28 **Abstract**

29 PM<sub>2.5</sub> aerosol samples were collected from a Chinese mega-city in Nanjing  
30 (32.21°N and 118.73°E) during winter and analyzed for more than 100 compounds of  
31 twelve organic compound classes. The most abundant classes of compounds are *n*-  
32 alkanes (average, 205 ng m<sup>-3</sup>), followed by fatty acids (76.3 ng m<sup>-3</sup>), polycyclic  
33 aromatic hydrocarbons (PAHs) (64.3 ng m<sup>-3</sup>), anhydro-sugars (56.3 ng m<sup>-3</sup>), fatty  
34 alcohols (40.5 ng m<sup>-3</sup>), and phthalate esters (15.2 ng m<sup>-3</sup>), whereas hydroxy-/polyacids  
35 (8.33 ng m<sup>-3</sup>), aromatic acids (7.35 ng m<sup>-3</sup>), hopanes (4.19 ng m<sup>-3</sup>), primary sugars and  
36 sugar alcohols (4.15 ng m<sup>-3</sup>), lignin and resin products (2.94 ng m<sup>-3</sup>), and steranes (2.46  
37 ng m<sup>-3</sup>) are less abundant. The carbon preference index of *n*-alkanes (0.83-1.38)  
38 indicated that they were significantly originated from the fossil fuels combustion.  
39 Diagnostic concentration ratios of organic tracers suggested that PAHs and hopanes are  
40 mostly originated from coal burning and traffic emissions, respectively in Nanjing  
41 urban area. Positive matrix factorization analysis demonstrated that fossil fuel  
42 combustion is the major source (28.7%) in Nanjing winter aerosols. Most of the  
43 compounds generally showed higher concentrations in nighttime compared to daytime,  
44 due to the accumulation process associated with the inversion layers and enhancement  
45 of emissions from heavy trucks at night. We conclude that fossil fuel combustion  
46 largely influences the winter organic aerosols in urban Nanjing area. Based on the  
47 comparison of present results with previous studies, we found that pollution levels on  
48 organic aerosols have been decreased in the urban Nanjing atmosphere for the last  
49 decade.

## 54 **1 Introduction**

55           Organic aerosol (OA) is one of the major constituents of airborne particulates,  
56 accounting for up to 70% of the fine aerosol mass. They can play a crucial role in the  
57 radiative forcing of the Earth and more generally to the environment (Kanakidou et al.,  
58 2005). In the last two decades, more attention has been paid to identify organic aerosol  
59 optical and cloud formation properties that link OA directly to hydrological cycle and  
60 thereby sustainability issues (Dusek et al., 2006; Riipinen et al., 2012). They can affect  
61 the climate, air quality, human health, visibility, and ecosystems on the local, regional  
62 and global scale (Salma et al., 2017). There are two major sources of atmospheric  
63 aerosols that include both primary emissions and secondary aerosol formation. Primary  
64 organic aerosols (POA) are directly derived from various sources such as biomass  
65 burning, fossil fuels combustion, dust particles, microbial activities, and plant materials,  
66 etc., whereas secondary organic aerosols (SOA) are formed by the oxidation process of  
67 organic species in the atmosphere.

68           Various types of volatile organic compounds (VOCs) are emitted from natural  
69 and anthropogenic sources into the atmosphere. VOCs can be further photo-oxidized by  
70 OH, NO<sub>x</sub>, O<sub>3</sub> to form SOA in the atmosphere (Haque et al., 2016). Both POA and SOA  
71 can contribute to the organic particulate matter (PM) formation in the atmosphere,  
72 which can significantly control the physicochemical properties of aerosol particles  
73 (Kanakidou et al., 2005). The chemical characterization and the contributions of various  
74 sources of aerosol particles are essential to figure out the role and potential impacts of  
75 OA in the atmosphere. Moreover, OA poses adverse physiological effects on human  
76 health causing asthma, bronchitis, cancer, and heart disease, etc. (Pope et al., 2009;  
77 Ramírez et al., 2011).

78           Several studies have reported that OA plays an important role in both the direct  
79 and indirect aerosol forcing, affecting the earth's radiation balance and global air  
80 quality (Cooke et al., 1999; Lohmann et al., 2000; Jacobson, 2001; Chung and Seinfeld,  
81 2002). Based on the model study (Chung et al., 2012), black carbon (BC) is a climate-  
82 warming agent whereas organic matter (OM) is a cooling agent. The combined climatic  
83 effect of BC and OM can balance the radiative forcing. Model simulation proposed that  
84 OA can enhance the cloud droplet concentration and act as an important element of  
85 aerosol-cloud-climate feedback system (O'Dowd et al., 2004). Particularly, water-  
86 soluble organic carbon (WSOC) influences the hygroscopic properties of atmospheric  
87 particles and intensifies their cloud condensation nuclei (CCN) activity (Asa-Awuku et  
88 al., 2011). Enhanced CCN number concentrations might be increased the indirect  
89 radiative forcing by aerosol, resulting in a more reflective cloud formation (Twomey,  
90 1977) and less precipitation (Albrecht, 1989). The OA components uptake water vapor  
91 and their interactions with the inorganic salts dissolved in the same aqueous phase can  
92 alter the water contents and properties of aerosol particles (Kanakidou et al., 2005).  
93 Aerosol particles improved with OM can make the aerosol surfaces more hydrophilic or  
94 hydrophobic based on the mixing state and aerosol composition, which further modify  
95 the CCN activities of particles.

96           The large emissions of atmospheric particles from China have a major effect on  
97 regional and global climate changes (Huebert et al., 2003). Atmospheric pollution in  
98 China is a serious problem due to its rapid industrialization and urbanization. Globally,  
99 one-fourth of anthropogenic POA are originated in China (Cooke et al., 1999). Many  
100 studies have been performed to characterize inorganic aerosols from China because the  
101 significant dust emissions are familiar from the deserts area of western China. (Bergin  
102 et al., 2001; VanCuren and Cahill, 2002). However, studies on OAs of Chinese mega-

103 cities are still poorly understood (Guo et al., 2003; Bi et al., 2003; Yao et al., 2003).  
104 Nanjing is a highly industrialized mega-city located in east China with a population of  
105 over 8 million where air pollution is a critical problem. Previous studies of Wang et al.  
106 (2002a; 2002b) reported that the aerosol mass of fine particles ( $< 2.5 \mu\text{m}$ ) in Nanjing  
107 atmosphere was about 2-4 times higher than the United States Environmental Protection  
108 Agency (USEPA) regulations.

109 To better understand the molecular composition and sources of OAs in Chinese  
110 urban area, aerosol sampling campaign was carried on a day and night basis in the  
111 mega-city of Nanjing during winter period from 11 December 2014 to 11 January 2015.  
112 The objective of this study is to determine more than 100 organic compounds including  
113 aliphatic lipids, sugar compounds, polycyclic aromatic hydrocarbons (PAHs), hopanes,  
114 lignin and resin products, aromatic acids, polyacids, and steranes in the aerosol particles  
115 from Nanjing. Their chemical characteristics, diurnal patterns, and potential sources are  
116 discussed in comparison with previous studies conducted a decade ago.

## 117 **2 Experimental**

### 118 **2.1 Sample collection**

119  $\text{PM}_{2.5}$  sampling was performed from the rooftop of a six-story building at  
120 Nanjing University of Information Science and Technology, Nanjing, China using  
121 medium volume sampler (Laoshan, Qingdao, China) from 11 December 2014 to 11  
122 January 2015 (Figure 1). Daytime and nighttime sampling was conducted from 9:30 to  
123 21:00 and 21:30 to 9:00, respectively. Total of 62 samples was collected on prebaked  
124 ( $450^\circ\text{C}$  for 6 h) quartz fiber filters (80 mm) with an air flow rate of  $100 \text{ L min}^{-1}$ . After  
125 sampling, the filter samples were wrapped with aluminum foil, transported to the  
126 laboratory and stored at  $-20^\circ\text{C}$  until the analysis.

