

Interactive comment on “Consequences of dynamic and timing properties of new aerosol particle formation and consecutive growth events” by Imre Salma and Zoltán Németh

Anonymous Referee #4

Received and published: 14 January 2019

The manuscript presents a data set of particle size distribution by 5 years DMPS measurements at Budapest city center and 1 year measurement upwind of the city. Analysis of new particle formation is presented by particle formation rate J_6 and growth rate GR_{10} as well as starting time and duration time interval. Factors affecting NPF are explored by relating to gas-phase H_2SO_4 proxy, condensation sink (CS), meteorological data, and concentrations of SO_2 , O_3 , NO_x and CO . Despite there is no measurement for sub-6 nm particle and potential precursors for NPF, it is still an interesting data set could potentially contribute to a better understanding towards urban aerosols and constrain the atmospheric model. However, more detailed explore into the data would still be needed apart from performing correlation test between single parameters and

C1

conclude there is no correlation.

Specific comments:

Page8, line 256: the mean new-to-old rate ratios of J_6 were 1.23 for city center and 1.20 for near-city background. I would expect that traffic emission causes overestimation of formation rates because it is a source of nanoparticles. Please specify why correcting traffic emission in formation rates calculation gives higher J_6 .

Section 4.2: Discussion on NPF events frequency should include conditions of NPF days as well as non-NPF days. Properties discussed in the section are only based on events days. This could be misleading because non-events day conditions are not discussed. Line 484 conclude gas-phase H_2SO_4 are unlikely to be the limiting factor of NPF occurrence in Carpathian Basin including Budapest from the misalignment between the monthly occurrence frequency and the other properties. To make this statement solid, H_2SO_4 proxy for events days and non-events days is needed.

Page18, line548: Direct compare the numbers of J and GR or saying something contribute equally to the formation of particle and to their growth don't make sense because they are different physical variables. Correlation between J and GR are expected but comparison of the regression line with $J_6=GR_{10}$ doesn't give any useful information.

Page20: Lacking correlation with single parameters to J/GR doesn't tell too much as NPF is controlled by multiple parameters. With the size of the data set, authors could perform analysis on subsets of the data with certain constrains like temperature or H_2SO_4 proxy.

Page 20, line 625 to 636 and figure 4: $GR/H_2SO_4 \text{ proxy} = b * (1/H_2SO_4 \text{ proxy}) + a$ is equivalent to $a * H_2SO_4 \text{ proxy} + b = GR$. A negative 'a' means the higher H_2SO_4 , the lower the GR . This is contradictory to the interpretation of increasing gas-phase H_2SO_4 related to larger contribution of other vapors to particle growth. Another concern would be special care should be taken when combine H_2SO_4 proxy at sub-urban site and

C2

urban site as the VOCs and NO_x condition could be totally different but not taken into consideration.

Page 24, line 739: To make the full potential of the data set, more detailed studies on the contribution of NPF to regional particle concentration could be performed.

Spelling:

Line 113: mean see level-> mean sea level

Line 751: cloud -> CLOUD
