33

34 **Abstract**

35

36 Summertime Arctic aerosol size distributions are strongly controlled by natural regional
37 emissions. Within this context, we use a chemical transport model with size-resolved
38 aerosol microphysics (GEOS-Chem-TOMAS) to interpret measurements of aerosol size
39 distributions from the Canadian Arctic Archipelago during the summer of 2016, as part of
40 the “NETwork on Climate and Aerosols: addressing key uncertainties in Remote
41 Canadian Environments” (NETCARE). Our simulations suggest that condensation of
42 secondary organic aerosol (SOA) from precursor vapors emitted in the Arctic and near
43 Arctic marine (open ocean and coastal) regions plays a key role in particle growth events
44 that shape the aerosol size distributions observed at Alert (82.5° N, 62.3° W), Eureka
45 (80.1° N, 86.4° W), and along a NETCARE ship track within the Archipelago. We refer
46 to this SOA as Arctic marine SOA (Arctic MSOA) to reflect the Arctic marine-based and
47 likely biogenic sources for the precursors of the condensing organic vapors.

48

49 Arctic MSOA from a simulated flux ($500 \mu\text{g m}^{-2} \text{d}^{-1}$, north of 50° N) of precursor vapors
50 (assumed yield of unity) reduces the summertime particle size distribution model-
51 observation mean fractional error by 2- to 4-fold, relative to a simulation without this
52 Arctic MSOA. Particle growth due to the condensable organic vapor flux contributes
53 strongly (30-50%) to the simulated summertime-mean number of particles with diameters
54 larger than 20 nm in the study region, and couples with ternary particle nucleation
55 (sulfuric acid, ammonia, and water vapor) and biogenic sulfate condensation to account
56 for more than 90% of this simulated particle number, a strong biogenic influence. The
57 simulated fit to summertime size-distribution observations is further improved at Eureka
58 and for the ship track by scaling up the nucleation rate by a factor of 100 to account for
59 other particle precursors such as gas-phase iodine and/or amines and/or fragmenting
60 primary particles that could be missing from our simulations. Additionally, the fits to
61 observed size distributions and total aerosol number concentrations for particles larger
62 than 4 nm improve with the assumption that the Arctic MSOA contains semi-volatile
63 species; reducing model-observation mean fractional error by 2- to 3-fold for the Alert
64 and ship track size distributions. Arctic MSOA accounts for more than half of the
65 simulated total particulate organic matter mass concentrations in the summertime

66 Canadian Arctic Archipelago, and this Arctic MSOA has strong simulated summertime
67 pan-Arctic-mean top-of-the-atmosphere aerosol direct (-0.04 W m^{-2}) and cloud-albedo
68 indirect (-0.4 W m^{-2}) radiative effects. Future work should focus on further understanding
69 summertime Arctic sources of Arctic MSOA.

70

71 **1. Introduction**

72

73 Aerosols have an important role in the summertime Arctic climate system. Similar to
74 their effects in other regions, aerosols interact directly with incoming solar radiation by
75 scattering and absorption (Charlson et al., 1992; Hegg et al., 1996; Yu et al., 2006;
76 Shindell and Faluvegi, 2009; Yang et al., 2014) and indirectly through modification of
77 cloud properties by acting as the seeds for cloud droplet formation (Lohmann and
78 Feichter, 2005; McFarquhar et al., 2011). In the summertime Arctic, efficient wet
79 removal by precipitation and the smaller extent of the polar dome limit transport of
80 pollution from lower latitudes and maintain an atmosphere that is more pristine than in
81 the Arctic winter and springtime (Barrie, 1995; Polissar et al., 2001; Quinn et al., 2002;
82 Stohl, 2006; Garrett et al., 2011; Brock et al., 2011; Fisher et al., 2011; Sharma et al.,
83 2013; Xu et al., 2017). As a result, natural regional Arctic sources make strong
84 contributions to summertime Arctic aerosol, to the related radiative effects, and to
85 associated uncertainties (Korhonen et al., 2008; Leck and Bigg, 2010; Heintzenberg and
86 Leck, 2012; Karl et al., 2013; Carslaw et al., 2013; Heintzenberg et al., 2015; Croft et al.,
87 2016a; Willis et al., 2016; Burkart et al., 2017a; Mungall et al., 2017; Willis et al., 2017;
88 Dall'Osto et al., 2017; Breider et al., 2017; Dall'Osto et al., 2018b; Leaitch et al., 2018).

89

90 Observations indicate that aerosol particle formation and growth events occur frequently
91 in the summertime Canadian Arctic Archipelago region (within $60\text{-}130^\circ \text{ W}$ and
92 $60\text{-}85^\circ \text{ N}$) (Chang et al., 2011b; Leaitch et al., 2013; Willis et al., 2016; Willis et al.,
93 2017; Croft et al., 2016a; Burkart et al., 2017a; Burkart et al., 2017b; Collins et al., 2017;
94 Tremblay et al., 2018). These events contribute towards shaping a summertime aerosol
95 number size distribution that is characterized by a dominant Aitken mode (particles with
96 diameters between 10 and 100 nm) in this region (Croft et al., 2016b), similar to
97 observations at other pan-Arctic sites (Tunved et al., 2013; Asmi et al., 2016; Nguyen et

98 al., 2016; Freud et al., 2017; Gunsch et al., 2017; Heintzenberg et al., 2017; Kolesar et al.,
99 2017). Summertime Arctic aerosol size distributions are also characterized by a
100 suppressed accumulation mode (particles with diameters between 100 and 1000 nm) due
101 to the efficient wet removal processes in frequently drizzling low clouds (Browse et al.
102 2014) and the limited transport from lower latitudes (Stohl, 2006; Law and Stohl, 2007;
103 Korhonen et al., 2008)

104

105 Evidence points to a strong marine biogenic influence on summertime Arctic aerosols
106 (Leck and Bigg, 2010; Chang et al., 2011a; Heintzenberg et al., 2015; Dall'Osto et al.,
107 2018b). The oceans provide the atmosphere with many particle-relevant trace gases
108 (Carpenter et al., 2012; Carpenter and Nightingale, 2015; Ghahremaninezhad et al., 2017;
109 Mungall et al., 2017), as well as primary particles (Gantt and Meskhidze, 2013; Grythe et
110 al., 2014; Wilson et al., 2015). Arctic melt ponds and melting ice are also sources of
111 vapors such as dimethyl sulfide (DMS) (Hayashida et al., 2017; Gourdal et al., 2018),
112 which yield condensable products following oxidation (Barnes et al., 2006) that can form
113 and grow particles (Kirkby et al., 2011). As well, observations suggest a key role for
114 Arctic marine secondary organic aerosol (Arctic MSOA) in the Canadian Arctic
115 Archipelago (Willis et al., 2017; Burkart et al., 2017a; Köllner et al., 2017; Leaitch et al.,
116 2018). The condensing vapors that contribute to particle growth by formation of
117 secondary organics in the Canadian Arctic Archipelago may be more volatile than at
118 lower latitudes because smaller modes (particle diameters around 20 nm) grow somewhat
119 more slowly than larger modes (particle diameters around 90 nm) (Burkart et al., 2017a).
120 However, these vapors are still capable of growing newly formed particles, and the
121 details about the origin and composition of Arctic MSOA precursors are not well
122 understood.

123

124 In this study, the terminology Arctic MSOA indicates SOA formed from any organic
125 precursor vapors emitted in open ocean and coastal regions north of 50° N, excluding
126 methane sulfonic acid, which we treat as a separate aerosol component, consistent with
127 most filter-based aerosol species mass measurements. In the Canadian Arctic
128 Archipelago, Arctic MSOA is likely strongly controlled by marine biogenic activity

129 (Willis et al, 2017; Leaitch et al., 2018). Due to the spatial and temporal variability, and
130 diversity of organic precursor vapor sources and chemistry, the chemical character of
131 Arctic MSOA is not necessarily the same as other types of MSOA arising from
132 precursors originating in other marine regions, which could be more strongly influenced
133 by shipping and differing types of marine biogenic activity (Facchini et al., 2008; Rinaldi
134 et al., 2010). As well, under our definition of Arctic MSOA, the presence of Arctic
135 MSOA is not limited to the atmospheric marine boundary layer or marine environment
136 due to transport of precursors and Arctic MSOA to continental regions.
137

138 There are few measurements of size-resolved aerosol mass concentrations in the
139 summertime Arctic (Zábori et al., 2015; Giamarelou et al., 2016; Tremblay et al., 2018).
140 Such measurements can provide insight about the processes that control the size
141 distributions. Limited observations indicate that growing Aitken-mode particles with
142 diameters between 60 and 100 nm in the Canadian Arctic Archipelago are composed
143 almost entirely of organics, suggesting a strong role for secondary organics (Tremblay et
144 al., 2018). On the other hand, observations from the Svalbard region (within 74-81 °N
145 and 10-35 °E) indicate that the smaller sub-12 nm particles are composed primarily of
146 ammonium sulfate, suggesting that ternary nucleation and early growth involving gas-
147 phase water, ammonia (NH₃) and sulfuric acid (H₂SO₄) play a key role in the
148 development of nucleation-mode aerosols (particle diameters smaller than 10 nm) in the
149 region (Giamarelou et al., 2016). In the Canadian Arctic Archipelago, summertime gas-
150 phase NH₃ concentrations have been observed to be in the range of a few hundred pptv
151 (Wentworth et al., 2016), levels that could contribute to initial particle formation (Napari
152 et al., 2002; Kirkby et al., 2011; Almeida et al., 2013). Sources for NH₃ in this region are
153 not yet fully understood, but contributors include Arctic seabird colonies, biomass
154 burning, and possibly other terrestrial sources such as tundra ecosystems that can
155 contribute to bi-directional exchange (Skrzypek et al., 2015; Croft et al., 2016a; Lutsch et
156 al., 2016; Wentworth et al., 2016). In addition to NH₃, H₂SO₄ and gas-phase water, other
157 components of nucleation mode particles (diameters less than 10 nm) could include, but
158 are not limited to, iodine (Allan et al., 2015; Dall'Osto et al., 2018a), amines (Almeida et

159 al., 2013) and fragmentation of primary particles as clouds and fog evaporate (Leck and
160 Bigg, 2010).

161

162 Given the complexity of interacting processes and source-related uncertainties described
163 above, a coupled model-measurement-based approach enables exploration of the role of
164 particles of biogenic origin in development of summertime aerosol size distributions in
165 the Canadian Arctic Archipelago. In this study, we use the GEOS-Chem-TOMAS model
166 (<http://geos-chem.org>) with size-resolved aerosol microphysics to interpret aerosol
167 measurements taken during the summer of 2016 in the Canadian Arctic Archipelago, at
168 both Alert and Eureka, in Nunavut, Canada, and also along the 2016 *CCGS Amundsen*
169 ship track. These measurements include aerosol mass loading, total aerosol number and
170 aerosol size distributions, some of which were taken as part of the NETwork on climate
171 and aerosols: addressing key uncertainties in Remote Canadian Environments
172 (NETCARE) (Abbatt et al. (in prep.)). Section 2 describes our methodology, including
173 further details about the observations, a model description, and a summary of simulations.
174 Section 3 interprets simulations and observations to explore the contribution of both
175 marine primary organic aerosol (arising from sea spray) and Arctic MSOA in shaping the
176 summertime aerosol size distributions and mass concentrations in the Canadian Arctic
177 Archipelago. We also consider the role of ternary nucleation, the simulated contribution
178 to particle nucleation events and size distributions, and comparison with observations.
179 Section 3 also presents sensitivity studies to explore the role of the volatility of the Arctic
180 MSOA during growth events, and in shaping aerosol size distributions. Finally, Sect. 3
181 presents estimates of the contribution of Arctic MSOA to summertime Arctic direct and
182 indirect aerosol effects. Section 4 presents a summary, and highlights key directions for
183 future research.