### 127 **2.2 Analysis of polar organics**

128           Several polar organic compounds containing COOH and OH groups were  
129 analyzed by gas chromatography-mass spectrometry (GC-MS) using solvent extraction  
130 followed by TMS-derivatization technique (Table S1). Filter aliquots (6.28 cm<sup>2</sup>) were  
131 extracted three times with 5 mL of dichloromethane/methanol mixture (2:1) under ultra-  
132 sonication for 10 min. The solvent extracts were filtered through quartz wool packed in  
133 a Pasteur pipette to remove all insoluble matrixes, concentrated using a rotary  
134 evaporator under vacuum and then totally dried under a gentle nitrogen stream. The  
135 dried extracts were derivatized with 50 µL of N,O-bis-(trimethylsilyl)trifluoroacetamide  
136 (BSTFA) plus 1% trimethylsilyl chloride and 10 µL of pyridine in a glass vial (1.5 mL)  
137 with a Teflon-lined screw cap at 70°C for 3h. The C<sub>13</sub> *n*-alkane (diluted in *n*-hexane)  
138 was used as an internal standard (1.43 ng µL<sup>-1</sup>) prior to injection into a GC-MS for  
139 identification. Detailed information on the chemical analysis is interpreted elsewhere  
140 (Wang and Kawamura, 2005).

141           The derivatives were analyzed using Hewlett-Packard (HP) model 6890 GC  
142 coupled to an HP model 5973 mass-selective detector (MSD). The sample was injected  
143 into a splitless mode with the injector temperature at 280°C. The GC oven temperature  
144 was set at 50°C for 2 min and then increased from 50 to 120°C at 30°C min<sup>-1</sup>, and then  
145 to 300°C at 6°C min<sup>-1</sup> with a final isothermal hold at 300°C for 16 min. The GC  
146 separation was performed on a DB-5MS fused silica capillary column (30 m long ×  
147 0.25 mm inner diameter × 0.5 µm film thickness) with a carrier gas of helium (rate 1.0  
148 mL min<sup>-1</sup>). The mass spectrometer was conducted at 70 eV on an electron impact (EI)  
149 mode with a scan range from 50 to 650 Daltons (Da).

150           The organic components were determined by comparison with the retention  
151 times and mass spectra of authentic standards as well as literature and National Institute  
152 of Standards and Technology (NIST) library data of mass fragmentation patterns

153 (Medeiros and Simoneit, 2007). GC-MS relative response factor (RRF) of each  
154 compound was calculated using authentic standards and surrogate compounds. We  
155 performed a recovery experiment three times and acquired the average value of more  
156 than 80% for target compounds. The field blank filters ( $n = 5$ ) were analyzed by the  
157 procedures as described above. The target species were not noticed in the blank filters.  
158 The analytical errors based on replicate analyses ( $n = 5$ ) were  $<10\%$ .

### 159 2.3 Analysis of nonpolar organics

160 Non-polar organics, including *n*-alkanes, PAHs, hopanes, and steranes were  
161 analyzed using thermal desorption gas chromatography-mass spectrometry (TD-GC-  
162 MS) technique. It should be noted that higher recoveries ( $>90\%$ ) were obtained for  
163 nonpolar organics using TD-GC-MS compared to TMS-derivatization/GC-MS ( $<70\%$ )  
164 technique. The filter aliquots (3 mm diameter) were cut into two pieces and then placed  
165 into a TD quartz tube (78 mm long  $\times$  4 mm inner diameter) and spiked with internal  
166 standard mixture (isotope-labeled reference compounds) for quantification. The internal  
167 standards consisted of 3 deuterated PAHs, e.g., Nap- $d_8$ , Ace- $d_{10}$ , and Phe- $d_{10}$ .

168 Thermal desorption was performed on an Agilent GC-MS system model  
169 7890B/5977A. A capillary column (HP-5MS UI, 5% biphenyl/95% dimethylsiloxane,  
170 30 m long  $\times$  0.25 mm inner diameter  $\times$  0.25  $\mu\text{m}$  film thickness) was used to separate the  
171 target compounds. The GC oven temperature programmed from 35°C (3 min) to 120°C  
172 at 10°C  $\text{min}^{-1}$ , ramped from 120°C to 146°C at 4°C  $\text{min}^{-1}$  and continued to 310°C at  
173 8°C  $\text{min}^{-1}$ , then held at 310°C for 16 min. The sample on the filter punch was inserted  
174 into the TD tube with the initial temperature at 35°C before running and increased up to  
175 300°C manually at 12°C  $\text{sec}^{-1}$  after starting the analysis. Column flow rate was 2 mL  
176  $\text{min}^{-1}$  and split flow was 10 mL  $\text{min}^{-1}$  for the first 3min, then column and split flow rate  
177 changed to 1 mL  $\text{min}^{-1}$  and 25 mL  $\text{min}^{-1}$ , respectively. The electron ionization mass

178 spectra (70 eV) were conducted on a scan mode range from 50 to 650 Da. The  
179 temperatures of the ion source, quadruples and transfer line were set at 310, 150 and  
180 310°C, respectively.

#### 181 **2.4 Carbonaceous components analysis**

182 Organic carbon (OC) and elemental carbon (EC) were measured using a Sunset  
183 Laboratory carbon analyzer following the IMPROVE (Interagency Monitoring of  
184 Protected Visual Environments) thermal-optical evolution protocol and assuming  
185 carbonate carbon to be insignificant in the sample (Boreddy et al., 2018). An area of  
186 1.54 cm<sup>2</sup> of each quartz filter sample was insert in a quartz boat inside the thermal  
187 desorption chamber of the analyzer, and then stepwise heating was performed.

188 A filter cut of 3.14 cm<sup>2</sup> of each sample was extracted with 20 mL organic-free  
189 ultrapure water (resistivity >18.2 MΩ cm, Sartorius arium 611 UV) under  
190 ultrasonication for 30 min. The water extracts were then passed through a membrane  
191 disc filter to throw away the insoluble filter matrixes and analyzed for water-soluble  
192 organic carbon (WSOC) using a total organic carbon (TOC) analyzer (Shimadzu, TOC-  
193 Vcsh) (Boreddy et al., 2018). The analytical errors in the triplicate analyses were within  
194 5% for all carbonaceous components and the concentrations reported here were  
195 corrected for the field blanks.

### 196 **3 Results and Discussion**

#### 197 **3.1 Diurnal variations and meteorological conditions**

198 No significant difference was observed between day- and night-time for organic  
199 compounds in winter aerosols from Nanjing urban area (Figure 2, Tables 1 and S1).  
200 Nevertheless, concentrations of organic compounds in nighttime were slightly higher  
201 than daytime in most of the cases. It is notable that the planetary boundary layer height  
202 (PBLH) is generally lower in nighttime than daytime causing higher concentrations of

203 aerosol particles at night. Interestingly, we found high loadings of organics in daytime  
204 sample collected on 15 December when PBLH was high (632 m), whereas lower levels  
205 of organics were observed in nighttime of 14 December (PBLH = 82.2 m) (Figures 3  
206 and S1b).

207 We observed one episode (E1) during 2 - 5 January while  $PM_{2.5}$  and all organic  
208 compounds showed similar temporal variations with high loadings (Figure 3).  
209 Fascinatingly,  $NO_2$  showed high concentration during E1, whereas relative humidity  
210 (RH) and ozone ( $O_3$ ) levels were not high (Figure S1). Our results suggest that  $NO_2$   
211 influences the organic molecular compositions in urban aerosols. It is noteworthy that  
212 the major source of  $NO_2$  is of vehicular exhaust origin (Kendrick et al., 2015). Previous  
213 studies also reported that  $NO_x$  could affect SOA formation (Kanakidou et al., 2005;  
214 Zhang et al., 2015; Mochizuki et al., 2015). Moreover, PAHs, hopanes, and steranes  
215 showed another episode on 23 and 24 December 2014 probably due to the coal  
216 combustion event. It should be noted that higher RH (81-88%) and  $PM_{2.5}$  levels (152-  
217  $226 \mu g m^{-3}$ ) cause less visibility on 29 December (1.7 km), 10 January (1.8 km), and 11  
218 January (1.6 km), which might be due to the haze formation. It is remarkable that the  
219 levels of organics were not high during these periods (Figures 3 and S1). These results  
220 imply that  $NO_x$  chemistry is important than aqueous phase chemistry for OAs in the  
221 Nanjing atmosphere.

