

23 **ABSTRACT**

24 Hygroscopicity plays a crucial role in determining aerosol optical properties and aging
25 processes in the atmosphere. We investigated submicron aerosol hygroscopicity and
26 composition by connecting an aerosol time-of-flight mass spectrometer (ATOFMS) to the
27 downstream of a hygroscopic tandem differential mobility analyzer (HTDMA), to
28 simultaneously characterize hygroscopicities and chemical compositions of ambient aerosols
29 in Shanghai, China. Major particle types, including biomass burning, EC, Dust/Ash, organics
30 particles, cooking particles and sea salt, were shown to have distinct hygroscopicity
31 distributions. It is also found that particles with stronger hygroscopicities were more likely to
32 have higher effective densities. Based on the measured hygroscopicity-composition relations,
33 we developed a statistical method to estimate ambient particle hygroscopicity just from their
34 mass spectra. This method was applied to another ambient ATOFMS dataset sampled from
35 September 12nd to 28th, 2012 in Shanghai, and it is found that ambient particles were present in
36 three major hygroscopicity modes, whose growth factors at relative humidity 85% peaked at
37 1.05, 1.42 and 1.60, respectively. The temporal variations of the estimated particle
38 hygroscopicity were consistent with the back-trajectory analysis and atmospheric visibility
39 observations. These hygroscopicity estimation results with single particle mass spectra analysis
40 can provide critical information on particulate water content, particle source apportionment and
41 aging processes.

42

43 **1. INTRODUCTION**

44 Atmospheric particles have critical influences on climate and the environment. They affect
45 climate by directly interacting with sunlight and changing the energy balance of earth's
46 atmosphere (Facchini et al., 1999;Lohmann and Feichter, 2005). Additionally, they act as cloud
47 condensation nuclei or ice nuclei and impact cloud formation (Lohmann et al., 2007). Aerosol
48 particles also participate many important atmospheric reactions (Gard et al., 1998;Qiu and
49 Zhang, 2013). The climate-relevant properties and chemical reactivity of aerosols are largely
50 determined by their hygroscopic property. In the ambient condition the hygroscopic growth of
51 particles introduce aqueous surface to particles and their optical effects are importantly altered
52 (Cheng et al., 2008;Titos et al., 2014), which exerts impacts on atmospheric aging processes of
53 particles and visibility degradation (Qu et al., 2015;Liu et al., 2012;Qiu and Zhang, 2013;Wang
54 et al., 2009;Chen et al., 2012;Li et al., 2018).

55 Atmospheric particles are a mixture of a complicated variety of chemical compounds. The bulk
56 chemical composition of particulate matter (PM) usually refers to its dry composition (Li et al.,
57 2016;Herich et al., 2011). However, in ambient condition the particulate water is also an
58 important constitution of PM which has not been accounted for in conventional gravitational
59 analysis. The mass of particulate water may be times higher than the total mass of dried PM at
60 elevated RHs (Swietlicki et al., 2008). The factors that affect water contents in particles include
61 the particle hygroscopicity, the particle size distributions and ambient RH. Particle
62 hygroscopicity determines the particle's ability to hygroscopic growth. It directly relates to
63 particle composition and size. To accurately predict particulate water content, a detailed
64 knowledge on both of particle hygroscopicity and composition is needed (Gysel et al.,

65 2007;Sjogren et al., 2008;Laborde et al., 2013;Healy et al., 2014).

66 Aerosol hygroscopicity could be determined quantitatively by techniques such as the

67 Hygroscopic Tandem Differential Mobility Analyzer (HTDMA) (Swietlicki et al., 2008).

68 Previous studies have obtained particle hygroscopicity and chemical composition in the same

69 time by deploying HTDMA and chemical composition measurements in parallel (Gysel et al.,

70 2007;Sjogren et al., 2008;Laborde et al., 2013). The measured hygroscopicity was compared

71 with the reconstructed values using the mixing rules of variant compositions (Gysel et al., 2007).