184

185 **2. Methodology**

186

187 **2.1 Aerosol measurements in the Canadian Arctic Archipelago**

188

189 Figure1 shows the locations of aerosol measurements, taken at both Alert (82.5° N, 62.3°
190 W) and Eureka (80.1° N, 86.4° W), in Nunavut, Canada and along the 2016 ship track of
191 the *CCGS Amundsen* through the Canadian Arctic Archipelago that we interpret using the
192 GEOS-Chem-TOMAS model. The measurements at Alert, Nunavut, Canada are made at
193 the Global Atmospheric Watch (GAW) observatory. Weekly samples of ambient aerosol
194 are collected on Teflon filters, using a cyclone to limit particles to diameters smaller than
195 1 µm (PM_{1.0}), and analyzed by ion chromatography for several inorganic ions including
196 sulfate, ammonium, nitrate, and methane sulfonic acid (MSA). Further details are
197 provided in Leitch et al. (2013) and Li and Barrie (1993). Weekly samples are also
198 collected on quartz filters behind the cyclone (PM_{1.0}) and analyzed for organic and
199 elemental carbon by thermal volatilization and combustion (Huang et al., 2006), as
200 described in Sharma et al. (2017) and Leitch et al. (2018). There is a possibility that
201 volatile organic carbon (VOC) vapors could also be absorbed on the quartz filters
202 (Leitch et al., 2018). As a result, we view these measurements as an upper limit on
203 organic carbon mass concentrations at Alert as discussed further in Sect. 3.1. Since 2011,
204 hourly-mean size distributions for particles with diameters from 20 to 500 nm are
205 measured at Alert using a TSI 3034 Scanning Mobility Particle System (SMPS), which is
206 verified for sizing on site using mono-disperse particles of polystyrene latex and of
207 ammonium sulfate generated with a Brechtel Manufacturing Incorporated Scanning
208 Electrical Mobility Spectrometer. Total particle number concentration for particles larger
209 than 10 nm in diameter is measured at Alert with a TSI 3772 Condensation Particle
210 Counter (CPC). The CPC and SMPS agree to within 10% when all particles are large
211 enough to be counted by both instruments. Data that could be influenced by local camp
212 activities are filtered from the data set by removing data 1) when the wind direction was
213 within a 45° angle centred on the Alert camp; 2) during line zeroes to check the
214 connections to the instruments and any other repetitive occurrence that might influence
215 the measurements; 3) when logs indicated potential sources nearby (e.g. trucks); and 4) to
216 account for unknown factors, when data spikes remain that lasted two hours or less.

217

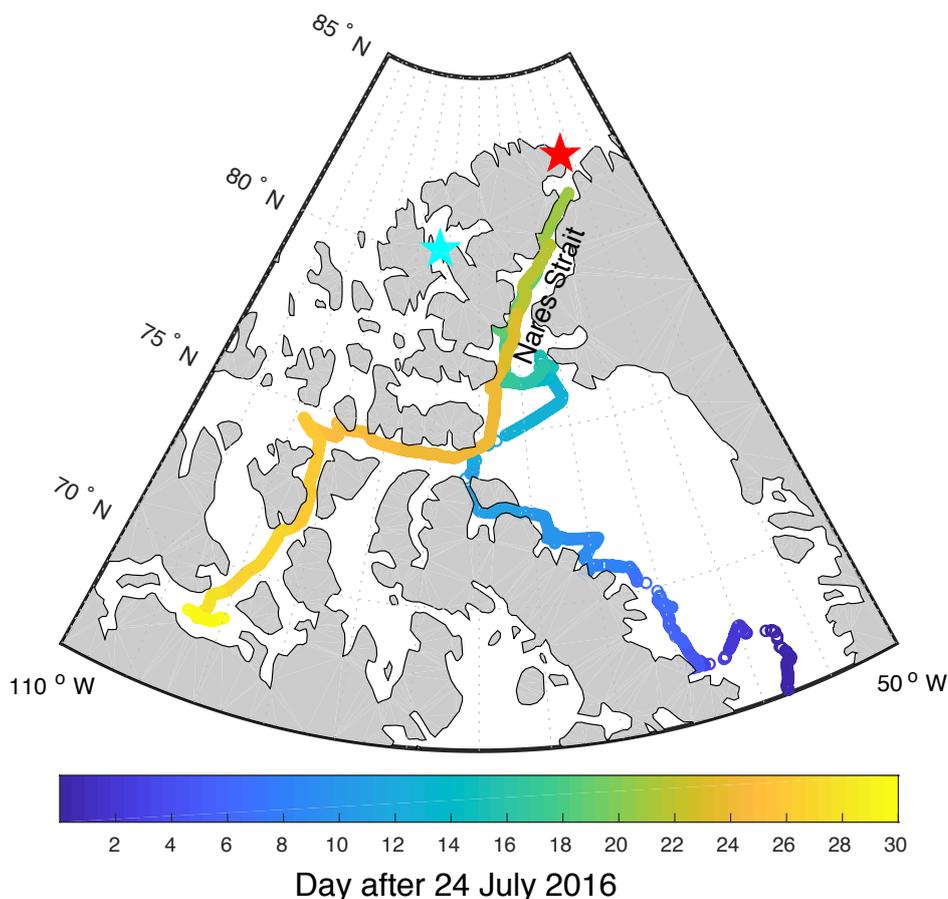

218 At Eureka, Nunavut, Canada, aerosol measurements are taken at the RidgeLab of the
219 Polar Environment Atmospheric Research Laboratory (PEARL) (Fogal et al., 2013),

220 which is located on Ellesmere Island at 610 m above sea level and about 480 km
221 southwest of Alert. Since 2015, size distributions for particles with diameters between 10
222 and 500 nm have been measured at the RidgeLab using a TSI 3034 SMPS. Data are
223 recorded every three minutes and averaged to hourly means. Further details about the
224 instrument and sampling are presented in Tremblay et al. (2018).

225

226

227

228

229

230

231

232

233 During the summer of 2016, the research icebreaker *CCGS Amundsen* travelled through
234 the Canadian Arctic Archipelago as a part of the NETCARE project (Abbatt et al. (in

235 prep)). Figure 1 shows the cruise track for 24 July - 23 August 2016. During the cruise,
236 total number concentrations of aerosols with diameters larger than 4 nm were measured
237 with a TSI 3776 ultrafine condensation particle counter (UCPC). Aerosol size
238 distributions for particles with diameters between 10 nm to 430 nm were measured with a
239 TSI 3080/3087 SMPS. Data collected while the wind direction was less than 60° to port
240 and less than 90° to starboard of the ship's orientation were accepted for further analysis.
241 We consider all measurements taken over 23 July 2016 to 24 August 2016, when the ship
242 was north of 66° N. Further details about the instrumental setup and sampling are in
243 Collins et al. (2017). Measurements of NH₃ were also taken during the cruise with a
244 Quantum Cascade Tunable Infrared Laser Differential Absorption Spectroscopy (QC-
245 TILDAS) analyzer (Ellis et al., 2010). The instrument has a fast response time that
246 enabled measurements at 1 Hz during the cruise, with measurements taken from 29 July
247 2016 to 23 August 2016. NH₃ data were also filtered for wind direction, ship speed and
248 measured aerosol number concentrations to exclude periods that indicated influence from
249 the ship exhaust.

250

251 Tundra samples were collected in triplicate from three sites near Alert, NU on 14 and 15
252 July 2016 to estimate tundra NH₃ emission potential. The sites ranged from
253 approximately 1 to 9 km west of the GAW observatory. Sampling and subsequent
254 analysis for ammonium concentration ([NH₄⁺]) and pH were carried out according to
255 Wentworth et al. (2014). From mid June to the end of July 2016, hourly measurements of
256 tundra temperature were recorded adjacent to the GAW observatory using commercially
257 available soil temperatures sensors (iButtons, Maxim Integrated). Tundra [NH₄⁺], pH,
258 (both based on the 14 and 15 July 2016 soil samples) and hourly temperature were used
259 to calculate the hourly NH₃ tundra compensation, which reflects the predicted
260 equilibrium NH₃ concentration in the atmosphere above the tundra (Wentworth et al.,
261 2014). A tundra-air exchange velocity was calculated using a resistance-in-series scheme
262 with parameterizations from Wesley (1989) and Walker et al. (2014). The average NH₃
263 emissions at the three sites were then calculated as the mean of the products of the
264 exchange velocity and compensation point, resulting in estimated emission rates of 0.12,
265 1.4, and 2.2 ng m⁻² s⁻¹. Here, we adopt the highest value to provide an upper estimate on

266 the contribution of the tundra to atmospheric NH₃. It should be noted that extrapolating
267 calculated emissions from discrete tundra samples to the entire Canadian Arctic
268 Archipelago carries a very large degree of uncertainty. However, the paucity of necessary
269 tundra measurements and the lack of any terrestrial Arctic NH₃ fluxes prevent a more
270 rigorous approach.

271

272

273 2.2 Model description

274

275 The GEOS-Chem (GC) chemical transport model version v10-01 (<http://geos-chem.org>)
276 coupled to the Two-Moment Aerosol Sectional (TOMAS) microphysics model (Adams
277 and Seinfeld, 2002; Kodros et al., 2016; Kodros and Pierce, 2017) is employed in this
278 study. Our model version has 47 vertical levels and a 4° x 5° horizontal resolution. The
279 GEOS-FP reanalysis (<http://gmao.gsfc.nasa.gov>) provides the meteorological fields. We
280 use a TOMAS version with 15 size sections, including dry diameters ranging from 3 nm
281 to 10 µm (Lee and Adams, 2012). Tracers within each size bin include particle number
282 and mass of sulfate, black carbon (hydrophobic and hydrophilic), organic carbon
283 (hydrophobic and hydrophilic), sea salt, dust and water. All simulations are for the
284 months of July and August 2016, with a one-month spin-up during June that is not
285 included in our analysis.

286

287 2.2.1 TOMAS aerosol microphysics

288

289 The TOMAS aerosol microphysics scheme employed in our simulations has 13
290 logarithmically spaced size sections for aerosol dry diameters from approximately 3 nm
291 to 1 µm, and 2 additional size sections to represent aerosol dry diameters from 1 to 10 µm
292 (Lee and Adams, 2012). Particle formation is treated according to the ternary H₂SO₄–
293 NH₃–H₂O nucleation scheme described by Baranizadeh et al. (2016). The formation rate
294 of particles at about 1.2 nm in mass diameter is determined from a full kinetics simulation
295 by Atmospheric Cluster Dynamics Code (ACDC) (Olenius et al., 2013) using particle
296 evaporation rates based on quantum chemistry. The scheme is implemented as a look-up

297 table as a function of gas-phase H_2SO_4 and NH_3 concentrations, relative humidity,
298 temperature and condensation sink for condensable vapors. Growth and loss of particles
299 smaller than 3 nm are approximated with the Kerminen et al. (2004) scheme.
300 Implementation of this scheme is supported by the findings of Giamarelou et al. (2016)
301 that nucleation-mode particles in the summertime Arctic are predominantly ammoniated
302 sulfates. All simulations use the Brownian coagulation scheme of Fuchs (1964) and
303 consider coagulation between all particle sizes, an important sink for particle number,
304 particularly for those particles with diameters smaller than 100 nm. Coagulation between
305 aerosols contained in cloud hydrometeors and interstitial aerosols is parameterized as
306 described in Pierce et al. (2015). An overview of the condensational-growth assumptions
307 follows the discussion of inventories and secondary organic aerosol (SOA) scheme
308 below.

309

310 2.2.2 Natural emissions

311

312 Several natural emissions inventories and parameterizations are used in our study.
313 Emissions of dimethyl sulfide (DMS) are based on the seawater DMS climatology of
314 Lana et al. (2011) with modifications for the Canadian Arctic Archipelago region as
315 described in Mungall et al. (2016), who found that the climatology seawater DMS was
316 biased low relative to observations from summer 2014. The air-water transfer velocities
317 for DMS are based on the scheme of Johnson (2010). Natural sources of NH_3 , along with
318 biofuel and anthropogenic sources are from the Global Emissions Initiative (GEIA)
319 (Bouwman et al., 1997). For some of our simulations, as described in Sect. 2.3, Arctic
320 seabird colony NH_3 emissions are implemented following Riddick et al. (2012a), Riddick
321 et al (2012b), Croft et al. (2016a) and Wentworth et al. (2016). Our simulations also
322 implement an NH_3 source from Arctic tundra with a fixed emission rate of $2.2 \text{ ng m}^{-2} \text{ s}^{-1}$,
323 an upper estimate based on inferred bi-directional exchange fluxes calculated using soil
324 measurements made during the summer of 2016 near Alert, which found the tundra can
325 act as a source of NH_3 to the atmosphere (Murphy et al. (in prep)). Given the uncertainty
326 in the tundra source, this source can be viewed as a surrogate for the missing emissions
327 needed to bring the simulated NH_3 mixing ratios to agreement with measurements as

328 discussed in Sect. 3.1. Additionally, natural sources of NH_3 and organic carbon (OC)
329 aerosol are included in the biomass burning emissions from the 3-hourly Global Fire
330 Emissions Database, version 4 (GFED4) for 2016 (Giglio et al., 2013; Van Der Werf et
331 al., 2017), which is employed in all simulations. Dust emissions employ the Dust
332 Entrainment and Deposition (DEAD) scheme of Zender et al. (2003), developed in
333 GEOS-Chem by Fairlie et al. (2007).

