might be restricted by the low NF of the

354 oxalate precursors.

355

356 **4 Atmospheric implications**

357 Previous laboratory and modeling studies focused on the cloud processing of Fe-containing
358 particles from dust sources (Hand et al., 2004; Mahowald et al., 2005; Shi et al., 2009). Some
359 modeling studies argued that the combustion Fe sources should be taken into account over East
360 Asia (Luo et al., 2008; Ito, 2015). Several field studies also confirmed the importance of
361 combustion sources to the Fe-containing particles over East Asia (Furutani et al., 2011; Moffet
362 et al., 2012; Zhang et al., 2014). This study includes the first report of the abundant Fe-rich
363 particles related to the participation of combustion sources in cloud processing over East Asia.

364 Luo et al. (2008) performed a modeling calculation to estimate the influence of atmospheric
365 process on soluble Fe by assuming that cloud processing had sufficient acidic species to process
366 more Fe soluble. However, they did not definite the specific acid types. In the current study, the
367 in-cloud formation of nitrate and chloride was enhanced in the Fe-dust type relative to the Fe-
368 rich type. Laboratory studies also showed that Fe dissolution in the HCl solution differed from
369 that in the H₂SO₄ and HNO₃ solutions (Fu et al., 2010; Rubasinghege et al., 2010). In order to
370 accurately predict bioavailable Fe during cloud processing, the impact of different acids on Fe
371 dissolution in varied Fe types might be considered for future modeling study.

372 Modeling calculations showed that relative to proton-promoted Fe dissolution, the addition
373 of oxalate accompanied with photolysis of Fe-oxalate complexes in aqueous chemistry more
374 than doubled the soluble Fe deposition from combustion sources in global oceanic regions (Ito,
375 2015). Our data showed that aqueous-phase oxidation of the oxalate precursors was an

376 important contributor to the in-cloud formation of oxalate in the Fe-rich particles. The Fenton
377 reaction would further promote the conversion of the oxalate precursors to oxalate in the Fe-
378 rich particles during cloud processing. At the same time, the photolysis of Fe-oxalate complexes
379 in the Fe-rich cloud residues also existed. These results supported the role of oxalate in aqueous
380 chemistry in soluble Fe deposition from combustion sources. However, the modeling study
381 assumed that oxalate was entirely mixed with Fe-containing particles from combustion sources
382 (Ito, 2015). In this work, nearly 50% of the Fe-rich cloud residues contained only oxalate. The
383 relative low number of oxalate in the Fe-rich cloud residues may reduce or suppress the
384 contribution of oxalate to the Fe dissolution during cloud processing (Ito, 2015). Ito (2015) also
385 proposed that the formation of Ca-oxalate complexes may reduce the availability of oxalate for
386 Fe-oxalate complexes, leading to the suppression of Fe dissolution. Less content (13%) of Ca-
387 containing particles in the Fe-rich type suggests that Ca-oxalate complexes are a minor
388 contributor to the Fe-rich type. Hence, the suppression of Fe dissolution due to Ca-oxalate
389 complexes in the Fe-rich type was not important during cloud processing in this study.

390

391 **5 Conclusions**

392 The Fe-rich type was dominant in the Fe-containing cloud residues, highlighting the major
393 contribution from combustion sources. This work also identified the in-cloud formation of
394 secondary species on the Fe-containing particles. No enhancement of sulfate was found in the
395 Fe-containing cloud residues. The enhancement of nitrate and chloride in the Fe-containing
396 particles was produced via partitioning and heterogeneous/aqueous chemistry of gaseous HNO_3
397 and HCl or other precursors. The in-cloud formation of oxalate was mostly attributed to the

398 aqueous oxidation of its precursors. The Fenton reaction and presence of ammonium species
399 further facilitated the in-cloud formation of oxalate. These results have important implications
400 for improving the modeling of atmospheric processes of aerosol Fe and evaluating Fe
401 bioavailability during cloud processing.