72 The hygroscopicity reconstructed in this way is representing the averaged hygroscopicity of

73 ensembled particles and therefore could not reflect the mixing states of particles (Healy et al.,

74 2014). Ambient studies suggested that atmospheric aerosols were commonly externally mixed,

75 as shown by the separated modes in hygroscopicity distributions (Swietlicki et al.,

76 2008;Massling et al., 2007;Liu et al., 2011). The alternative way to obtain simultaneous

77 information on hygroscopicity and composition is connecting the HTDMA with particle

78 composition measurement techniques in tandem (Buzorius et al., 2002;Zelenyuk et al.,

79 2008;Herich et al., 2008;Laborde et al., 2013). In this configuration, the HTDMA acts as

80 hygroscopicity selector, with hygroscopicity segregated particles being analyzed subsequently

81 by other techniques. More direct connection between hygroscopicity and composition could be

82 established in this way. For particle composition measurement, sensitive methods such as single

83 particle mass spectrometers are preferred since they can analyze particles in low concentrations

84 in the outflow of HTDMA (Herich et al., 2008;Herich et al., 2009). The merit of single particle

85 techniques is that particle mixing state is preserved during analysis (Healy et al., 2014).

86 Only a few previous studies have reported simultaneous characterization of hygroscopicity and

87 composition using the tandem method (Herich et al., 2008; Herich et al., 2009; Buzorius et al.,
88 2002; Zelenyuk et al., 2008). Zelenyuk et al. (Zelenyuk et al., 2008) connected HTDMA and a
89 single particle mass spectrometer SPLAT in series to perform multiple measurement of aerosol
90 composition, hygroscopicity and effective density. Herich et al. have firstly applied the
91 HTDMA-ATOFMS system to investigate particle composition as a function of hygroscopicity
92 in Switzerland (Herich et al., 2008) and then in a subarctic site (Herich et al., 2009). In a
93 preliminary study, we applied HTDMA-ATOFMS to characterize chemical compositions of
94 ambient particles with a few hygroscopicities (Wang et al., 2014). However, this obtained
95 dataset is not sufficiently large to provide a hygroscopicity distribution for each aerosol particle
96 type. Therefore, the primary objective of the present study is to establish thorough connections
97 between hygroscopicity and single particle signatures, which could be utilized to predict
98 hygroscopicity of ambient particles. Here we conducted a comprehensive HTDMA-ATOFMS
99 characterization experiment with a more complete GF range (GF 0.9~1.7, 85% RH), which
100 accounts for a main number fraction of atmospheric particles in urban atmosphere (Liu et al.,
101 2014; Liu et al., 2011; Ye et al., 2013). Moreover, we developed and tested a method that utilize
102 the established dataset to estimate the hygroscopicity of ambient particles analyzed by
103 ATOFMS.

104 **2. EXPERIMENTAL SECTION**

105 **2.1. HTDMA**

106 The custom-built HTDMA (Ye et al., 2009; Angelino et al., 2001) consists of two DMAs and a
107 humidifier (Figure 1). Aerosol was dried before entering HTDMA (RH ~10%) by a diffusional

108 silica gel tube. The dried aerosol reached its charge equilibrium in a Kr-85 neutralizer. The
109 DMA1 (Model 3081, TSI Inc.) selected particles based on their electrical mobility size D_{dry} .
110 Then, the monodisperse particles grew in a Nafion humidifier (RH=85%). The sizes of
111 humidified particles D_{RH} was scanned by the second DMA and a CPC. The sheath flow rate in
112 DMA2 (3 l/min) was regulated by mass flow controller. The RH of the DMA2 sheath flow was
113 managed to match the humidifier (85% RH) by adjusting the water-saturated air. The DMAs,
114 the humidifier and other parts were installed in thermostatic chamber in which temperature was
115 controlled to 25°C. The total aerosol flow was 0.4 L/min (the sum flow rate of the CPC, 0.3
116 L/min and the ATOFMS, 0.1 L/min). Aerosol residence time in humidifier was ~10 s. PSL
117 spheres of known size and $(NH_4)_2SO_4$ salt were used to calibrate the HTDMA.