334

335 Emissions of sea spray in our simulations are based on the Mårtensson et al. (2003)
336 parameterization. We view this parameterization as yielding an upper bound on ultrafine
337 primary marine emissions. Comparisons with the Jaeglé et al. (2011) parameterization,
338 employed in the standard GEOS-Chem-TOMAS model, indicate that the Mårtensson et
339 al. (2003) parameterization yields greater sub-100 nm fluxes by up to a few orders of
340 magnitude (Jaeglé et al., 2011). This choice of emissions inventory enables evaluation of
341 the contribution of sea-spray to simulated ultrafine particle concentration under one of the
342 inventories that is most favorable to ultrafine sea-spray particle production. Additionally,
343 as opposed to assuming that all sea spray is sodium chloride, we emit sea spray particles
344 with diameters smaller than 100 nm as hydrophobic organic carbon aerosol and particles
345 larger than 100 nm as sodium chloride. This modification was introduced based on
346 measurements indicating that sub-100 nm sea spray particles are composed mostly of
347 organics, whereas larger particles have a progressively more dominant salt component
348 (Collins et al., 2013; Prather et al., 2013; Gantt and Meskhidze, 2013; Quinn et al., 2015).
349 However, knowledge gaps remain related to the spatial distribution of sea spray
350 composition and hygroscopicity (Collins et al., 2016).

351

352 2.2.3 Anthropogenic emissions

353

354 Our simulations also include global anthropogenic emissions from the Emissions
355 Database for Global Atmospheric Research
356 (http://edgar.jrc.ec.europa.eu/archived_datasets.php) (EDGAR) inventory. The EDGAR
357 inventory is overwritten by regional inventories for Europe (European Monitoring and
358 Evaluation Program (EMEP) (Crippa et al., 2016)), Canada (Criteria Air Contaminant

359 Inventory), the United States (National Emission Inventory (NEI)), and Asia (MIX
360 inventory (Li et al., 2017)). As well, the Bond et al. (2007) inventory overwrites the
361 EDGAR fossil-fuel and biofuel emissions for black and organic carbon.

362

363 2.2.4 Chemical mechanism

364

365 The GEOS-Chem-TOMAS chemical mechanism represents the reactions of more than
366 100 gas-phase species, including particle-relevant reactions such as DMS oxidation by
367 the hydroxyl radical (OH) to produce sulfur dioxide (SO₂) by both the addition and
368 abstraction channels, and also reaction with the nitrate radical (NO₃) (Chatfield and
369 Crutzen, 1990; Chin et al., 1996; Alexander et al., 2012). SO₂ then undergoes either gas-
370 phase reactions with OH to produce H₂SO₄ or aqueous oxidation with either hydrogen
371 peroxide (H₂O₂) or ozone (O₃) to produce particulate sulfate. For the aerosol
372 microphysics scheme, gas-phase H₂SO₄ can join with water vapor and gas-phase NH₃ for
373 ternary nucleation of nascent particles, and it can also condense to grow pre-existing
374 particles. The sulfate produced by aqueous-phase reactions is added to particles that are
375 large enough to have activated to form cloud droplets, only contributing to the growth of
376 these larger particles. In general, particles with diameters of 50 nm or larger activate in
377 our simulations, although observations from the Canadian Arctic Archipelago indicate
378 that particles as small as 20 nm could activate under some conditions (Leitch et al.,
379 2016). Methane sulfonic acid (MSA) that is produced by the DMS-OH-addition channel
380 contributes to condensational growth of existing particles, as described in Hodshire et al.
381 (in prep), but does not contribute to particle nucleation in our simulations. In this study,
382 we did not include additional chemistry related to production of dimethylsulfoxide
383 (DMSO). As a result, our simulated yields of MSA may be slightly underpredicted, and
384 sulfate formation slightly overpredicted (Breider et al., 2014).

385

386 2.2.5 Secondary organic aerosol scheme

387

388 Arctic MSOA is treated with the simplified SOA scheme developed by Kim et al. (2015),
389 which for all simulations includes SOA precursors from non-marine sources associated

390 with terrestrial biogenic, fossil fuel, biofuel, and biomass burning emissions. The scheme
391 introduces two additional tracers, a gas-phase SOA precursor, and a SOA tracer that is
392 available to condense on the particles. The gas-phase SOA precursor oxidizes to form
393 SOA on a fixed timescale of 1-day. For biogenic sources the emissions are distributed
394 between these two tracers with a 50/50 split to represent the fast oxidation timescale of
395 biogenic precursors of typically shorter than 1 day. The model employed for this study
396 does not include aqueous-phase production of SOA. As a part of our sensitivity
397 simulations (described in Sect. 2.3), additional fixed-flux organic vapor emissions
398 yielding Arctic MSOA are implemented in the region north of 50° N over open seawater
399 with a 50/50 split between the gas-phase precursor and the phase that is available for
400 condensation.

401

402 While our simulations do not include initial formation of nascent particles by clusters of
403 organic vapors, we do allow growth of particles by condensation of organic vapors, as
404 well as by condensation gas-phase H₂SO₄ and MSA. In the standard model, all vapors
405 condense proportional to the Fuchs-corrected aerosol surface area distribution, behaving
406 like a non-volatile condensing gas (Donahue et al., 2011; Pierce et al., 2011; Riipinen et
407 al., 2011; Liu et al., 2016; Tröstl et al., 2016; Ye et al., 2016). The important role of
408 organic condensation was found at lower latitude continental sites (Riipinen et al., 2011).
409 Our simulations investigate this role for the Arctic. We also conduct additional sensitivity
410 simulations (described in Sect. 2.3), which allow condensation of a fraction of the vapors
411 according to the mass distribution, behaviour like a semi-volatile as opposed to non-
412 volatile condensing organic.

413

414 2.2.6 Wet and dry deposition

415

416 Removal of simulated aerosol mass and number occurs by both wet and dry deposition.
417 The wet deposition parameterization includes both in-cloud and below-cloud scavenging
418 as developed by Liu et al. (2001) and Wang et al. (2011), with modifications as described
419 in detail in Croft et al. (2016b) to more closely link the wet removal to the meteorological
420 fields for cloud liquid, ice water content, and cloud fraction. To represent the impact of

421 drizzle from summertime Arctic low-level clouds, we implemented wet removal from all
422 Arctic clouds below 500 m using a fixed efficiency of 0.01 s^{-1} , similar to the approach of
423 Browse et al. (2012). In-cloud wet removal in GEOS-Chem-TOMAS is limited to the size
424 range that can activate to form cloud hydrometeors. Size-dependent dry deposition uses
425 the resistance in series approach of Wesley (1989). Simulated gas-phase species are also
426 removed by dry and wet deposition as described in Amos et al. (2012). Removal depends
427 on solubility such that aerosol precursors including ammonia, and sulphur dioxide are
428 removed by precipitation, while SOA precursors and dimethyl sulphide are not.

429

430 2.2.7 Radiative calculations

431

432 The following radiative transfer calculations are conducted off-line using the simulated
433 summertime-mean aerosol mass and number concentrations to examine the effects of
434 organic condensation. For calculation of the direct radiative effect (DRE), aerosol optical
435 depth, single-scattering albedo and asymmetry factor are calculated with Mie code
436 (Bohren and Huffman, 1983) and use refractive indices from the Global Aerosol Dataset
437 (GADS) (Koepke et al., 1997). These optical properties, along with cloud fraction and
438 surface albedo from GEOS-FP assimilated meteorology are input to the Rapid Radiative
439 Transfer Model for Global Climate Models (RRTMG) (Iacono et al., 2008), to determine
440 the change in top-of-the-atmosphere solar flux between two simulations, treating all
441 particles except black carbon as internally mixed and spherical.

442

443 We also calculate the cloud-albedo aerosol indirect effect (AIE) with the method
444 described in Croft et al. (2016a) and Kodros et al. (2016). The cloud droplet number
445 concentration (CDNC) is calculated off-line using the parameterization of Abdul-Razzak
446 and Ghan (2002), again using the summertime mean aerosol mass and number
447 concentrations from our simulations. We assume an updraft velocity of 0.5 m s^{-1} and treat
448 all aerosols as internally mixed to determine the hygroscopicity parameter of Petters and
449 Kreidenweis (2007). For each model grid box, we assume cloud droplet radii (r) of $10 \mu\text{m}$
450 and perturb this value with the ratio of summertime-mean CDNC from simulations

451 (acronyms described in Table 1 and simulations described in Sect. 2.3), following Rap et
452 al. (2013), Scott et al. (2014) and Kodros et al. (2016),

453

$$454 \quad r_{perturbed} = 10 \left(\frac{CDNC_{BASE+TUNDRA+BIRDS+100xnuc}}{CDNC_{BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv}} \right)^{1/3}. \quad (1)$$

455

456 Then RRTMG is used to determine the change in top-of-the-atmosphere solar flux
457 attributed to the change in effective cloud droplet radii, again using the summertime
458 meteorological data from GEOS-FP. Our AIE calculation is limited to this single aerosol
459 indirect effect; the impact of Arctic MSOA on additional indirect effects (Lohmann and
460 Feichter, 2005) requires further investigation in future studies.

461

462 **2.3 Overview of simulations**

463

464 Our simulations are conducted with a focus on interpreting the summertime 2016 aerosol
465 measurements from the Canadian Arctic Archipelago. These simulations are used to
466 explore the role of biogenic sources in shaping the aerosol size distributions by the
467 processes of nucleation of particles from gas-phase molecules followed by growth, with a
468 focus on Arctic MSOA. We also consider the role of marine primary particle emissions.

469

470 Table 1 presents simulation acronyms used in the following discussion. Simulation BASE
471 employs the standard GEOS-Chem-TOMAS model described in Sect. 2.2. We examine
472 the potential contribution of regional terrestrial NH₃ sources to aerosol size distributions
473 with simulations BASE+BIRDS, BASE+TUNDRA, and BASE+TUNDRA+BIRDS.
474 Simulation BASE+BIRDS implements seabird-colony NH₃ emissions of 35 Gg spread
475 uniformly in time between 1 May and 30 September, based on the Riddick et al. (2012a)
476 and Riddick et al. (2012b) inventory with modifications and spatial distribution as
477 described in Croft et al. (2016a) and Wentworth et al. (2016). Simulation
478 BASE+TUNDRA includes a fixed NH₃ emission of 2.2 ng m⁻² s⁻¹ from all Arctic tundra
479 as discussed in Sect. 2.2.2. Simulation BASE+TUNDRA+BIRDS uses both the seabird
480 colony and tundra NH₃ sources.

481

482

483

484

485

Simulation Acronyms	Description
BASE	Base simulation, described in detail in Sect. 2.2.
BIRDS	Seabird-colony ammonia emissions included
TUNDRA	Tundra ammonia emissions included
AMSOAnv	Non-volatile Arctic MSOA
AMSOAnv/sv	30% non- and 70% semi-volatile Arctic MSOA
2xAMSOAnv/sv	Double organic vapor emissions of AMSOAnv/sv
100xnuc	Particle formation rate scaled by 100-fold

486

487 Table 1: Description of acronyms that are used in the simulation names. Simulations are described in detail
488 by full simulation name in Sect. 2.3.