592 Figure captions:

593 Figure 1. The averaged mass spectra of the four Fe-containing types.

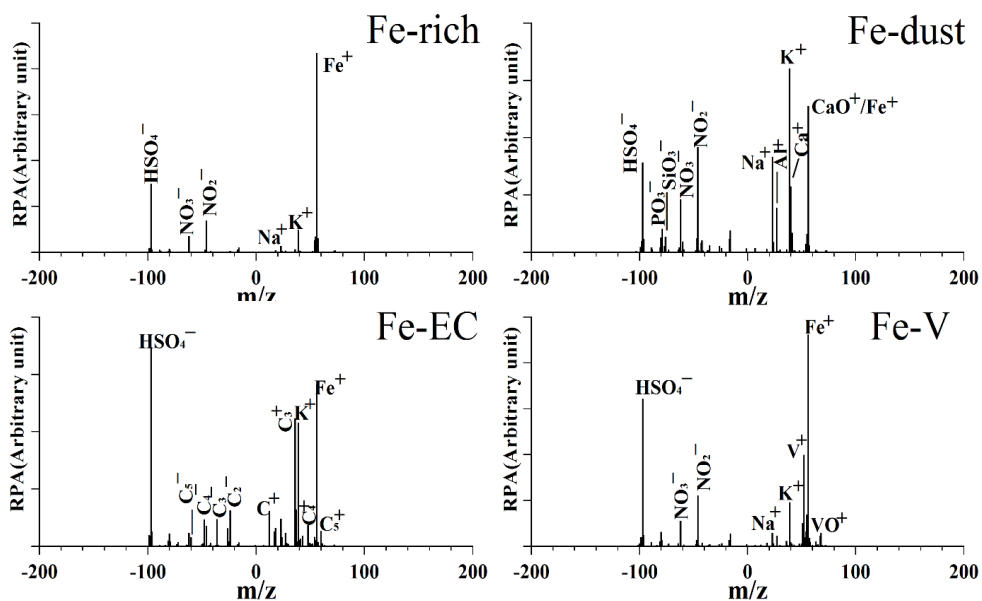

594 Figure 2. Number fraction of the four Fe-containing types in the Fe-containing cloud residues,
595 interstitial particles, and cloud-free particles during the whole study period. The uncertainties
596 were calculated assuming Poisson statistics for the analyzed particles (Pratt et al., 2010).

597 Figure 3. Comparison in number fractions of sulfate, nitrate, chloride, ammonium, oxalate
598 precursors, and oxalate between the Fe-containing cloud residues, interstitial particles and
599 cloud-free particles. Sulfate (m/z -97), nitrate (m/z -46 or -62), chloride (m/z -35 or -37),
600 ammonium (m/z 18), oxalate precursors (m/z -59 acetate or m/z -71 methylglyoxal or m/z -73
601 glyoxylate or m/z -87 pyruvate or m/z -103 malonate or m/z -117 succinate), and oxalate (m/z
602 -89).

603 Figure 4. Comparison in number fractions of sulfate (a), nitrate (b), chloride (c), and ammonium
604 (d), oxalate precursors (e), and oxalate (f) in the Fe-rich, Fe-dust, and all Fe-containing (total-
605 Fe) types between the cloud residues and cloud-free particles types and their difference during
606 daytime and nighttime. The comparison was not performed for the interstitial particles due to
607 the low number of detected particles.

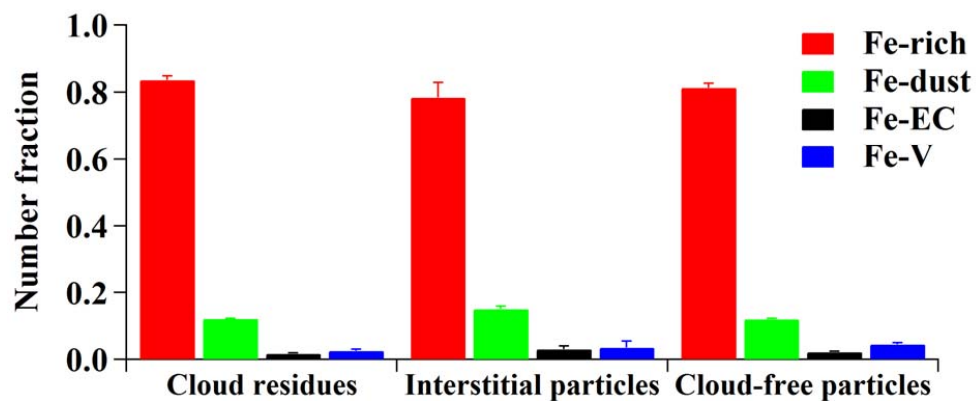

608 Figure 5. Peak area ratio of oxalate to its precursors in the total-Fe and non-Fe types (a); Peak
609 area ratio of oxalate to its precursors in the Fe-rich, Fe-dust, total-Fe and non-Fe types during
610 daytime and nighttime (b).

611 Figure 6. Mixing state of the four Fe-containing cloud residues.