### 222 3.2 Carbonaceous components

223 The results of OC, EC, and WSOC are mentioned in Table 1. The values of OC  
224 and EC were found to be  $8.76-40.0 \mu g m^{-3}$  (ave.  $18.6 \mu g m^{-3}$ ) and  $2.41-30.3 \mu g m^{-3}$  ( $8.25$   
225  $\mu g m^{-3}$ ) in daytime, and  $2.98-40.1 \mu g m^{-3}$  ( $19.1 \mu g m^{-3}$ ) and  $0.87-22.9 \mu g m^{-3}$  ( $8.86 \mu g$   
226  $m^{-3}$ ) in nighttime, respectively. We found that the day and night variations of OC and  
227 EC values are also not significant. The mass ratio of OC to EC (OC/EC) is often used to

228 characterize fossil fuels and biomass burning emissions. Several investigators have used  
229 OC/EC ratios to classify the sources of carbonaceous aerosols (Ram et al., 2008;  
230 Sandradewi et al., 2008; Saarikoski et al., 2008). The higher OC/EC ratios imply that  
231 major source of carbonaceous species is from biomass burning, whereas lower ratios are  
232 characteristics of emissions from fossil fuels combustion. Sandradewi et al. (2008) have  
233 documented an average OC/EC ratio of 1.1 for vehicular emission and 7.3 for wood  
234 burning emission. Saarikoski et al. (2008) pointed out OC/EC ratios of 0.71 for  
235 vehicular emission and 6.6 for biomass burning. Watson et al. (2001) proposed the  
236 OC/EC ratios of 1.1 for vehicular emission, 2.7 for coal combustion and 9.0 for biomass  
237 burning emission. The OC/EC ratios ranged from 1.30 to 3.80 with a mean value of  
238 2.40 in this study, which is comparable to the values reported for coal combustion and  
239 vehicular emission. These results suggest that fossil fuel combustion such as coal  
240 combustion and vehicular emissions were the major source of carbonaceous aerosols in  
241 Nanjing urban area.

242         The ratios of OC to EC are also used to differentiate the relative contribution of  
243 primary vs. secondary sources; high OC/EC ratios (>2.0) were reported for the aerosols  
244 with significant contributions of SOA (Kunwar and Kawamura, 2014; Pani et al., 2017).  
245 The OC/EC ratio in this study was on average 2.40, suggesting the significant  
246 contribution of SOA in Nanjing aerosols that is consistent with PMF results (see section  
247 3.4). The concentration range of WSOC was 5.52-26.6  $\mu\text{g m}^{-3}$  (11.7  $\mu\text{g m}^{-3}$ ) in daytime  
248 and 2.51-20.2  $\mu\text{g m}^{-3}$  (11.8  $\mu\text{g m}^{-3}$ ) in nighttime. The WSOC/OC ratios often used to  
249 discuss the SOA formation via photochemical aging of atmospheric aerosol particles.  
250 The WSOC/OC ratios exceeding 0.4 indicate the aged aerosols with the significant  
251 contribution of SOA (Boreddy et al., 2018). The average WSOC/OC ratio of 0.64 in the  
252 present study indicates that OAs in Nanjing were relatively aged.

### 253 3.3 Organic molecular compositions

254 We detected twelve organic compound classes, including sugars, lignin and  
255 resin acids, fatty acids, fatty alcohols, *n*-alkanes, PAHs, hopanes, steranes, glycerol and  
256 polyacids, and phthalate esters, and aromatic acids in the aerosol samples from Nanjing.  
257 The total concentrations of organics were on average 424 ng m<sup>-3</sup> in daytime and 555 ng  
258 m<sup>-3</sup> in nighttime with the predominance of *n*-alkanes followed by fatty acids, PAHs,  
259 anhydro-sugars, fatty alcohols, phthalate esters, glycerol and polyacids, aromatic acids,  
260 sugars, hopanes, lignin and resin acids, and steranes (Figure 2). Table S1 shows the  
261 values of identified organic compounds. Levoglucosan was the single dominant species  
262 followed by C<sub>16</sub> and C<sub>24</sub> fatty acids, and C<sub>29</sub> *n*-alkane (Table S1).

#### 263 3.3.1 Aliphatic lipid components

264 The lipid compounds, e.g., fatty acids, fatty alcohols, and *n*-alkanes are mainly  
265 originated from marine or microbial detritus, terrestrial higher plant waxes, and fossil  
266 fuels combustion. Homologues of *n*-alkanes (C<sub>13</sub>-C<sub>39</sub>) were detected with higher  
267 concentrations in nighttime (74.8-535 ng m<sup>-3</sup>, ave. 228 ng m<sup>-3</sup>) than daytime (97.6-497  
268 ng m<sup>-3</sup>, 184 ng m<sup>-3</sup>) with a maximum at C<sub>29</sub> (14.0 ng m<sup>-3</sup> during daytime and 17.9 ng m<sup>-3</sup>  
269 during nighttime) in Nanjing aerosols (Tables 1 and S1, Figure 4a). These  
270 concentrations are comparable to those reported from urban cities in Hong Kong (195  
271 ng m<sup>-3</sup>) and Shanghai (259 ng m<sup>-3</sup>) (Wang et al., 2006), but much higher than the  
272 western North Pacific region (0.11-14.1 ng m<sup>-3</sup>) (Kawamura et al., 2003). Concentration  
273 levels of *n*-alkanes in this study are not significantly different from previous studies in  
274 Nanjing (112-265 ng m<sup>-3</sup>, 172 ng m<sup>-3</sup> during daytime; 61.0-503 ng m<sup>-3</sup>, 278 ng m<sup>-3</sup>  
275 during nighttime) (Table 2) (Wang and Kawamura, 2005). *n*-Alkanes originated from  
276 fossil fuel combustion are dominated by low molecular weight (LMW) homologues

277 ( $\leq C_{25}$ ) (Wang et al., 2009), whereas those derived from plant wax are dominated by  
278 high molecular weight (HMW) ones ( $>C_{25}$ ) (Hays et al., 2005).

279 Biogenic *n*-alkanes showed stronger odd/even carbon number predominance  
280 with a carbon preference index (CPI) of  $>5$ , whereas anthropogenic *n*-alkanes CPI value  
281 is usually close to unity (Simoneit et al., 1991a, 2004c). CPI values obtained in this  
282 study ranged from 1.18-1.32 (ave. 1.28) in daytime and 1.10-1.37 (1.24) in nighttime,  
283 which is close to unity. This result suggests that the major contributor of *n*-alkanes is  
284 the anthropogenic activity such as fossil fuels combustion with less contribution from  
285 higher plants in Nanjing aerosols. The present CPI values are similar with those from  
286 other Chinese urban areas (ave. 1.16) (Wang et al., 2006) and Tokyo (1.10-2.80, ave.  
287 1.50) (Kawamura et al., 1995). On the contrary, higher CPI values were reported for  
288 Mt. Tai (4.60) (Fu et al., 2008) and Chichi-jima aerosols (4.50) (Kawamura et al.,  
289 2003), where *n*-alkanes were mainly originated from terrestrial higher plant waxes.  
290 Plant wax derived *n*-alkanes are estimated as the excess of odd homologues minus  
291 adjacent even homologues (Simoneit et al., 1991b, 2004c), which is attributable to  
292 vascular plant waxes (Tables 1 and S1). Concentrations ranges of higher plant wax  
293 derived *n*-alkanes were 2.12-48.1 ng m<sup>-3</sup> (ave. 15.5 ng m<sup>-3</sup>) in daytime and 0.86-58.9 ng  
294 m<sup>-3</sup> (17.6 ng m<sup>-3</sup>) in nighttime, both of which are much lower than total *n*-alkanes,  
295 indicating that *n*-alkanes in Nanjing urban area are derived mainly from fossil fuel  
296 combustion.