489

490

491 Simulation BASE+TUNDRA+BIRDS+AMSOAnv adds a source of Arctic MSOA. This
492 source draws upon measurements presented by Mungall et al. (2017) indicating that the
493 marine microlayer is a source of oxygenated volatile organic compounds (OVOCs), key
494 precursors to secondary organic aerosol. Furthermore, Willis et al. (2017) identified a
495 positive relationship between the ratio of organic to sulfate aerosol mass concentrations
496 and time spent over open water, suggesting a marine SOA source. Studies from other
497 regions also identified biogenic VOCs of marine origin, but their marine sources are not
498 fully identified (Carpenter and Nightingale, 2015; Tokarek et al., 2017; Chiu et al., 2017).
499 Likewise for the Arctic, the emission rates for these vapors are not well understood
500 (Burkart et al., 2017a). Given this uncertainty, we identified a fixed Arctic MSOA-
501 precursor vapor source flux (Arctic MSOA formed with a mass yield of unity) from the
502 ice-free seawater in the Arctic and near Arctic (north of 50° N). The marine organic
503 vapors are emitted into the simplified SOA scheme described in Sect. 2.2.5 with a 50/50
504 split between precursor gas (with a 1-day lifetime before forming SOA) and vapor that
505 instantly condenses to particles in the marine boundary layer. This split represents
506 variability in the VOCs lifetime for aging to sufficiently low volatility that they can
507 condense on the particulate phase. At the point of condensation, we assume the vapors to
508 be effectively non-volatile, with condensation according to the Fuchs-corrected surface
509 area. A top-down estimate of the flux ($500 \mu\text{g m}^{-2} \text{d}^{-1}$; simulated flux magnitude of $468 \mu\text{g}$

510 $\text{m}^{-2} \text{d}^{-1}$ north of 50°N , reported to one significant figure due to uncertainty) is adopted
511 that best represents observations as shown in the following sections within the context of
512 our simulations, which are an upper limit on primary organic aerosol contribution. To put
513 the implemented flux in context, this is within an order of magnitude of the isoprene flux
514 estimated from a north temperate deep lake (Steinke et al., 2018). Future work should
515 include a bottom-up estimate of the SOA-precursor source flux.

516

517 Simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv examines the impact of
518 particle precursors in addition to H_2SO_4 , NH_3 and water that could nucleate nascent
519 particle clusters in the Arctic. These precursors could include (but are not limited to) gas-
520 phase iodine (Allan et al., 2015; Dall'Osto et al., 2018a), amines (Almeida et al., 2013)
521 and organics (Riccobono et al., 2014). It is unclear if marine biological activity creates
522 organic vapors that participate in particle nucleation. Disintegration of larger particles
523 from evaporating clouds and fog could contribute to the number of nascent particles
524 (Leck and Bigg, 2010). Unfortunately, a nucleation parameterization does not exist that is
525 suitable to include interactions of all these materials simultaneously (Riccobono et al.,
526 2014; Dunne et al., 2016; Gordon et al., 2017). To explore these effects, we scale up the
527 ternary nucleation by 100-fold to represent the potential effects of particle precursors
528 with similar spatial origin to those involved in ternary nucleation. Almeida et al. (2013)
529 and Riccobono et al. (2014) observed increases in nucleation rates by about 100-fold
530 above the sulfate-ammonia-water vapor system when amines or monoterpene-oxidation
531 products were added. We treat the 100-fold increase as an estimate of how additional
532 materials could enhance nucleation. We also conduct simulation
533 BASE+TUNDRA+BIRDS+100xnuc, which is otherwise similar to
534 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv, but without the condensable marine
535 organic vapors.

536

537 Finally, we conduct simulations to examine the impact of Arctic MSOA volatility.
538 Burkart et al. (2017a) found that condensing gas-phase materials in the Canadian Arctic
539 Archipelago were surprisingly more volatile than at lower latitudes. Simulation
540 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv is similar to simulation

541 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv, except that 30% of the Arctic MSOA
542 behaves as non-volatile compounds and condenses according to Fuchs-corrected surface
543 area, whereas 70% of the Arctic MSOA behaves as idealized semi-volatile compounds
544 and condenses according to the particle mass distribution (quasi-equilibrium
545 condensation). This is a larger fraction of semi-volatile vapors than the 50/50 semi-/non-
546 volatile split employed by Riipinen et al. (2011) for lower latitude continental sites, and
547 consistent with the findings of Burkart et al. (2017a) for the Canadian Archipelago region
548 that the condensing vapors were more semi-volatile than at lower latitudes. Simulation
549 BASE+TUNDRA+BIRDS+100xnuc+2xAMSOAnv/sv is similar to simulation
550 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv, except that for the former, we
551 double the flux of marine organic vapors to examine the impact of a change in flux since
552 the geographic distribution of the source rate is highly uncertain.

553

554 We calculate the mean fraction error (MFE) (Boylan and Russell, 2006) between our
555 simulations and observed aerosol size distributions using the following equation.

556

$$557 \text{ MFE} = \frac{1}{N} \sum_{i=0}^{i=N} \frac{\text{abs}|C_m(i) - C_o(i)|}{(C_m(i) + C_o(i))/2} \quad (2)$$

558

559 where $C_m(i)$ is the integrated value for the i^{th} moment of the simulated aerosol size
560 distribution and $C_o(i)$ is the integrated value for the i^{th} moment of the observed size
561 distribution, for the N moments (zeroth to third). Fractional bias is calculated likewise, but
562 without the absolute value of the numerator.

563

564 **3. Results and Discussion**

565

566 **3.1 Summertime aerosol mass concentrations at Alert**

567

568 Table 2 shows the observed climatological- (data available for years 2011 to 2015),
569 summertime- (July and August) mean mass concentrations for organic carbon (OC),
570 NH_4^+ , sulfate (SO_4^-) and MSA from filter measurements at Alert and also the
571 summertime mean for our 9 simulations (all for 2016). These long-term observations at

572 Alert provide a useful climatology for comparison with our simulations, even if not for
573 the same years. An organic matter (OM) to OC ratio of 2.1 was applied to convert the
574 simulated OM to OC. There is uncertainty in the OM/OC ratio, which can range from
575 about 1.4 to 2.4; however, the larger values are generally associated with rural and remote
576 regions (Turpin and Lim, 2001; Russell, 2003; Philip et al., 2014). This ratio (2.1) is
577 within 4% of summertime-mean OM/OC ratios from the Organic Functional Groups
578 (OFG) measurements from available years (2012-2014) at Alert that are detailed in
579 Leaitch et al. (2018). Simulation BASE underpredicts the observed annual mean OC
580 mass concentrations by a factor of about 3, and is below the inter-annual range shown in
581 Table 2. The simulated OC is strongly sensitive to Arctic MSOA, increasing by a factor
582 of 2.5 for simulation BASE+TUNDRA+BIRDS+AMSOAnv relative to simulation
583 BASE+TUNDRA+BIRDS, to yield better consistency with the measurement mean. As
584 described in Leaitch et al. (2018), these measurements could also include organics from
585 condensation of volatile organic compounds directly onto the quartz filters, contributing
586 to a factor of 1.1-2.5 increase in concentrations relative to OFG analysis by Fourier
587 transform infrared (FTIR) spectroscopy. This is only one of the potential issues with
588 determining OC based on sampling at such low concentrations over one week.
589 Furthermore, the measurement OC mass concentrations were not available for the year of
590 our simulations, and inter-annual variability in summertime OC is large. As a result of
591 these complexities, we also compare between the year-matched simulated and SMPS
592 volume distributions (Sect. 3.3), which we consider to be a more robust evaluation of the
593 simulated particle mass concentrations.

594

595 The simulated OC mass concentration is also sensitive to the rate of formation of nascent
596 particles in our simulations. With an increase in nucleation rate, as in simulation,
597 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv relative to simulation
598 BASE+TUNDRA+BIRDS+AMSOAnv, the simulated OC mass concentrations increase
599 by about 15% because there are more nucleation- and Aitken-mode particles available to
600 ‘catch’ the condensing vapors, and these smaller particles are less efficiently removed by
601 wet scavenging. Additionally, the simulations of OC mass concentrations are sensitive to
602 the assumed volatility of the Arctic MSOA. For the 30/70 split of non-volatile and semi-

603 volatile vapors as in simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv, the
 604 OC mass concentrations are reduced by about 15% relative to simulation
 605 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv. The semi-volatile vapors condense to
 606 larger particles (Pierce et al., 2011; D'Andrea et al., 2013; Hodshire et al. (in prep.)) that
 607 are more efficiently removed by precipitation. The emissions flux of Arctic MSOA-
 608 precursor
 609 vapors has a nonlinear impact on the simulated OC mass concentrations. Table 2 shows
 610 that the change in mean OC concentrations differs between simulation pairs with the
 611 same absolute change in Arctic MSOA-precursor emissions (simulations
 612 BASE+TUNDRA+BIRDS+100xnuc+2xAMSOAnv and
 613 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv, relative to
 614 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv and
 615 BASE+TUNDRA+BIRDS+100xnuc).
 616

	OC	NH ₄ ⁺	MSA + SO ₄ ²⁻
Observations	85.0 (37.7, 132.9)	16.3 (7.6, 31.2)	58.8 (30.8, 97.5)

617

618 Table 2: July and August mean aerosol mass concentrations (ng m⁻³) at Alert from measurements (2011-
 619 2015) (brackets show the minimum and maximum annual mean over the measurement period) and GEOS-
 620 Chem-TOMAS simulations (2016) as described in Table 1 and Sect. 2.3 for organic carbon (OC),
 621 ammonium (NH₄⁺), and methane sulfonic acid (MSA) and sulfate (SO₄²⁻).
 622

623

624 We also evaluated the simulation of relevant inorganic ions. Simulation BASE strongly
 625 underpredicts measured ammonium concentrations by a factor of 8. Implementation of

626 the seabird-colony and tundra NH_3 sources (simulation BASE+TUNDRA+BIRDS) yields
627 closer model-measurement agreement (within about 40%), although this is a challenging
628 simulation given the uncertainties in the NH_3 sources within these remote regions.
629 Relative to measurements taken during the summer 2016 cruise track, simulation BASE
630 also underpredicts grid-box mean NH_3 mixing ratios with a mean fractional bias (MFB,
631 described in Sect. 2.3) (Boylan and Russell, 2006) of -1.98, which is reduced for
632 simulations BASE+BIRDS (-1.23), BASE+TUNDRA (-0.22), and
633 BASE+TUNDRA+BIRDS (+0.06).

634

635 Implementation of seabird-colony and tundra NH_3 sources (simulation
636 BASE+TUNDRA+BIRDS) also increases the simulated summertime (July and August)
637 mean sulfate concentrations by about 20% over simulation BASE. The extra free NH_3
638 (simulation BASE+TUNDRA+BIRDS relative to BASE) promotes particle nucleation,
639 which decreases the mean diameter of the particles available for H_2SO_4 condensation as
640 sulfate, slowing sulfate wet scavenging as the smaller particles have less efficient
641 removal. Scaling up the nucleation rate further increases the sulfate concentrations by
642 about 10-15% as the concentrations of nucleation- and Aitken-mode particles are further
643 increased, further reducing the mean diameter of the particles available for condensation
644 of H_2SO_4 , and slowing wet scavenging of sulfate. All simulations are within 20% of the
645 measured sulfate concentrations. As well, we evaluated the model-measurement
646 agreement for sodium ions and found agreement within a factor of two for all
647 simulations. These mass-based comparisons offer confidence that the simulations which
648 include Arctic MSOA are reasonable. In the following sections, we consider the impact
649 of Arctic MSOA on total aerosol number concentrations and the moments of the aerosol
650 size distributions.

651

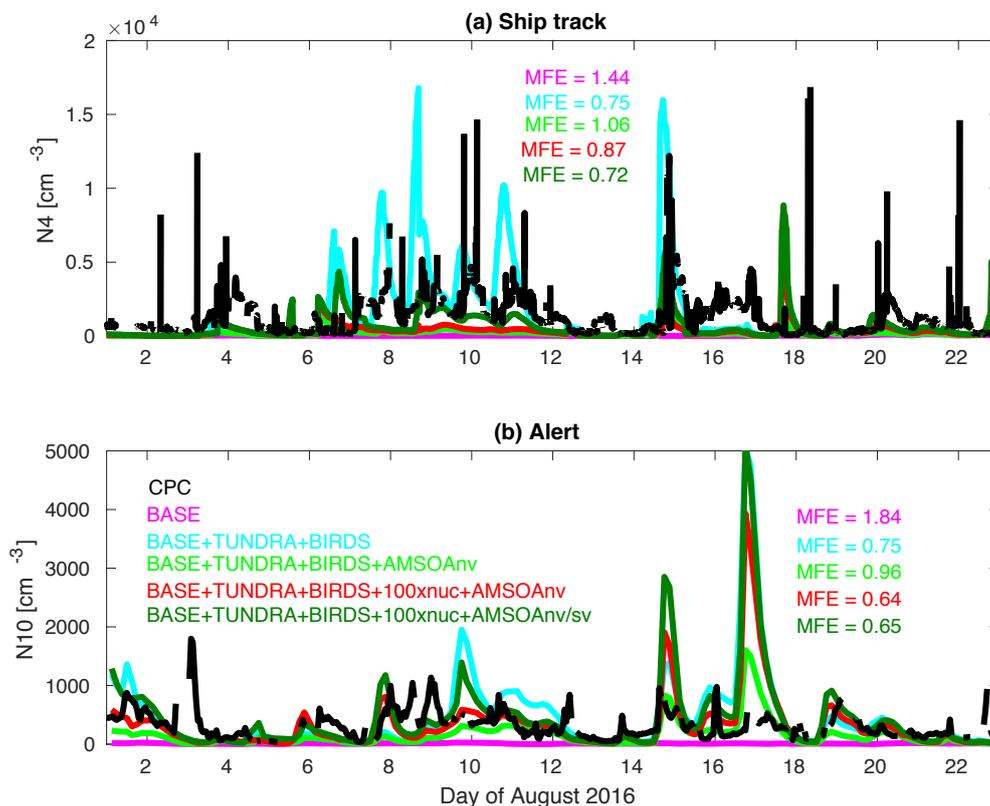

652 **3.2 Total aerosol number concentrations along the 2016 ship track and at Alert**

653

654 Figure 2 shows time series measurements during August 2016 of total particle number
655 concentration for particles with diameters larger than 4 nm conducted from the *CCGS*
656 *Amundsen* (Collins et al., 2017) and for particles with diameters larger than 10 nm at

657 Alert. The measurement time series shows episodic bursts of particle number
658 concentration greater than 500 cm^{-3} . Interestingly, at several times the elevated number
659 concentrations occur at both Alert and at the ship, such as on August 3, 8, 9, 10, 11, 15
660 and 16. Both time series also show relatively lower total number concentrations on
661 August 5 and August 13 to 14, when there was precipitation, and when the ship was in
662 the Nares Strait region shown on Fig.1.