118 2.2. ATOFMS

119 The principle functional parts of ATOFMS (Model 3800, TSI. Inc) is illustrated in Figure 1.
120 After particles entered the inlet orifice of ATOFMS, they were focused into narrow beam
121 through successive expansions and contractions in the aerodynamic focusing Lens (AFL).
122 Particles leaving the AFL have drifting velocities which are depended on their vacuum
123 aerodynamic sizes. In ATOFMS sizing region the particles pass through two orthogonally
124 oriented continuous lasers (Nd:YAG, 532 nm) to scatter light. The scattered light generates two
125 pulses in two photomultiplier tubes (PMT) and the signal delay between the two pulses is used
126 to calculate particle velocity considering the distance between two lasers is known. Particle
127 velocity information was also used to trigger ionization laser (Nd:YAG, 266 nm) at appropriate
128 time to ionize individual particles. The ions are recorded by a dual polar time-of-flight mass
129 spectrometer to generate positive and negative mass spectra for each particle. More details of

130 ATOFMS were described elsewhere (Gard et al., 1997; Su et al., 2004).

131 **2.3. Field sampling**

132 During Feb-26 to Mar-7, 2014, the HTDMA-ATOFMS characterization was performed at the
133 building of department of environmental science and technology in Fudan university (31°18'N,
134 121°29'E). Aerosol inlet was installed at the building roof about 6 m above the ground. The
135 Fudan campus was influenced by local emissions sources from transportation, residential,
136 business and cooking activities from surrounding areas which can be viewed as an urban
137 environment. A period of ambient ATOFMS data, which persisted from Sep-12 to Sep-28, 2012,
138 was obtained at the same site in Fudan campus.

139 The sampling procedure was similar to our previous study (Wang et al., 2014). The HTDMA
140 GF distributions obtained during sampling intermittence usually show two hygroscopicity
141 modes. The first mode centered at GF ~1.05 and the second mode at GF ~1.45 at RH 85%,
142 which will be termed as Near-Hydrophobic (NH) and More-Hygroscopic (MH) mode,
143 respectively. These modes were also typically found in other types of environment (Liu et al.,
144 2011; Swietlicki et al., 2008). The majority of particles (>97 %) were shown to have growth
145 factors in 0.9-1.7 range. Therefore, in this study we preselected particles with GFs from 0.9 to
146 1.7 (0.1 GF step) in HTDMA for ATOFMS characterizations.

147 To set the desired GFs, the two DMAs in HTDMA system were maintained at fixed diameters
148 D_{dry} , D_{RH} according to $\text{GF} = D_{\text{RH}}/D_{\text{dry}}$. The DMAs were kept to select the desired diameters
149 before significant number of particle were chemical analyzed by ATOFMS. In this study the
150 DMA1 (D_{dry}) was set to 250 nm, while the DMA2 (D_{RH}) was set to diameters as shown in Table

151 1, where the length of sampling duration, the number analyzed particles are given. The number
152 of particles analyzed by ATOFMS was affected by the ambient particle number concentrations.
153 Because the particle concentrations in the outflow of HTDMA are generally low and even lower
154 at some GFs, longer sampling time was planned to obtain statistically significant particle
155 numbers (See the CPC concentrations in Figure S1). Usually the ATOFMS has lower detection
156 efficiencies at smaller than 250 nm range due to the reduced scattering efficiency, while larger
157 particles usually have less number concentrations. Therefore, the selection of D_{dry} as 250nm is
158 a compromise between the two issues (Wang et al., 2014; Herich et al., 2008; Herich et al., 2009).