297 A homologous series of C<sub>12:0</sub>-C<sub>32:0</sub> saturated fatty acids, including two  
298 unsaturated fatty acids (C<sub>18:1</sub> and C<sub>18:2</sub>), were identified in Nanjing samples. The values  
299 of total fatty acids ranged from 14.3 to 254 ng m<sup>-3</sup> (ave. 66.8 ng m<sup>-3</sup>) during daytime,  
300 whereas they ranged from 8.59 to 252 ng m<sup>-3</sup> (91.3 ng m<sup>-3</sup>) during nighttime. It is  
301 notable that fatty acids are less abundant compared to *n*-alkanes in Nanjing samples

302 (Figure 2). The molecular distributions of fatty acids are observed by a strong even  
303 carbon number predominance with  $C_{\max}$  at  $C_{16:0}$  and  $C_{24:0}$  (Table S1 and Figure 4b). CPI  
304 values of fatty acids are found to be 5.41 in daytime and 5.52 in nighttime samples. A  
305 similar distribution pattern has been proposed in marine and continental aerosols  
306 (Mochida et al., 2002; Kawamura et al., 2003; Fu et al., 2008). LMW fatty acids  
307 ( $<C_{20:0}$ ) are originated from various sources, e.g., vascular plants, microbial sources,  
308 and marine phytoplankton, while HMW fatty acids ( $>C_{20:0}$ ) are derived from terrestrial  
309 higher plant waxes (Kawamura et al., 2003; Kolattukudy, 1976; Simoneit, 1978).  
310 Biomass burning, motor vehicles, and cooking can also be the important sources of fatty  
311 acids in urban areas (Fu et al., 2010). The values of  $C_{18:1}$  was observed lower in daytime  
312 than nighttime, suggesting an enhanced emission to the atmosphere and oxidation with  
313 a higher rate in daytime (Kawamura and Gagosian, 1987).

314 Concentration ranges of  $C_{12}$ - $C_{34}$  fatty alcohols were 7.30-165  $\text{ng m}^{-3}$  (ave. 36.9  
315  $\text{ng m}^{-3}$ ) during daytime and 4.61-129  $\text{ng m}^{-3}$  (43.8  $\text{ng m}^{-3}$ ) during nighttime (Table S1  
316 and Figure 2). Their molecular distributions are characterized by a strong even-to-odd  
317 carbon number predominance with  $C_{\max}$  at  $C_{28}$  or  $C_{30}$  (Figure 4c). We found that the  
318 CPI values of fatty alcohols in Nanjing aerosols (2.56-10.3, ave. 5.22 in daytime and  
319 3.06-15.5, 6.32 in nighttime) are lower than those of aerosols from Chennai, India  
320 ( $9.75 \pm 2.94$ ) (Fu et al., 2010) and Mt. Tai, China (CPIs 7.95-66.5, ave. 25.6 in daytime  
321 and 12.2-53.4, 22.8 in nighttime) (Fu et al., 2008). HMW fatty alcohols ( $>C_{20}$ ) are  
322 dominant in the terrestrial higher plant, soils, and loess deposits, whereas LMW fatty  
323 alcohols ( $<C_{20}$ ) are dominant in marine biota and soil microbes (Simoneit et al., 1991b).  
324 Moreover, a large amount of fatty alcohols together with fatty acids and  $n$ -alkanes can  
325 also be derived from biomass burning (Simoneit, 2002). A positive correlation was  
326 observed between fatty alcohols and levoglucosan ( $r = 0.60$ ,  $p < 0.001$ ), indicating that

327 fatty alcohols are partly originated from biomass burning in Nanjing winter aerosols  
328 (Figure S2c). This conclusion is further supported by the factors resolved by PMF  
329 analysis, where high loading of fatty alcohols was found with a biomass burning tracer  
330 levoglucosan.

### 331 3.3.2 Biomass burning tracers

332 Levoglucosan, galactosan, and mannosan are class of anhydro-sugars, which are  
333 produced by the pyrolysis of cellulose and hemi-cellulose (Simoneit, 2002).  
334 Levoglucosan is a unique tracer of biomass burning, and has been reported in urban  
335 (Wang et al., 2006; Fu et al., 2010; Yttri et al., 2007), marine (Simoneit et al., 2004b;  
336 Ding et al., 2013), and polar regions (Stohl et al., 2007; Fu et al., 2009). Levoglucosan  
337 is a relatively stable species in the atmospheric aerosol and could be transported long  
338 distances (Mochida et al., 2010). We found that levoglucosan is one of the most  
339 abundant single tracer among all the identified compounds in the presents tudy, with a  
340 concentration range of 4.79-179 ng m<sup>-3</sup> (ave. 38.4 ng m<sup>-3</sup>) during daytime and 4.96-354  
341 ng m<sup>-3</sup> (66.0 ng m<sup>-3</sup>) during nighttime (Tables 1 and S1, Figure 5a), although the values  
342 are lower than previous results reported in Nanjing (Wang and Kawamura, 2005).

343 Levoglucosan could account for up to 90% of total sugars in Chinese urban  
344 aerosols (Wang et al., 2006). The contribution of levoglucosan to OC and WSOC were  
345 0.02-0.51% (ave. 0.09%) and 0.03-0.57% (0.13%) in daytime and 0.02-0.48% (0.13%)  
346 and 0.03-0.78% (0.22%) in nighttime, respectively. The amount of galactosan was  
347 found to be 0.65-7.47 ng m<sup>-3</sup> (ave. 2.26 ng m<sup>-3</sup>) during daytime and 0.48-7.75 ng m<sup>-3</sup>  
348 (3.13 ng m<sup>-3</sup>) during nighttime, whereas those of mannosan were 0.36-4.30 ng m<sup>-3</sup> (1.62  
349 ng m<sup>-3</sup>) in daytime and 0.27-5.73 ng m<sup>-3</sup> (2.06 ng m<sup>-3</sup>) in nighttime (Table S1 and Figure  
350 5a). Galactosan and mannosan were also detected in the aerosol samples. Levoglucosan  
351 showed similar temporal trends and strong correlations with galactosan ( $r = 0.87$ ,

352  $p < 0.001$ ) and mannosan ( $r = 0.84$ ,  $p < 0.001$ ) (Figure S2a). It should be noted that the  
353 levoglucosan level in this study is 4-6 times lower than that of a previous study in  
354 Nanjing (Table 2) (Wang and Kawamura, 2005). This result implies that biomass-  
355 burning emissions have been decreased significantly in the last decade in the Nanjing  
356 area during winter.