663

664

665 Figure 2: Time series for August 2016 observed number concentration from condensation particle counter
666 (CPC) for aerosols with (a) diameters larger than 4 nm (N_4) along Amundsen ship track (Fig. 1) and (b)
667 diameters larger than 10 nm (N_{10}) at Alert (described in Sect. 2.1) and for the simulations as described in
668 Table 1 and Sect. 2.3 (color coded as shown on legend). MFE: mean fractional error between observations
669 and simulations, color-coded to match simulation names.

670

671 Figure 2 also shows the time series of coincidentally sampled simulated number
672 concentrations for five of the simulations described in Table 1 and Sect. 2.3. We
673 calculated the model-to-measurement mean fractional error (MFE) (Eq. (2)) for the

674 simulations of total number concentration shown on Fig. 2. The BASE simulation is
675 associated with the greatest MFE values for the ship track (1.44) and Alert (1.84). The
676 simulations better capture the bursts of particle number when including NH₃ sources from
677 seabird colonies and tundra, similar to the findings of Croft et al. (2016a) with MFE
678 values reduced to 0.75 for both the Alert and ship track time series for simulation
679 BASE+TUNDRA+BIRDS.

680

681 Implementation of Arctic MSOA in simulation BASE+TUNDRA+BIRDS+AMSOAnv
682 increases the MFE relative to simulation BASE+TUNDRA+BIRDS, to 1.06 for the ship
683 track and 0.96 for the Alert time series. This MFE increase occurs because more vapors
684 are available to condense on to the particle surface area, building the condensation sink
685 for H₂SO₄, which reduces the simulated formation of nascent particles by ternary
686 nucleation with H₂SO₄. These effects reduce the number of ultrafine particles, similar to
687 that described by D'Andrea et al. (2013), who investigated the impact of
688 anthropogenically enhanced SOA for a set of sites distributed around the world.

689

690 Scaling the nucleation rate by 100-fold reduces the MFE to 0.87 for the ship track and
691 0.64 at Alert, for simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv. This
692 scaling acts as a surrogate for the parameterization of particle nucleation by materials in
693 addition to the simulated gas-phase NH₃, H₂SO₄ and water, as described in Sect. 2.3. This
694 increased nucleation rate enables ultrafine particles to become more numerous, despite
695 the increased condensation sink associated with the implemented Arctic MSOA source.

696

697 Considering both the 2016 ship track and Alert time series together, the lowest MFE pair
698 is found for simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv, 0.72 and
699 0.65, respectively. This simulation treats the Arctic MSOA as a 30/70 mix of non- and
700 semi-volatile species. Higher volatility condensing vapors enable simulated growth of the
701 nascent particles at a slower rate (relative to larger particles) than lower volatility
702 condensing vapors. As a result, the newly formed particles grow more slowly with semi-
703 volatile Arctic MSOA, which lowers the condensation and coagulation sinks (relative to
704 non-volatile Arctic MSOA), and increases the total number of particles. As well, there is

705 relatively more condensation of the semi-volatile Arctic MSOA to larger particles, which
706 contribute proportionately less to surface area and more to aerosol mass. These larger
707 particles are efficiently removed by the frequent low-cloud drizzle of the summertime
708 Arctic in our simulations. As shown on Fig. 2, the net effect is an increase in the number
709 of ultrafine particles that better matches the observed time series of total number
710 concentration.

711

712 **3.3 Moments of the aerosol size distribution for Alert, Eureka and ship track**

713

714 Figures 3, 4 and 5 show the 2016 summertime (July and August) median aerosol size
715 distributions from SMPS measurements at Alert (Fig. 3), Eureka (Fig. 4), and for the
716 2016 ship track (Fig. 5). The figure panels show the zeroth through third moments of the
717 aerosol size distribution, aerosol number, integrated diameter (length), surface area and
718 volume. We define the aerosol number distribution (zeroth moment) as

719

$$720 \quad n_N(D_p) = \frac{dN}{d\log_{10}D_p}. \quad (3)$$

721

722 The aerosol integrated diameter (length) distribution (first moment) is

723

$$724 \quad n_D(D_p) = \frac{dD}{d\log_{10}D_p} = D \frac{dN}{d\log_{10}D_p}. \quad (4)$$

725

726 The aerosol surface area (second moment) is

727

$$728 \quad n_S(D_p) = \frac{dS}{d\log_{10}D_p} = \pi D^2 \frac{dN}{d\log_{10}D_p}. \quad (5)$$

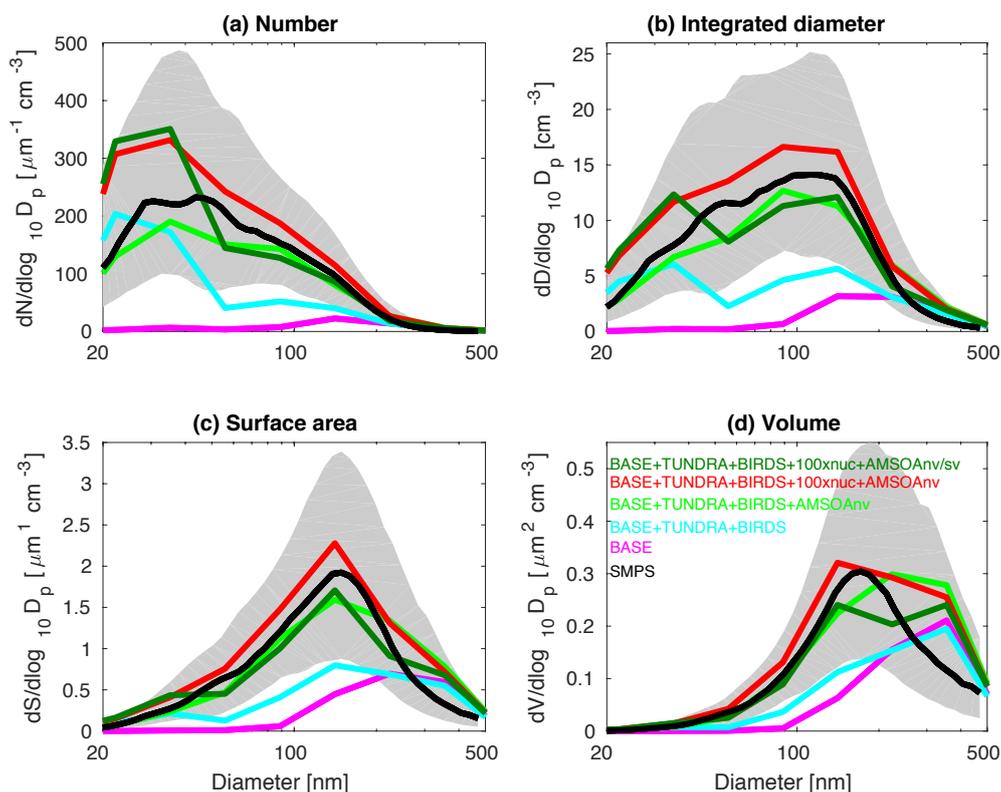

729

730 The aerosol volume (third moment) is

731

$$732 \quad n_V(D_p) = \frac{dV}{d\log_{10}D_p} = \frac{\pi}{6} D^3 \frac{dN}{d\log_{10}D_p}. \quad (6)$$

733

734

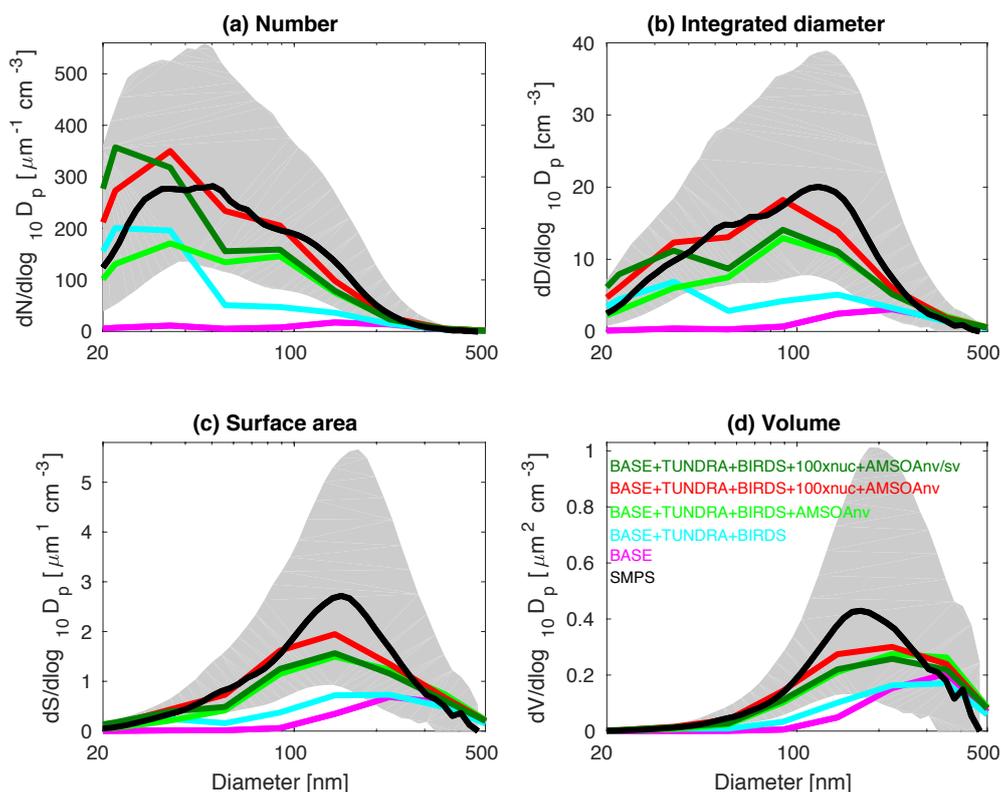

735

736 Figure 3: July and August 2016 median aerosol size distributions from scanning mobility particle sizer
 737 (SMPS) measurements at Alert (82.5° N, 62.3° W) (black) (described in Sect. 2.1) and for five GEOS-
 738 Chem-TOMAS simulations (color coded as shown on legend). Grey shading shows SMPS 20th to 80th
 739 percentile. Simulations are described in Table 1 and Sect. 2.3. Panels show aerosol distribution moments
 740 (a) aerosol number, (b) integrated aerosol diameter, (c) aerosol surface area, and (d) aerosol volume
 741 distributions. Note the different vertical scale relative to Figs. 4 and 5.

742

743

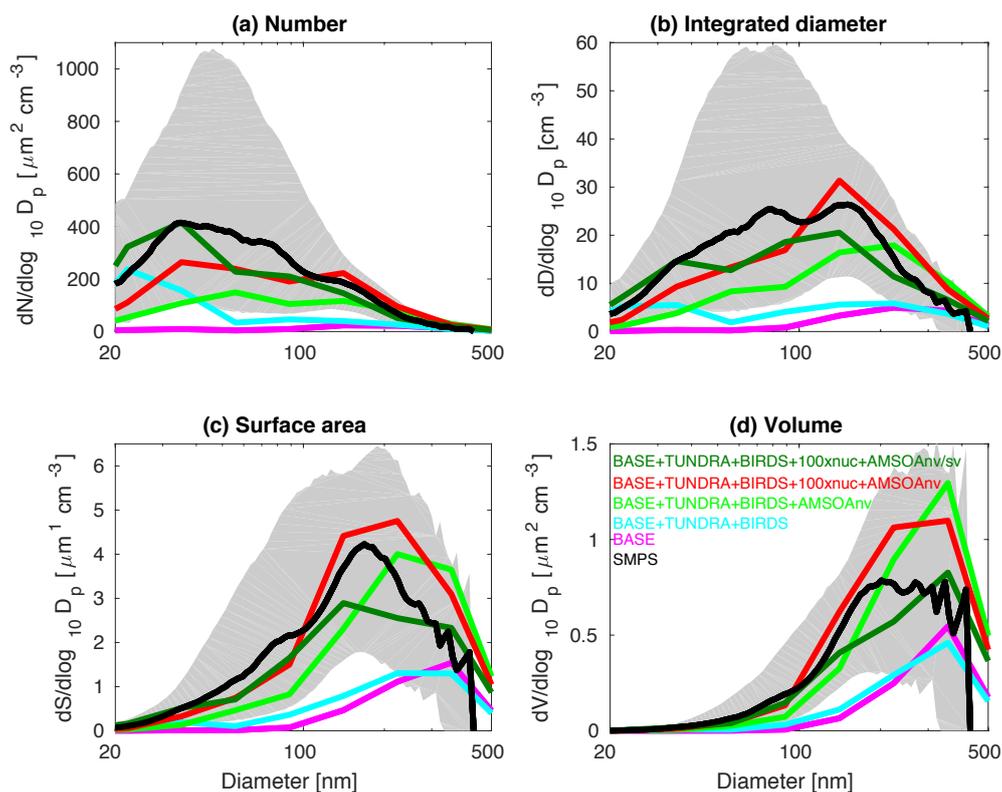

744 The observed distributions are similar between the three measurement sets. The number
 745 distributions peak in the Aitken mode at the particle diameter of 30-50 nm, which is

746

 751
 752
 753
 754
 755

Figure 4: July and August 2016 median aerosol size distributions from scanning mobility particle sizer (SMPS) measurements at Eureka (80.1° N, 86.4° W) (black) (described in Sect. 2.1) and for five GEOS-Chem-TOMAS simulations (color coded as shown on legend). Grey shading shows SMPS 20th to 80th percentile. Simulations are described in Table 1 and Sect. 2.3. Panels show aerosol distribution moments (a) aerosol number, (b) integrated aerosol diameter, (c) aerosol surface area, and (d) aerosol volume distributions. Note the different vertical scale relative to Figs. 3 and 5.

756 similar to summertime observations at other pan-Arctic sites (Tunved et al., 2013; Asmi
 757 et al., 2016; Nguyen et al., 2016; Freud et al., 2017; Gunch et al., 2017; Heintzenberg et
 758 al., 2017; Kolesar et al., 2017) and also in the central Arctic marine boundary layer
 759 (Heintzenberg and Leck, 2012; Karl et al., 2013; Heintzenberg et al., 2015). Interestingly,
 760 the value for the mode for the number distributions ($dN/d\log D_p$) has its smallest
 761 magnitude of about 200 cm^{-3} at the most northerly site (Alert), and increases moving
 762 southward to about 300 cm^{-3} at Eureka and 400 cm^{-3} for the ship track, which includes the
 763

764

765

766 Figure 5: July and August 2016 median aerosol size distributions from scanning mobility particle sizer
 767 (SMPS) measurements for the *CCGS Amundsen* 2016 ship track (black) (described in Sect. 2.1) and for five
 768 GEOS-Chem-TOMAS simulations (color coded as shown on legend). Grey shading shows SMPS 20th to
 769 80th percentile. Simulations are described in Table 1 and Sect. 2.3. Panels show aerosol distribution
 770 moments (a) aerosol number, (b) integrated aerosol diameter, (c) aerosol surface area, and (d) aerosol
 771 volume distributions. Note the different vertical scale relative to Figs. 3 and 4.

772

773

774 most southward extent. This pattern is consistent with the hypothesis of an important role
 775 for open water in building summertime aerosol size distributions (Heintzenberg et al.,
 776 2015; Willis et al., 2017; Dall'Osto et al., 2018b). A similar pattern is noted for the other
 777 three moments of the aerosol distribution.

778

779 Figures 3, 4 and 5 also show the simulated moments for the 3 sets of aerosol
 780 distributions. Simulation BASE strongly underpredicts all four moments of the
 781 distribution relative to all three of the measurement sets. Table 3 shows the MFE (Eq. (2))

782 between the simulations and measurements, using integrated values from the 4 moments
 783 of the distributions, similar to the approach employed by Hodshire et al. (2018). The
 784 MFEs are 1.17, 1.36 and 1.34 for Alert, Eureka, and the ship track, respectively, for
 785 simulation BASE. Implementation of sources of NH₃ from seabird-colonies (simulation
 786 BASE+BIRDS) reduces the MFE for all sites, and additional NH₃ from a tundra source
 787 for simulation BASE+TUNDRA+BIRDS further lowers the MFE at all sites (0.53 for
 788 Alert, 0.80 for Eureka and 0.97 for the ship track).

789

790

Mean Fractional Error	Ship	Eureka	Alert	3-site mean
BASE	1.34	1.36	1.17	1.29

791

792

793 Table 3: Mean fractional error (MFE) (Eq. (2)) between the nine GEOS-Chem-TOMAS simulations
 794 (described in Table 1 and Sect. 2.3) and the SMPS measurements (described in Sect. 2.1) for summertime-
 795 (July and August 2016) median aerosol size distributions at Alert, Eureka and during the *CCGS Amundsen*
 796 cruise shown in Figs. 3, 4, and 5, respectively.

797

798

799 Figures 3-5 also show that with the NH₃ from seabird colonies and tundra (simulation
 800 BASE+TUNDRA+BIRDS), an Aiken mode peak develops around 20-30 nm, but there is
 801 an underprediction of the number of aerosols with diameters between 30 nm to 200 nm
 802 and a strong underprediction of the aerosol diameter, surface area and volume moments.
 803 Simulation BASE+TUNDRA+BIRDS also underpredicts the organic carbon mass
 804 concentrations as shown in Table 2. This simulation suggests that condensation of H₂SO₄
 805 and MSA alone do not yield sufficient particle growth to match observations from the
 806 Canadian Arctic Archipelago, which show frequent particle growth events (Willis et al.,
 807 2016; Collins et al., 2017; Burkart et al., 2017b; Tremblay et al., 2018) and suggest a key

808 role for growth by organic vapor condensation (Burkart et al., 2017a; Willis et al., 2017;
809 Mungall et al., 2017). Marine primary organic aerosols could contribute to the Aitken
810 mode as investigated further in the following Sect. 3.5.

811

812 With the implementation of Arctic MSOA (simulation
813 BASE+TUNDRA+BIRDS+AMSOAnv), all four moments of the simulated aerosol
814 distributions are more consistent with the measurements. The MFE is reduced for the ship
815 track (0.43), Eureka (0.35) and Alert (0.13). These additional vapors condense on the
816 simulated particles and build the aerosol diameter, surface area, and volume distributions
817 to better represent the observations. For the ship track and at Eureka, scaling up the
818 nucleation rate further reduces the MFE (simulation
819 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv) by maintaining the number of
820 ultrafine particles despite the increase in the condensation sink that arises with the growth
821 from the Arctic MSOA. This scaling acts as a surrogate for nucleating vapors that could
822 be missing in our simulations such as iodine (Allan et al., 2015; Dall'Osto et al., 2018a)
823 and amines (Almeida et al., 2013), and also possible contribution from primary particle
824 fragmentation (Leck and Bigg, 2010). For Alert, the MFE deteriorates with nucleation
825 scaling suggesting that the standard ternary scheme yields sufficient particle formation
826 for that portion of the Canadian Arctic Archipelago under the assumption of growth by
827 non-volatile vapors.

828

829 The simulation with a 30/70 mix of non- and semi-volatile Arctic MSOA, respectively,
830 (simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv) yielded the lowest
831 MFE for the ship track (0.11) and for Alert (0.10). We find a similarly low MFE for
832 Eureka (0.09) with a doubling of the Arctic MSOA source under the assumption of a
833 30/70 mixed volatility (simulation
834 BASE+TUNDRA+BIRDS+100xnuc+2xAMSOAnv/sv). Given that our simulations
835 employ a fixed flux of Arctic MSOA-precursor vapors, and there is likely spatial
836 variability in their source flux and oxidative aging to become available for condensation
837 that is not well captured in our simulations; these intra-regional differences in the flux
838 strength required to match observations are expected. For the same reasons, the

839 simulations do not perfectly capture the increase in the magnitude of the mode for the
840 number, diameter, area and volume distributions between Alert and Eureka. However,
841 simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv (having lowest 3-site-
842 mean MFE) does capture the larger magnitude of the mode value for all four moments for
843 the ship track relative to those for Alert and Eureka.

844

845 Our finding that a mixture of non- and semi-volatile Arctic MSOA gives a closer fit
846 between the simulations and observations is in agreement with the measurement-based
847 findings of Burkart et al. (2017a) that the condensing vapors were surprisingly more
848 volatile than at lower latitudes. As discussed by Burkart et al. (2017a), these semi-volatile
849 (as opposed to non-volatile) vapors enable slower growth of the smallest mode of
850 particles with diameters around 20 nm and faster growth of the larger mode with
851 diameters around 90 nm. This larger mode is more efficiently removed by precipitation,
852 maintaining a relatively pristine environment with lower particle mass concentrations that
853 favors particle formation and growth.

854

855 The general improvements of the simulations with the addition of Arctic MSOA offers
856 support for a key role of marine biogenic emissions in shaping the Arctic size
857 distributions. Simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv,
858 specifically, yielded the lowest MFE for the total number concentration time series
859 comparisons (Fig. 2), and had close agreement with the observed summertime mean
860 organic carbon mass concentration at Alert (within about 10%, Table 2). As discussed in
861 Sect. 3.1, several uncertainties affect the interpretation of the model-measurement
862 comparisons for the quartz filter OC mass concentrations. The model-measurement
863 fractional bias (FB) for the volume distribution (Table 4) provides a year-matched
864 constraint on the total aerosol mass concentrations in our simulations without the
865 complications associated with the quartz filter measurements such as the possibility of
866 VOC uptake on the filters. Simulation
867 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv has the lowest volume distribution
868 FB for both Alert (+0.07) and the ship track (+0.01), while for Eureka two simulations
869 had the lowest FB, BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv (-0.06) and

870 BASE+TUNDRA+BIRDS+100xnuc+2xAMSOAnv/sv (+0.06). For all three sites,
871 implementation of Arctic MSOA reduced the fractional bias for the volume distribution
872 relative to an otherwise similar simulation without Arctic MSOA. As shown in Table 2,
873 all simulations generally matched the mass of sulfate+ammonium+MSA (and
874 contributions of other measured species, e.g. nitrate, were minor) so organic aerosol is
875 likely the most uncertain species.