357 We detected four lignin and resin products, i.e., 4-hydroxybenzoic, vanillic  
358 syringic, and dehydroabietic acids, which have been used as biomass-burning tracers  
359 (Simoneit et al., 2004c). Lignin is a wood polymer, which can produce phenolic acids  
360 during burning whereas dehydroabietic acid is more specific to conifer resin (Simoneit,  
361 2002). We found that 4-hydroxybenzoic acid was dominant among all lignin and resin  
362 products identified in Nanjing samples (Figure 5b). The concentration ranges of 4-  
363 hydroxybenzoic, vanillic and syringic acids in day- and night-time were  $0.65\text{--}4.31\text{ ng m}^{-3}$   
364  $^3$  (ave.  $1.80\text{ ng m}^{-3}$ ) and  $0.62\text{--}4.96\text{ ng m}^{-3}$  ( $2.01\text{ ng m}^{-3}$ ),  $0.04\text{--}0.92\text{ ng m}^{-3}$  ( $0.25\text{ ng m}^{-3}$ )  
365 and  $0.08\text{--}0.66\text{ ng m}^{-3}$  ( $0.25\text{ ng m}^{-3}$ ), and  $0.04\text{--}0.57\text{ ng m}^{-3}$  ( $0.17\text{ ng m}^{-3}$ ) and  $0.05\text{--}0.43\text{ ng}$   
366  $\text{m}^{-3}$  ( $0.20\text{ ng m}^{-3}$ ), respectively. The value of dehydroabietic acid was observed  $0.11\text{--}$   
367  $1.16\text{ ng m}^{-3}$  ( $0.46\text{ ng m}^{-3}$ ) during daytime and  $0.00\text{--}8.29\text{ ng m}^{-3}$  ( $0.93\text{ ng m}^{-3}$ ) during  
368 nighttime. The levels of lignin and resin acids in this study are 1-10 orders of magnitude  
369 lower than those from India (Fu et al., 2010) and China (Wang et al., 2006). Lignin  
370 products showed strong correlations with levoglucosan ( $r = 0.60\text{--}0.72$ ,  $p < 0.001$ ),  
371 suggesting the similar sources and origins. In contrast, there is no correlation of  
372 dehydroabietic acid with levoglucosan ( $r = 0.07$ ), indicating a different source of  
373 dehydroabietic acid in Nanjing aerosols. The low concentrations of dehydroabietic acid  
374 imply that boreal conifer forest fires are not important for the Nanjing aerosols.

### 375 3.3.3 Primary sugars and sugar alcohols

376 Sugar compounds are considered as tracers for primary biological aerosol  
377 particles, which are water-soluble and thus contribute to WSOC in aerosol particles  
378 (Elbert et al., 2007; Medeiros et al., 2006; Yttriet al., 2007). Four primary sugars  
379 (glucose, fructose, trehalose, and sucrose) and four sugar alcohols (erythritol, arabitol,  
380 mannitol, and inositol) were identified in the aerosol samples from Nanjing. The sugar  
381 compounds are generated from micro-organism (pollen, fungi, and bacteria), plants,  
382 flowers, resuspension of surface soil and unpaved road dust (Graham et al., 2003;  
383 Simoneit et al., 2004a; Yttri et al., 2007). They can also be originated during biomass  
384 burning. Total concentrations of primary sugars measured were 0.78-7.02 ng m<sup>-3</sup> (ave.  
385 2.90 ng m<sup>-3</sup>) in daytime and 0.50-6.58 ng m<sup>-3</sup> (2.98 ng m<sup>-3</sup>) in nighttime, whereas those  
386 of sugar alcohols were 0.30-2.90 ng m<sup>-3</sup> (1.16 ng m<sup>-3</sup>) during daytime and 0.19-2.75 ng  
387 m<sup>-3</sup> (1.27 ng m<sup>-3</sup>) during nighttime.

388 Most primary sugars exhibited higher concentrations in daytime than nighttime  
389 except for glucose (Figure 5c). Graham et al. (2003) proposed that fructose and glucose  
390 along with sucrose are emitted as fern spores, pollen, and other “giant” bioaerosol  
391 particles in daytime. Glucose showed a significant correlation with levoglucosan ( $r =$   
392 0.75,  $p < 0.001$ ) (Figure S2d), indicating that it is associated with biomass burning,  
393 which can interpret high levels of glucose in nighttime, whereas other primary sugars  
394 showed weak correlations with levoglucosan ( $r = 0.05-0.09$ ). Biomass burning as a  
395 source of glucose has also been proposed by Fu et al. (2008). Trehalose is mostly  
396 derived from microorganisms such as bacteria, fungi, and yeast and also small amount  
397 from higher plants, and invertebrates (Medeiros et al., 2006). It is also considered as a  
398 product of unpaved road dust and resuspension of surface soil (Simoneit et al., 2004b;  
399 Wang and Kawamura, 2005).

400 On the contrary, all sugar alcohols presented higher concentrations in nighttime  
401 than in daytime while the scenario is opposite for primary sugars. Significant  
402 correlations were observed between sugar alcohols and levoglucosan ( $r = 0.51-0.75$ ,  
403  $p < 0.001$ ), suggesting a contribution of biomass burning to primary bio-aerosol particles,  
404 which can explain their higher concentrations in nighttime. Previous articles proposed  
405 that a huge amount of sugars and sugar alcohols can be emitted through the combustion  
406 of green vegetation from temperate forests (Medeiros and Simoneit, 2008). The sugar  
407 polyols are produced mainly from microbial sources, e.g., fungi, bacteria. They can also  
408 release from the bark of trees, leaves, and branches. The values of sugar compounds in  
409 this study are lower than other Chinese urban areas (Wang et al., 2006).

#### 410 **3.3.4 Polycyclic aromatic hydrocarbons**

411 PAHs have severe health effect due to their genotoxicity and carcinogenicity.  
412 These aromatic compounds are mainly emitted from anthropogenic activities, including  
413 biomass burning, coal combustion, vehicular emissions, and natural gas combustion.  
414 PAHs showed a weak positive correlation with levoglucosan ( $r = 0.20$ ), suggesting that  
415 there is no serious contribution of PAHs from biomass burning activities in Nanjing  
416 aerosols. Total seventeen PAHs were identified in the Nanjing samples with the  
417 concentration range of  $29.5-106 \text{ ng m}^{-3}$  (ave.  $54.5 \text{ ng m}^{-3}$ ) in daytime and  $21.7-223 \text{ ng}$   
418  $\text{m}^{-3}$  ( $72.5 \text{ ng m}^{-3}$ ) in nighttime (Tables 1 and S1, Figure 2). The higher concentrations of  
419 PAHs in nighttime might be due to the lower dispersion of the boundary layer at night  
420 (Figure 6a).

421 Furthermore, heavy-duty trucks that are permitted by the local government to  
422 work only at night as well as coal combustion should contribute to higher  
423 concentrations of PAHs into the air in nighttime. Our values are 3-4 times higher than  
424 those found in Hong Kong ( $14 \text{ ng m}^{-3}$ ) but lower than those in Beijing winter aerosols

425 (208 ng m<sup>-3</sup>) (Wang et al., 2006). Fluoranthene was found as a dominant PAH (ave.  
426 8.24 ng m<sup>-3</sup>) in Nanjing aerosol samples followed by chrysene (6.72 ng m<sup>-3</sup>), pyrene  
427 (6.42 ng m<sup>-3</sup>) and benzo(b)fluoranthene (BbF) (5.85 ng m<sup>-3</sup>) (Figure 6a). Wang et al.  
428 (2007a) proposed that coal burning was the dominant source for PAHs in Chinese urban  
429 aerosols. However, traffic emissions are also an important source for PAHs in Chinese  
430 urban areas (e.g., Guangzhou, 2003) during winter (Wang et al., 2006).

431 PAHs can be further photooxidized to form SOA, i.e., phthalic acid in the  
432 atmosphere (Zhang et al., 2016). Ding et al. (2007) proposed that PAHs could be  
433 degraded during long-range transport. Therefore, the ratios of PAH isomer pairs can be  
434 used to interpret the chemical aging of PAHs in the atmosphere. Benzo[a]anthracene  
435 (BaA) and benzo(a)pyrene (BaP) are expected to be degraded more easily than their  
436 isomers during transportation due to their higher reactivity. Thus, the lower ratios (<1.0)  
437 of benzo[a]anthracene (BaA)/chrysene (Chry) and benzo(a)pyrene (BaP)/  
438 benzo(e)pyrene (BeP) indicate relatively more photochemical processing of PAHs. The  
439 ratios of BaA/Chry and BaP/BeP were calculated 0.79 and 0.88, respectively, which  
440 imply that PAHs of Nanjing aerosols were more aged due to the atmospheric  
441 transportation from long distances.