876
877

879

880 Table 4: Fractional bias (as defined in Sect. 2.3) between the nine GEOS-Chem-TOMAS
881 simulations (described in Table 1 and Sect. 2.3) and the SMPS volume distribution
882 measurements (described in Sect. 2.1) for summertime- (July and August 2016) median
883 aerosol size distributions at Alert, Eureka and during the *CCGS Amundsen* cruise shown
884 in panel (d) on Figs. 3, 4, and 5, respectively

885

886

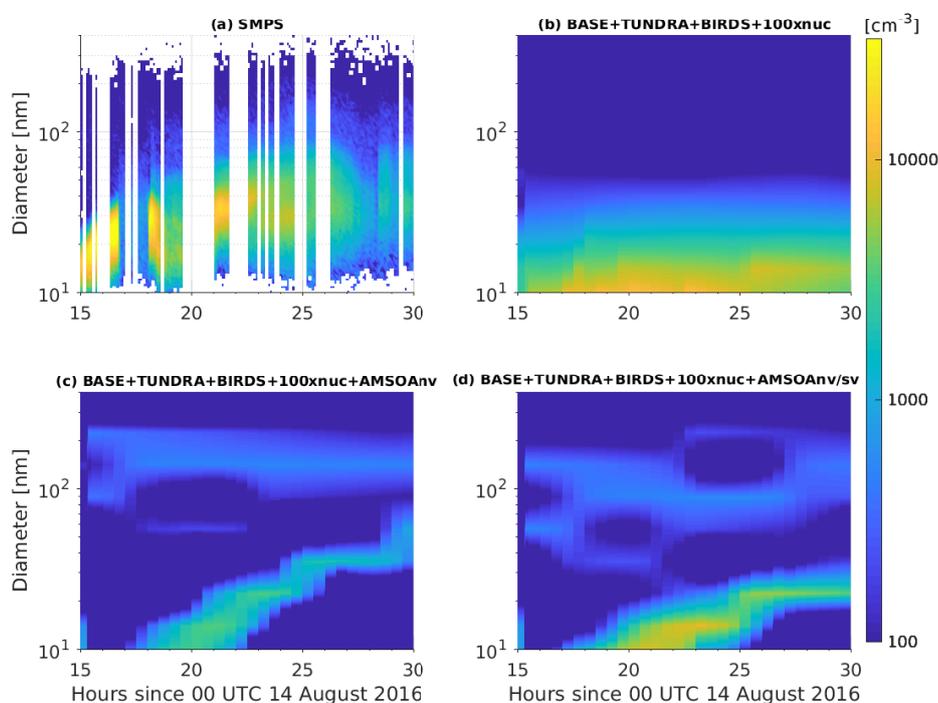

887 3.4 Role of Arctic MSOA during a growth event in Canadian Arctic Archipelago

888

889 Figure 6 provides an example of a particle growth event from the summer 2016 *CCGS*
890 *Amundsen* ship track through the Canadian Arctic Archipelago. The observations during
891 14-15 August 2016 show growth of particles from about 15 nm to about 35 nm over a
892 period of about 10 hours. Collins et al., 2017 and Burkart et al. (2017a) also report
893 growth rates of about 2-4 nm h⁻¹ for similar size aerosols during other growth events
894 observed from the *CCGS Amundsen* during the 2016 cruise. The top right panel shows

895 that without the source of Arctic MSOA (simulation
896 BASE+TUNDRA+BIRDS+100xnuc), the nascent particles do not exhibit sufficient
897 growth beyond about 15 nm by condensation of H₂SO₄ and MSA alone. The bottom left
898 panel shows that with the source of non-volatile

899

900

901 Figure 6: Time series of size-resolved aerosol number distributions (color contours show $dN/d\log D_p$) for
902 the growth event of 14-15 August 2016 as (a) observed along the Amundsen ship track (described in Sect.
903 2.1) and for the GEOS-Chem-TOMAS simulations along the ship track
904 (b) BASE+TUNDRA+BIRDS+100xnuc, (c) BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv and
905 (d) BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv. Simulations are described in Table 1 and Sect.
906 2.3.

907

908

909 Arctic MSOA for simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv, there is
910 growth from about 10 nm to about 50 nm over 10 hours, a growth rate that is faster than
911 observed for this event and faster than reported by Burkart et al., 2017a.

912

913 The bottom right panel of Fig. 6 shows for simulation
914 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv, particles grow from about 10 nm to

915 20 nm over about 8 hours, which is closer to the observed rate and slower than the
916 simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv, which assumed non-
917 volatile Arctic MSOA. Semi-volatile Arctic MSOA also enables faster growth of the
918 larger mode around 90 nm, in agreement with the observations of Burkart et al. (2017a)
919 that the larger mode grew faster. We note that the timing of the simulated event shown in
920 Fig. 6 is not a perfect match to the observations. Capture of the timing of individual
921 growth events is challenging for global models since sub-grid scale effects, including
922 spatial variations in the meteorological fields over the time frame of few hours, such as
923 cloud cover are not perfectly captured for the measurement site by the model resolution.
924 However, similar to our findings from the previous sections, a source of mixed non- and
925 semi-volatile Arctic MSOA also yields closer agreement with these measurements from
926 the Canadian Arctic Archipelago during the summer of 2016. This key role for semi-
927 volatile Arctic MSOA during the frequent summertime growth events in the Canadian
928 Arctic Archipelago is consistent with measurement-based studies for this region (Willis et
929 al., 2017; Collins et al., 2017; Burkart et al., 2017a; Leaitch et al., 2018; Tremblay et al.,
930 2018).

931

932 **3.5 Size-resolved aerosol composition**

933

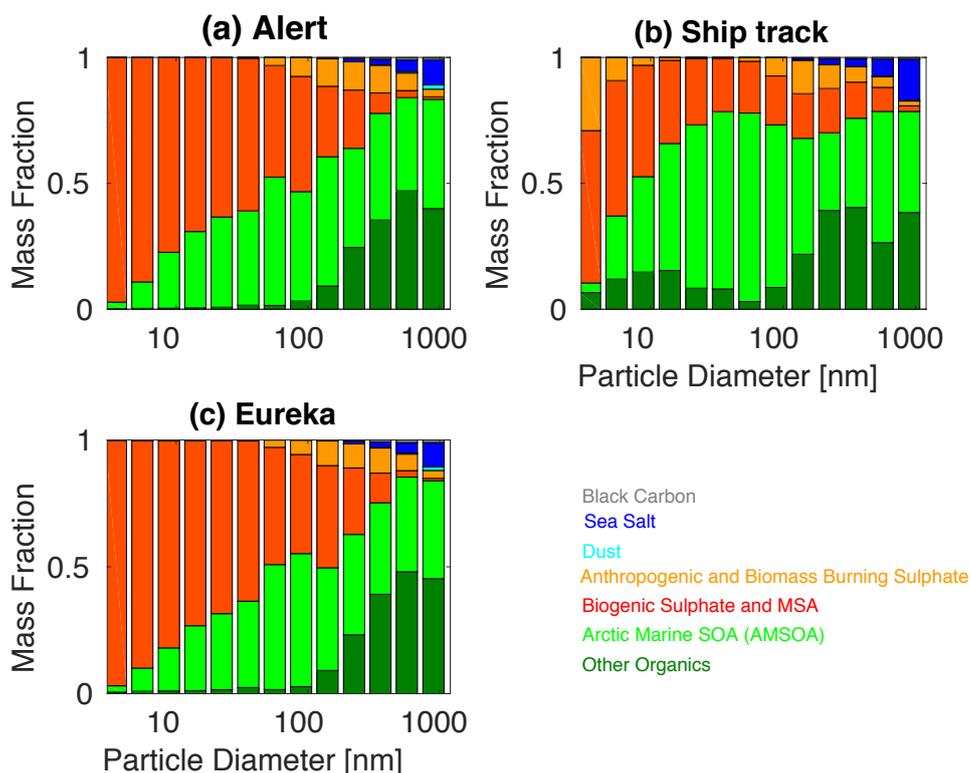

934 Few measurements are available of the composition of the summertime Arctic Aitken
935 mode due to insufficient instrument detection limits to detect the extremely low mass
936 concentrations in this size range (less than 100 ng m^{-3}). However the limited information
937 available does provide insight into the processes that shape the size distribution. For
938 example, Giamarelou et al. (2016) found that sub-12 nm particles in the Svalbard region
939 were primarily ammoniated sulfates, pointing to the importance of particle formation by
940 ternary nucleation of gas-phase NH_3 , H_2SO_4 and water and initial growth by lower
941 volatility sulfur-containing vapors.

942

943 Figure 7 shows the size-resolved mass fractions for the various aerosol components for
944 simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv. For the simulated sub-
945 10 nm particles, the simulated summertime (July and August) mean mass fractions at

946 Alert, Eureka and for the ship track are primarily biogenic sulfate and MSA, which arise
947 from oxidation of DMS, which is released to the atmosphere by marine biological
948 activity. Thus, the simulated composition exhibits similarities with the Svalbard
949 measurements, with the additional identification of a biogenic source. Figure 7 is also
950 consistent with the strong summertime biogenic sulfate component observed in the
951 Canadian Arctic Archipelago by Ghahremaninezhad et al. (2016).
952

953

954

955 Figure 7: Simulated summertime- (July and August 2016) mean size-resolved aerosol component mass
956 fractions for (a) Alert, (b) Amundsen ship track and (c) Eureka, for the simulation
957 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv as described in Table 1 and Sect. 2.3. Other organics
958 includes all organic aerosol except the Arctic marine secondary organic aerosol (AMSOA). Biogenic
959 sulfate includes all sulfate derived from the oxidation of dimethyl sulfide (DMS).
960

961

962

963

964 Limited measurements of the composition of particles with diameters between 60 to 100
965 nm during growth events at Eureka show that these particles are almost entirely
966 composed of organic compounds, which could also include a minor contribution from
967 MSA (Tremblay et al., 2018). Unfortunately, these measurements were limited to a few
968 growth events and cannot be directly compared with the simulated summertime mean
969 mass fractions shown in Fig. 7. Burkart et al. (2017a) calculated a cloud condensation
970 nuclei (CCN) hygroscopicity parameter (Petters and Kreidenweis, 2007) for the particles
971 during a growth event in the Canadian Arctic Archipelago and found a value also
972 indicating a mostly organic composition for those particles large enough to act as CCN.
973 Figure 7 shows that our simulation captures an increasing contribution of organics with
974 particle diameters towards 50-100 nm (sizes that can act as CCN), reflecting the key role
975 of organics in growth of particles towards sizes that can be climate-relevant by acting as
976 seeds for cloud droplet formation, or directly scattering and absorbing radiation
977 (diameters larger than about 100 nm). Semi-volatile organic vapors have also been shown
978 to have a role in growth of particles after they reach diameters of about 5 nm (Tröstl et
979 al., 2016). However, as noted by Karl et al. (2013) lower volatility vapors are needed for
980 initial growth over the first few nm. Thus, semi-volatile organic vapors are likely only
981 important in later growth beyond 10-20 nm.

982

983 Figure 7 shows that the simulated contribution of organics is greatest for the ship track,
984 reflecting the marine source of the condensable organics in our simulation. The ship track
985 also has the strongest contribution of ‘other organics’ in the sub-100 nm range, with a
986 peak contribution for particle diameters of 10-30 nm. This sub-100 nm organic
987 contribution (shaded in dark green on Fig. 7) represents the mass-fraction contribution of
988 primary marine organics in our simulation. These primary particles also grow to larger
989 sizes by condensation of Arctic MSOA in our simulations. As described in Sect. 2.2, all
990 sea spray emissions with diameters smaller than 100 nm are treated as hydrophobic
991 organic carbon. We use the Mårtensson et al. (2003) parameterization, which can be
992 considered as the upper limit of sea spray emissions for the sub-100 nm range, relative to
993 other parameterizations. As a result, we consider that our simulation provides an upper
994 limit on the mass fraction of marine primary organic aerosol in the Aitken mode in the

995 Canadian Arctic Archipelago region. The primary aerosol, particularly in the marine
996 boundary layer, is climate-relevant as it grows by condensation of Arctic MSOA towards
997 sizes of 50 nm to 100 nm. The dark green shading (‘other organics’) on Fig. 7 for sizes
998 larger than 100 nm represents contributions to the mass fractions by organics that have
999 been transported from lower latitudes, including those primary and secondary aerosols
1000 from biomass burning and other non-marine lower-latitude sources.