442 Characteristic ratios of PAHs are indicative of their specific sources. Previous  
443 studies (Wang et al., 2007a, 2009; Bi et al., 2005) pointed out that the concentration  
444 ratios of indeno(1,2,3-cd)pyrene to benzo(ghi)perylene (IP/BghiP), and  
445 benzo(ghi)perylene to benz(e)pyrene (BghiP/BeP), are indicative of different emission  
446 sources (Table 3). The ratios of IP/BghiP nearby 0.22, 0.50 and 1.3 are attributable to  
447 gasoline, diesel, and coal combustion sources, respectively. On the other hand,  
448 BghiP/BeP ratio of 2.0 indicates mobile exhausts and 0.8 indicates coal combustion  
449 emissions (Grimmer et al., 1983; Ohura et al., 2004). Furthermore, the

450 fluoranthene/(fluoranthene+pyrene) (Flut/(Flut + Pyr)) ratios of 0.46-0.56 indicate  
451 vehicular emissions, especially from catalytic converter-equipped automobiles (0.44),  
452 whereas IP/(BghiP+IP) ratios (0.18, 0.37 and 0.56) are for cars, diesel, and coal  
453 combustion, respectively (Bi et al., 2005).

454 In this study, we found the ratios of IP/BghiP, Bghi/BeP, Flut/(Flut + Pyr), and  
455 IP/(IP+BghiP) are 1.23, 1.17, 0.56, and 0.55, respectively. The ratios are closer to those  
456 in coal burning emissions than in vehicular exhausts. These results imply that PAH  
457 components in Nanjing winter aerosols are mainly derived from coal combustion. The  
458 PAH compositions of our study are different from those reported from Sacramento  
459 (Kleeman et al., 2008), Los Angeles and London (Finlayson-Pitts and Pitts Jr, 2000), in  
460 which BghiP/BeP ratios are 5.6, 3.5 and 1.7, respectively, when vehicular emissions  
461 were the major sources for PAHs in these cities. The present PAH concentrations in  
462 Nanjing aerosols are lower than those found in a previous study from Nanjing samples  
463 collected in 2004 (Table 2) (Wang et al., 2007a) and one-fourth of those collected in  
464 2001 ( $214 \text{ ng m}^{-3}$ ) (Yang et al., 2005), indicating the local air quality in Nanjing is  
465 improving since 2001.

### 466 3.3.5 Hopanes and Steranes

467 Hopane and sterane isomers are considered as biomarkers of fossil fuel  
468 emissions, which belong to the higher boiling fraction of crude oil and are more  
469 resistant to degradation than *n*-alkanes. They are abundantly originated from the crude  
470 oil and engine oil, and consequently in vehicle exhaust from unburned lubricating oil  
471 residues and road dust (Ding et al., 2009). Six hopane compounds were identified in the  
472 Nanjing urban samples (Table S1) with higher levels in nighttime ( $0.13\text{-}26.1 \text{ ng m}^{-3}$ ,  
473 ave.  $4.16 \text{ ng m}^{-3}$ ) and lower levels in daytime ( $0.09\text{-}20.8 \text{ ng m}^{-3}$ ,  $3.78 \text{ ng m}^{-3}$ ) (Figure 2).  
474 The concentrations of hopane in the present study are comparable with those from other

475 Chinese cities and Tokyo (0.7-15 ng m<sup>-3</sup>; 5.5 ng m<sup>-3</sup>) (Wang et al., 2006). Wang et al.  
476 (2009) reported that concentrations of hopanes in the urban samples were 2 orders of  
477 magnitude higher than those in the mountain samples whereas hopanes were not  
478 detectable in the marine samples.

479 The diagnostic ratios of hopanes can differentiate their sources (Table 3). The  
480 17 $\alpha$ (H)-21 $\beta$ (H)-29-norhopane (C<sub>29</sub> $\alpha\beta$ )/17 $\alpha$ (H)-21 $\beta$ (H)-hopane (C<sub>30</sub> $\alpha\beta$ ) ratios of 0.59-  
481 0.66, 0.42, and 0.58-2.0 are attributable to gasoline, diesel and coal burning emissions,  
482 respectively (Rogge et al., 1993a; Oros and Simoneit, 2000). In addition, the ratios of  
483 17 $\alpha$ (H)-21 $\beta$ (H)-22S-homohopane/(17 $\alpha$ (H)-21 $\beta$ (H)-22S-homohopane + 17 $\alpha$ (H)-21 $\beta$ (H)-  
484 22R-homohopane) [C<sub>31</sub> $\alpha\beta$ S/(C<sub>31</sub> $\alpha\beta$ S + C<sub>31</sub> $\alpha\beta$ R)] ranging from 0.60-0.62, 0.50, and  
485 0.05-0.37 indicate gasoline, diesel and coal burning emissions, respectively (Rogge et  
486 al., 1993a; Oros and Simoneit, 2000). We observed that concentration ratios of  
487 C<sub>29</sub> $\alpha\beta$ /C<sub>30</sub> $\alpha\beta$  and C<sub>31</sub> $\alpha\beta$ S/(C<sub>31</sub> $\alpha\beta$ S+ C<sub>31</sub> $\alpha\beta$ R) in this study are 0.58 and 0.48,  
488 respectively, which are near to those in vehicular emissions than coal combustion. Thus,  
489 hopanes in the Nanjing aerosol are predominantly emitted from traffic emissions due to  
490 rapidly increasing of automobiles in Chinese mega-cities.

491 A series of steranes were also identified in the present study. Concentration  
492 ranges of total steranes were 1.14-9.16 ng m<sup>-3</sup> (ave. 2.29 ng m<sup>-3</sup>) during daytime and  
493 1.09-11.1 ng m<sup>-3</sup> (2.64 ng m<sup>-3</sup>) during nighttime. The diurnal distribution patterns of  
494 steranes showed remarkable similarity with hopanes. The strong correlation coefficient  
495 was also observed between steranes and hopanes (r = 0.94, p<0.001), indicating their  
496 similar emission sources (Figure S3d). It is reasonable because homologues of hopanes  
497 and steranes are very stable and have similar atmospheric fates (Ding et al., 2009). In  
498 contrast, PAHs showed positive correlations with hopanes and steranes with a lower  
499 correlation coefficient (r = 0.42, p<0.001), indicating their partly similar sources.

### 500 3.3.6 Phthalates

501 Phthalates are common additives widely used as a softener and plasticizers in  
502 polyvinylchloride (PVC) and synthetic polymers, respectively. It can be emitted into the  
503 atmosphere through the evaporation process due to their weak bonding in the polymer.  
504 Phthalates have potential health effect due to their endocrine disrupting and  
505 carcinogenic properties (Sidhu et al., 2005). It is necessary to pay attention to phthalates  
506 as toxic components in the aerosol particles. However, few studies have reported their  
507 atmospheric distribution over China (Fu et al., 2008; Wang et al., 2006, 2007a). Four  
508 phthalate esters, i.e., diethyl (DEP), di-iso-butyl (DiBP), di-n-butyl (DnBP), and di-(2-  
509 ethylhexyl) (DEHP) phthalates were characterized in this study with total  
510 concentrations of  $13.9 \text{ ng m}^{-3}$  (range,  $2.66\text{--}40.0 \text{ ng m}^{-3}$ ) in daytime and  $16.3 \text{ ng m}^{-3}$   
511 ( $3.79\text{--}51.8 \text{ ng m}^{-3}$ ) in nighttime (Figure 7a). DnBP (ave.  $8.07 \text{ ng m}^{-3}$ ) is the dominant  
512 tracer, followed by DEHP ( $4.00 \text{ ng m}^{-3}$ ), DiBP ( $2.59 \text{ ng m}^{-3}$ ) and DEP ( $0.14 \text{ ng m}^{-3}$ ).  
513 The levels of phthalates in this study are 4–20 times lower than those proposed in other  
514 Chinese megacities in 2006 (Wang et al., 2006), although comparable than those  
515 observed from Paris, France ( $8.2 \text{ ng m}^{-3}$ ) (Teil et al., 2006), Sweden ( $3.7 \text{ ng m}^{-3}$ )  
516 (Thuren and Larsson, 1990), and Texas, USA ( $2.1 \text{ ng m}^{-3}$ ) (Weschler, 1984).

517 The evaporation of phthalates can be accelerated under high ambient  
518 temperature conditions. The higher values in nighttime than daytime of phthalates in  
519 Nanjing aerosol is opposite with the result of Mt. Tai aerosols (Fu et al., 2008) due to  
520 the decreased PBLH in nighttime. Moreover, there is no significant difference in  
521 temperature between day and night during the campaign in Nanjing (Figure S1).  
522 Significant correlations were found between DEP and DiBP ( $r = 0.85$ ,  $p < 0.001$ ) as well  
523 as DiBP and DnBP ( $r = 0.87$ ,  $p < 0.001$ ) (Figures S4a and S4b), suggesting that these  
524 compounds are commonly used as plasticizers in China and released in the same way

525 into the atmosphere. It should be noted that the concentration level of phthalates in this  
526 study is 1-2 orders of magnitude lower than those found in Nanjing aerosols collected in  
527 2004 (ave. 230 ng m<sup>-3</sup>) (Wang et al., 2007a), suggesting a significant improvement of  
528 local air quality in Nanjing regarding plastic emission.

### 529 3.3.7 Aromatic acids

530 We detected benzoic acid and three phthalic acids in the urban aerosols from  
531 Nanjing with total concentrations of 6.70 ng m<sup>-3</sup> (1.53-23.1 ng m<sup>-3</sup>) in daytime and 8.37  
532 ng m<sup>-3</sup> (1.99-18.5 ng m<sup>-3</sup>) in nighttime (Figure 7b). These acids can play a significant  
533 role to increase the formation of new particles in the atmosphere (Zhang et al., 2004).  
534 Benzoic acid ranged from 0.17-0.95 ng m<sup>-3</sup> (ave. 0.45 ng m<sup>-3</sup>) in daytime and 0.24-1.22  
535 ng m<sup>-3</sup> (0.54 ng m<sup>-3</sup>) in nighttime (Table S1), which is 1 and 4 orders of magnitude  
536 lower than summertime aerosol of Mt. Tai and wintertime aerosol of tropical India,  
537 respectively (Fu et al., 2008, 2010). Benzoic acid is primarily emitted from automobiles  
538 (Rogge et al., 1993b; Kawamura et al., 2000) but also been proposed as a secondary  
539 component via a photooxidation of several aromatic hydrocarbons (Fu et al., 2010).

540 Total phthalic acids varied from 1.40-21.9 ng m<sup>-3</sup> (ave. 6.25 ng m<sup>-3</sup>) during  
541 daytime and 1.76-16.8 ng m<sup>-3</sup> (7.83 ng m<sup>-3</sup>) during nighttime. Their concentrations are  
542 lower than those found during aircraft measurement over China in summer (17±13 ng  
543 m<sup>-3</sup>) (Wang et al., 2007b) but higher than the samples measured from the northwestern  
544 Pacific (ave. 1.5 ng m<sup>-3</sup>) (Simoneit et al., 2004a). The molecular distributions of  
545 phthalic acids showed the dominance of terephthalic acid (Figure 7b), which accounted  
546 for 82% of total aromatic acids in Nanjing samples. Phthalic acids are SOA products  
547 produced from several PAHs (Oliveira et al., 2007; Fine et al., 2004). It is noteworthy  
548 that PAHs mostly produce phthalic acids over the North China Plain (Fu et al., 2008).  
549 Terephthalic acid can be derived from plastics burning as well (Fu et al., 2010).

550           Aromatic acids showed positive correlations with 4 and 5 rings PAHs ( $r = 0.56$ ,  
551  $p < 0.001$ ) and phthalates ( $r = 0.71$ ,  $p < 0.001$ ) (Figure S3c), suggesting that they are  
552 primarily derived from PAHs. Furthermore, aromatic acids showed significant  
553 correlation with oxidation products of polyacids ( $r = 0.83$ ,  $p < 0.001$ ) (Figure S4c),  
554 indicating the secondary oxidation process is a major source of aromatic acids.  
555 However, higher concentrations of aromatic acids in nighttime rather than daytime may  
556 not explain photochemical oxidation. We propose two explanations for the high level of  
557 SOA products in nighttime. First, SOA products are formed during long-range  
558 atmospheric transport that is consistent with aged PAHs in the aerosols as discussed  
559 above (section 3.3.4). Second, NO<sub>x</sub> can play an important role to oxidize PAHs in  
560 nighttime when NO<sub>x</sub> concentration is high (Offenberg et al., 2007; Henze et al., 2008).  
561 However, further studies are needed for the justification of NO<sub>x</sub> influence in the  
562 Nanjing atmosphere.

### 563 **3.3.8 Hydroxy-/polyacids**

564           Glycerol and several polyacids were identified in all the samples from Nanjing  
565 (Table S1). Glycerol is a primary product of a metabolic reaction of soil organisms,  
566 while polyacids are secondarily produced by photo-oxidation of organic precursors  
567 (Simoneit et al., 2004c). Glycerol didn't show significant correlation with polyacids ( $r =$   
568  $0.21-0.38$ ), implying their different sources (i.e., primary and secondary). Kawamura  
569 and Ikushima(1993), and Matsunaga et al. (1999) reported that malic acid is a  
570 photooxidation product of succinic acid, which is one of the photooxidation products of  
571 biogenic unsaturated fatty acids (BUFAs) in the atmosphere. Moreover, SOA tracers,  
572 including malic and tartaric acids are produced by the photochemical oxidation of  
573 isoprene (Claeys et al., 2004).

574           The concentration range of glycerol was 0.66-5.99 ng m<sup>-3</sup> (ave. 2.67 ng m<sup>-3</sup>)  
575 during daytime and 0.73-8.72 ng m<sup>-3</sup> (3.50 ng m<sup>-3</sup>) during nighttime. Glycerol is a  
576 dominant component in this group (Table S1 and Figure 7c), which is consistent with  
577 the previous report from Nanjing aerosol in 2004-2005, whereas present concentration  
578 level is lower than that reported in Nanjing (Wang and Kawamura, 2005).  
579 Concentrations ranges of total polyacids were 1.21-23.5 ng m<sup>-3</sup> (5.1 ng m<sup>-3</sup>) during  
580 daytime and 2.05-11.2 ng m<sup>-3</sup> (5.80 ng m<sup>-3</sup>) during nighttime, among which tartaric acid  
581 (2.18 ng m<sup>-3</sup>) was dominant (Figure 7c). Tartaric acid presented a positive correlation  
582 with levoglucosan ( $r = 0.75$ ,  $p < 0.001$ ) (Figure S2b), suggesting an influence of biomass  
583 burning. Significant correlations were found among all polyacids ( $r = 0.50-0.75$ ,  
584  $p < 0.001$ ), indicating their similar source or formation pathway. Polyacids showed a  
585 strong correlation with WSOC ( $r = 0.85$ ,  $p < 0.001$ ) (Figure S4d), indicating their water-  
586 soluble and hygroscopic nature and therefore it might influence the CCN activities of  
587 aerosol particles. It should be noted that secondary oxidation products are formed  
588 during long-range atmospheric transport, which can explain high values of polyacids in  
589 nighttime. This result is consistent with the high WSOC/OC ratio in Nanjing aerosols  
590 (see section 3.2).