1001

1002 **3.6 Impact of Arctic MSOA on climate-relevant aerosol number concentrations,** 1003 **direct and indirect radiative effects**

1004

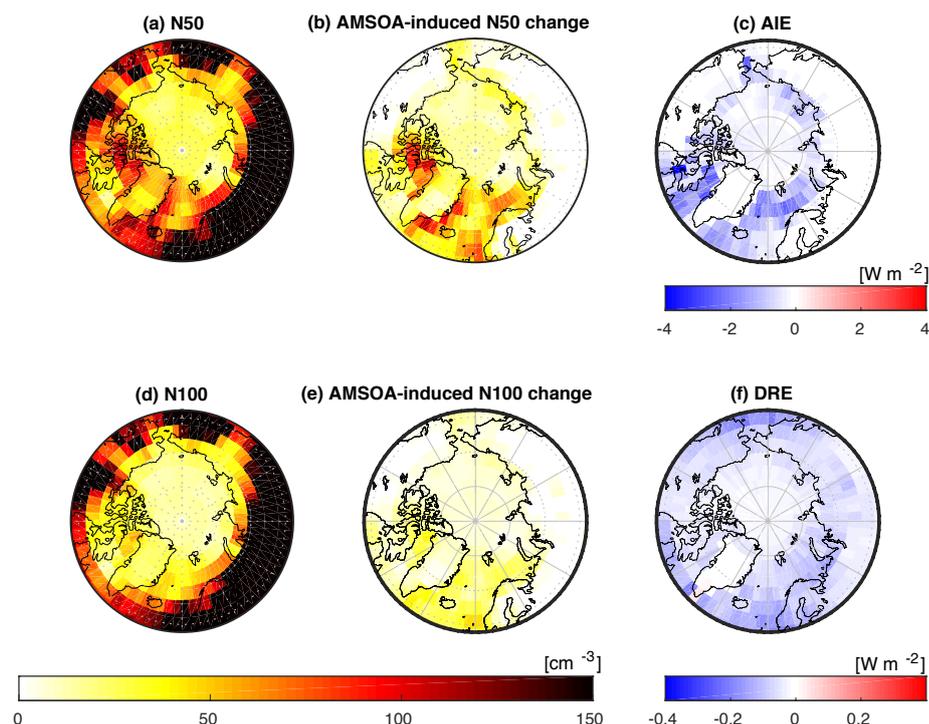

1005 In this section, we consider the role of Arctic MSOA on the simulated total number
1006 concentration of aerosols with diameter larger than 50 nm (N50) and 100 nm (N100) and
1007 the associated radiative effects using our simulation with the lowest overall model-
1008 measurement MFE (simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv)
1009 relative to the simulation without Arctic MSOA (BASE+TUNDRA+BIRDS+100xnuc).
1010 Figure 8 shows the pan-Arctic distribution of the simulated summertime- (July and
1011 August) mean surface-layer N50 and N100 for simulation
1012 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv. In the Canadian Arctic Archipelago
1013 region, the simulated summertime-mean N50 (50 cm^{-3} to 100 cm^{-3}) and N100 (10 cm^{-3} to
1014 30 cm^{-3}) ranges are consistent with monthly mean values from observations at Alert
1015 presented in Croft et al. (2016b). The panels in the middle column of Fig. 8 show that the
1016 addition of Arctic MSOA (simulation
1017 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv relative to
1018 BASE+TUNDRA+BIRDS+100xnuc) yields a N50 increase of about $50\text{--}75\text{ cm}^{-3}$ and a
1019 N100 increase of about 20 cm^{-3} in the Canadian Arctic Archipelago. These differences in
1020 the simulated N50 and N100 are attributed to the process of growth by condensation of
1021 Arctic MSOA, and will have climate-relevant impacts on aerosol radiative effects.

1022

1023

1024

1025

1026

1027

1028 Figure 8: Impact of Arctic MOSA, simulated summertime- (July and August 2016) mean geographic
 1029 distribution of surface-layer aerosol number concentrations for (a) particles with diameters larger than 50
 1030 nm (N50) for simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv, (b) surface-layer N50
 1031 difference for simulation BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv relative to simulation
 1032 BASE+TUNDRA+BIRDS+100xnuc, (c) aerosol indirect effect (AIE) at top of the atmosphere
 1033 (methodology described in Sect. 2.2) between these two simulations, attributed to Arctic MOSA
 1034 (AMSOA), (d) similar to a) but for N100, (e) similar to (b) but for N100 difference, (f) direct aerosol effect
 1035 (DRE) at top of the atmosphere (methodology described in Sect. 2.2) between these two simulations,
 1036 attributed to Arctic MOSA (AMSOA).

1037

1038

1039 Figure 8 also shows the geographic distribution of the top-of-the-atmosphere DRE and
 1040 cloud-albedo AIE (described in Sect. 2.2) for marine SOA (comparing between
 1041 simulations BASE+TUNDRA+BIRDS+100xnuc and
 1042 BASE+TUNDRA+BIRDS+100xnuc+AMSOAnv/sv). The pan-Arctic mean DRE
 1043 attributed to condensational growth by Arctic MOSA is -0.04 W m^{-2} . The simulated
 1044 Arctic MOSA effect is largest (about -0.1 W m^{-2} to -0.2 W m^{-2}) over the regions of open
 1045 water such as Baffin Bay, east of Greenland, and the Bering Sea. These are also regions

1046 of the largest N100 change since those particles with diameters larger than about 100 nm
1047 contribute strongly to scattering of solar radiation. Although our simulated Arctic
1048 MSOA-precursor vapor flux yielded particle distributions that were in close agreement
1049 with observations from the Canadian Arctic Archipelago (as shown in previous sections),
1050 there is considerable uncertainty about the Arctic MSOA source function such that
1051 terrestrial sources could also be missing from our simulations. These effects could change
1052 the spatial distribution and magnitude of the DRE. Further work is needed to better
1053 understand the source and nature of Arctic MSOA-precursor vapors in the Arctic to
1054 reduce uncertainties in the associated DRE.

1055

1056 The pan-Arctic mean cloud-albedo AIE attributed to Arctic MSOA is about -0.4 W m^{-2} .
1057 The AIE shows a similar geographic distribution to the changes in the N50, with largest
1058 values of -1 to -2 W m^{-2} in the Canadian Arctic Archipelago and east of Greenland, again
1059 related to the open water regions associated with the Arctic MSOA-precursor vapor flux
1060 implemented in our simulations. As with the DRE, there is a large uncertainty associated
1061 with the spatial distribution of this AIE due to the uncertainty about the source function
1062 for Arctic MSOA. However, we view this calculation as an indication that the impact of
1063 condensational growth by Arctic MSOA is expected to be relevant for the Arctic climate.
1064 Work is needed to better understand the composition and source flux of Arctic MSOA-
1065 precursor vapors.

1066

1067 **4. Conclusions**

1068

1069 We used the GEOS-Chem-TOMAS chemical transport model with size-resolved aerosol
1070 microphysics to interpret measurements conducted during the summertime of 2016 in the
1071 Canadian Arctic Archipelago, some as part of the NETwork on Climate and Aerosols:
1072 addressing key uncertainties in Remote Canadian Environments (NETCARE) project
1073 (Abbatt et al. (in prep.)). Three measurement platforms were considered. These platforms
1074 were located at Alert and Eureka, both in Nunavut, Canada and also onboard the *CCGS*
1075 *Amundsen*. We focused on examining the key processes that build summertime aerosol
1076 size distributions in this region, particularly the role of Arctic marine secondary organic

1077 aerosol (Arctic MSOA) condensation. The terminology Arctic MSOA was used to
1078 indicate secondary organic aerosol formed from precursors from marine (open ocean and
1079 coastal) sources north of 50° N, excluding MSA, which we treated as a separate aerosol
1080 component. In the Canadian Arctic Archipelago, Arctic MSOA is likely strongly
1081 controlled by emissions from marine biogenic activity (Willis et al., 2017; Leaitch et al.
1082 2018).

1083

1084 We find that Arctic MSOA contributes strongly to the summertime particle size
1085 distributions in the Canadian Arctic Archipelago. Building on measurement-based studies
1086 from the NETCARE project, we implemented a flux of condensable Arctic MSOA-
1087 precursor vapors into our GEOS-Chem-TOMAS simulations. This fixed flux of 500 μg
1088 $\text{m}^{-2} \text{d}^{-1}$ of Arctic MSOA-precursor vapors (with a yield of unity) emitted from open
1089 seawater in the Arctic and near Arctic (north of 50° N) was a crude representation of the
1090 source function because of the lack of knowledge about the nature and source of Arctic
1091 MSOA. However, implementation of condensable Arctic MSOA in our simulation
1092 reduced the model-to-measurement MFE for the summertime median aerosol size
1093 distributions by a factor of 2-4 across the three measurement platforms, indicating a
1094 strong sensitivity of the simulated size distributions to growth by Arctic MSOA. Without
1095 Arctic MSOA, particle growth to diameters of 50 nm to 200 nm was strongly
1096 underpredicted in our simulations. Increasing the particle nucleation rate by 100-fold
1097 further reduced the MFE for Eureka and the ship track, indicating that additional
1098 materials such as (but not limited to) gas-phase iodine, and/or amines and/or possibly
1099 extremely low volatility organics may be participating in nucleation, and/or other
1100 mechanisms such as particle fragmentation, leading to faster rates than our ternary
1101 scheme.

1102

1103 Introduction of a 30/70 non-/semi-volatile split for the simulated Arctic MSOA reduced
1104 by 2- to 3-fold the model-to-measurement MFE for the summertime aerosol size
1105 distributions for Alert (0.10) and the ship track (0.10), and also yielded the lowest MFE
1106 for Eureka (0.09) if the Arctic MSOA-precursor vapor source flux was doubled. These
1107 findings offer support that the condensing Arctic MSOAs contributing to growth of

1108 particles with diameters larger than about 20 nm in the Canadian Arctic Archipelago
1109 could contain a large fraction of semi-volatile species.

1110

1111 Size-resolved mass fractions indicated that initial growth of simulated nascent sub-10 nm
1112 particles (arising from ternary nucleation of ammonia sulfuric acid, water vapors)
1113 occurred primarily by condensation involving biogenic sulfate and MSA, both derived
1114 from oxidation of dimethyl sulfide of marine origin. Arctic MSOA contributed about 20-
1115 80% to size-resolved particle mass for diameters between 10 nm and 100 nm, with the
1116 largest contributions for the ship track simulation. The simulated contribution of primary
1117 organics of sea-spray origin to sub-100 nm particle mass fractions was largest for the ship
1118 track simulation in the marine boundary layer, with mass fractions approaching 20% for
1119 particles with diameters around 10 nm to 20 nm.

1120

1121 By comparing our best (lowest MFE) simulations with and without the Arctic MSOA
1122 formed from precursors with marine sources north of 50° N, we found that Arctic MSOA
1123 had a strong summertime- and pan-Arctic-mean top-of-the-atmosphere aerosol direct
1124 radiative effect (DRE) of -0.04 W m^{-2} , and cloud-albedo aerosol indirect effect (AIE) of
1125 -0.4 W m^{-2} . The comparison of these simulations with and without Arctic MSOA
1126 suggested a strong sensitivity of climate-relevant effects to Arctic MSOA. However, we
1127 caution that a high level of uncertainty is associated with our quantification of these
1128 effects, due to uncertainty about the composition, and source fluxes for these condensing
1129 vapors. Future studies are needed to reduce these uncertainties.

1130

1131 Many knowledge gaps remain regarding the role of organics within the processes that
1132 shape particle size distributions in the Arctic climate system. For example, Willis et al.
1133 (2017) found that the organics in the aerosol in the summertime Canadian Arctic
1134 Archipelago were not like typical biogenic SOA, having instead a character with a long
1135 hydrocarbon chain, implying a fatty-acid-type precursor, which is a common component
1136 of the marine microlayer. Additionally, Mungall et al. (2017) found that the marine
1137 microlayer in the Canadian Arctic Archipelago was a source of OVOCs, which could also
1138 be related to Arctic MSOA. Further measurements are needed to identify the organic

1139 vapors that yield Arctic MSOA through condensational particle growth, along with their
1140 sources, chemistry, and spatial distribution within the Arctic. Additionally, given the
1141 climate relevance of NH_3 through formation of nascent particles, measurements are
1142 needed to better identify and quantify its sources across the summertime Arctic, and to
1143 further examine the spatial distribution of the subsequent Arctic particle growth events.
1144 Further, size-resolved particle concentrations and composition measurements
1145 (particularly for sulfate and organic aerosol), would constrain the controlling processes
1146 for all sub-micron particle diameters. Such work could also reduce uncertainty related to
1147 aerosol effects within the Arctic climate system. This work will also lay a foundation for
1148 prediction of future aerosol effects within the context of our rapidly changing and
1149 warming Arctic, as sea ice extent, biological and anthropogenic activity are altered.

1150

1151 **Acknowledgements:**

1152

1153 We thank the Observatory operators at Alert, Desiree Toom, Alina Chivulescu, Dan
1154 Veber, Wendy Zhang, Darrell Ernst as well as Andrew Platt and Carrie Taylor for their
1155 support of the Environment and Climate Change Canada (ECCC) aerosol programme at
1156 Alert and Eureka. We are grateful for the hard work and dedication of the *CCGS*
1157 *Amundsen* crew and for the help of our colleagues on board. We thank O. Kupiainen-
1158 Määttä, T. Olenius, J. Julin, H. Vehkamäki, B. Murphy, and I. Riipinen for their support
1159 of this project through provision of the Atmospheric Cluster Dynamics Code (ACDC).
1160 The authors also thank Bonne Ford and Katelyn O'Dell for preparing the 2016 GFED4
1161 files in the format required for input to the GEOS-Chem-TOMAS model.