### 591 **3.4 Source apportionment of organic aerosols using PMF**

592           Positive matrix factorization (PMF5.0, USEPA) analysis was performed in this  
593 study for better understanding the sources of the identified components. It is a statistical  
594 source apportionment model widely used to verify underlying covariance among  
595 chemical parameters (Paatero and Tapper, 1994; Jaekels et al., 2007). Detailed  
596 information of the PMF model can be found elsewhere (Paatero, 1997; Paatero and  
597 Tapper, 1994). PMF model was applied for apportioning ambient PM to motor vehicle  
598 and wood combustion emission, SOA, and two point sources using organic molecular

599 markers (Jaekels et al., 2007). This model has also been extensively used for  
600 identifying source profile and source contribution of PM based elemental and organic  
601 markers data (Song et al., 2001; Buzcu et al., 2003; Jaekels et al., 2007; Jia et al.,  
602 2010). The analytical errors estimated for the measured values of chemical species in  
603 PMF analysis are 10%. The detected organic compound classes were subjected to  
604 source apportionment evaluation to make the classifications of sources using the model.  
605 PMF model application resolved 5 source factors based on Q values that contributed to  
606 ambient PM<sub>2.5</sub> in this study. OC, EC and some inorganic ions were also used to  
607 investigate possible different sources. We used PM<sub>2.5</sub> as the sum of total variables  
608 during the model convergence. Figure 8 shows composition source profiles for the five  
609 factors resolved by PMF analysis, where factor 3 is a dominant source.

610 Factor 1 is dominated by levoglucosan (69%) followed by fatty alcohol (C<sub>30</sub>)  
611 (56%), arabitol (44%) and *n*-alkane (C<sub>29</sub>) (34%). Factor 1 is associated with biomass  
612 burning because levoglucosan is a specific tracer of biomass burning. Moreover, fatty  
613 alcohols, fatty acids, *n*-alkanes, and sugar compounds can also be emitted from biomass  
614 burning. Biomass materials, including rice and wheat straws, and cotton stems, are  
615 widely used for domestic cooking in rural areas around Nanjing, particularly in the  
616 evening. Therefore, particles from biomass burning are abundantly released into the  
617 atmosphere and then transported to the Nanjing urban area. This idea is consistent with  
618 high loadings of biomass burning tracers during nighttime.

619 Factor 2 is enriched with nss-Ca<sup>2+</sup> (75 %), suggesting that the component is  
620 associated with soil dust because it is a specific tracer of soil dust (Athanasopoulou et  
621 al., 2010; Brahney et al., 2013). Many infrastructures of the urban area are constructing  
622 in China, which can produce dust particles largely and emit into the atmosphere. Factor  
623 3 is attributed to secondary oxidation products because of the dominant species in this

624 source profile is malic acid (69%). Malic acid is a secondary oxidation product as  
625 described above (see section 3.3.8).

626 Factor 4 was abundantly loaded by fluoranthene (representative PAH) (79%),  
627 C<sub>30</sub>αβ (representative hopane) (64%) and C<sub>29</sub> (representative *n*-alkane) (50%), implying  
628 their origination from the fossil fuel combustion. It should be noted that *n*-alkanes also  
629 showed a loading in factor 1, suggesting that *n*-alkanes are partly associated with  
630 biomass burning. PAHs can be emitted from fossil fuel combustion and biomass  
631 burning activities. However, we observed that PAHs are mainly derived from fossil fuel  
632 combustion in Nanjing (see section 3.3.4). Furthermore, *n*-alkanes can be originated  
633 from fossil fuel combustion and higher plant waxes, whereas fossil fuel was the  
634 dominant source for *n*-alkanes in Nanjing aerosols (see section 3.3.1). Hopanes are  
635 emitted from the vehicular exhaust as well as coal burning. Low-quality coals are  
636 extensively used in urban and rural areas in China for cooking and house heating. Many  
637 power plants in Chinese cities also used a large amount of coal for producing energy.  
638 Running vehicles have also increased severely in China, which can emit hopanes in the  
639 atmosphere. Factor 5 is dominated by di-(2-ethylhexyl) (DEHP) phthalate (63%)  
640 followed by terephthalic acid (35%), which should be associated with plastic burning.  
641 Terephthalic acid is a secondary oxidation product and also can be emitted from the  
642 open burning of plastics as discussed above.

643 PMF results can be further utilized to calculate the relative contributions of sources  
644 to the amount of ambient OC using a multiple linear regression between the isolated  
645 factor strengths and measured OC (Song et al., 2001). Results of this analysis are  
646 presented in Figure 9. Fossil fuel combustion was the dominant source (28.7%)  
647 considering the primary source, followed by emissions of biomass burning (17.1%), soil  
648 dust (14.5%), and plastic burning (6.83%) during this study period. However, secondary

649 oxidation products showed the highest contribution (32.9%) to PM<sub>2.5</sub> in Nanjing  
650 probably due to long-range atmospheric transport. These results indicate that fossil fuel  
651 combustion is an important contributor to Nanjing aerosol during winter.

#### 652 4. Summary and Conclusions

653 We collected PM<sub>2.5</sub> aerosol samples during winter from Nanjing, an urban area  
654 located in east China in 2014 to 2015. Twelve organic compound classes were  
655 identified in the aerosol samples with *n*-alkanes as the dominant compound class,  
656 followed by fatty acids, PAHs, anhydro-sugars, fatty alcohols, and phthalate esters. The  
657 concentrations of organic compounds were slightly higher at night samples than day  
658 samples because of the lower PBLH and more emissions from heavy-duty trucks as  
659 well as coal and biomass burning in nighttime.

660 The molecular signature of *n*-alkanes with a weak odd-carbon number  
661 predominance and maxima of C<sub>29</sub> (ave. CPI: 1.18) implies their significant emission  
662 from fossil fuels combustion. On the contrary, microbial and plant waxes are the major  
663 source of fatty acids and fatty alcohols in this study. Fatty alcohols are also significantly  
664 emitted from biomass burning. The biomass burning tracer, levoglucosan was the  
665 dominant species among the detected compounds. Levoglucosan and other biomass  
666 burning tracers are mainly originated from house cooking and heating during study  
667 period. Concentrations of secondary oxidation products, including aromatic acids and  
668 polyacids, maximized during nighttime possibly because of the influence of NO<sub>x</sub> or  
669 long-range atmospheric transport.

670 The diagnostic ratios of the tracer compounds suggest that coal burning is the  
671 major source of PAHs while hopanes are abundantly emitted from traffic emissions  
672 over Nanjing atmosphere. PMF analysis demonstrated that fossil fuel combustion is an  
673 important source (28.7%) in Nanjing winter aerosols. The concentrations of organic

674 tracers in this study are lower than previously reported Nanjing aerosols collected in  
675 2004-2005. Air quality in Nanjing may have been improved for last decade. However,  
676 fossil fuel combustion emissions have not been decreased significantly and still control  
677 the compositions of wintertime OAs in Nanjing atmosphere.

1060 **Table 2.** Comparisons of the average concentrations ( $\text{ng m}^{-3}$ ) of organic tracers with those  
1061 measured during 2004-2005 (Wang and Kawamura, 2005; Wang et al., 2007a<sup>b</sup>) in Nanjing  
1062 aerosols during winter.  
1063

Compounds	This study		2004-2005	
	Daytime	Nighttime	Daytime	Nighttime
<i>n</i> -Alkanes	177	218	172	278
Plant Wax Alkanes	15.5	17.6	18.8	20.6
Fatty acids	66.8	91.3	245	338
Fatty alcohols	36.9	43.8	74.5	120
Levogluconan	42.3	71.2	238	297
Sugars	3.44	3.43	59	53
Phthalate esters <sup>b</sup>	13.9	16.3	158	181
Glycerol and polyacids	7.78	9.30	41.4	41.8
Aromatic acids	6.70	8.37		Not detected
Lignin and resin products	2.68	3.39	24.6	59.0
PAHs <sup>b</sup>	54.5	74.8	69	104
Hopanes <sup>b</sup>	3.79	4.64	7.3	9.9
Steranes	2.29	2.65		Not detected
<b>Total organics</b>	<b>434</b>	<b>565</b>	<b>1108</b>	<b>1502</b>