159

160 **Table 1. Statistics of the D_{RH} , GF, sampling duration and the number of chemically analyzed**
161 **particles by ATOFMS ($D_{\text{dry}} = 250$ nm, RH = 85%).**

D_{RH} (nm)	225	250	275	300	325	350	375	400	425
Growth Factor	0.9	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7
Duration (hours)	42	67	11	20	8	11	34	20	11
Number of spectra detected	742	1665	709	1401	2330	4469	6399	723	262

162

163 2.4. Estimation of ambient particle hygroscopicity

164 When inspecting particle mass spectra obtained from HTDMA-ATOFMS experiment, it is
165 recognized that most of produced spectra were also frequently present in ATOFMS ambient

166 characterizations. This fact forms the basis of the idea to assign similar GF to ambient particles
167 if they have similar composition as in HTDMA-ATOFMS experiment.

168 To estimate hygroscopicity of ambient single particles, we compare the ambient particle mass
169 spectra with those obtained in HTDMA-ATOFMS experiment similarly as in ART-2a algorithm
170 (Song et al., 1999). In ATOFMS particle spectra, some metal (such as Na, K, Fe) were
171 producing inappropriately large peaks due to higher ionization efficiencies. This problem was
172 relieved by taking the 0.5 power (square root) of peaks intensities. After this treatment the
173 relative intensities of largest peaks were suppressed the while smaller peaks (such as organic
174 peaks) increased relatively in the evaluation of spectra similarities. Then we searched the
175 candidate particles in HTDMA-ATOFMS data which produced the highest similarities with the
176 atmospheric particle (similarities in the range of 95% to 100% maximum similarity). Since each
177 item of mass spectra acquired by HTDMA-ATOFMS was associated with a GF, we obtained a
178 collection of discrete GF values (from 0.9 to 1.7 spaced by 0.1) that were the most probable
179 candidate GFs. The estimated GF of the atmospheric particle was determined to be the weighted
180 mean of the candidate GFs, with weights being the number percentages of candidate particles
181 happened in each discrete GF groups:

$$182 \quad GF_{pred} = \frac{\sum GF_i \cdot F_i}{\sum F_i}$$

183 where: GF_{pred} = the estimated GF of atmospheric particle, GF_i = GF value from 0.1 to 1.7
184 interspaced by 0.1, F_i = number percentages of the candidate particles in each GF group.

185 From the descriptions above, this method is a statistical approach to find the most probable
186 hygroscopicity for each single particle, rather than estimating chemical compositions in

187 individual particles and then predicting particle hygroscopicity using the assumed composition,
188 as previously applied by (Healy et al., 2014). The latter approach is based on Zdanovskii-
189 Stokes-Robinson mixing rules, and it needs to assume a chemical composition for each single
190 aerosol particle, which might not be reliable due to the qualitative nature of ATOFMS analysis.
191 However, the new approach developed in this study infer particle hygroscopicity by comparing
192 the mass spectra of ambient particles with particles whose hygroscopicity has already been
193 experimentally determined by HTDMA. Therefore, this method derives GF from measured GF
194 values and the possible artifacts caused by assumptions are obviated.

195 **3. RESULTS AND DISCUSSIONS**

196 **3.1. Hygroscopicity distribution of particle types**

197 The sampled aerosols with similar mass spectra are grouped together to form many particle
198 types. The majority of analyzed particles were eventually grouped into 9 types, namely Biomass,
199 Fresh EC, Aged EC, Dust/Ash, HMOC, Amine-rich, Ammonium/OC, Cooking and Sea salt
200 types. Figure 2 presents the average mass spectra, particle numbers detected at different GF
201 stages for each types. Since the numbers of analyzed particle in each GF bin are not a constant
202 (Table 1), the normalized particle numbers by the total particle numbers in each GF bin were
203 calculated to show their occurrence probability (Fig. 2).

204 **3.1.1. Particle types and GF distributions**

205 As illustrated in Fig. 2, Biomass type particles have characteristic peaks at -26(CN), -42(CNO),
206 -59(C₂H₃O₂), -73(C₃H₅O₂) in negative spectra and dominant potassium peak at 39K and clusters
207 at 113(K₂Cl) or 213(K₃SO₄) (Silva et al., 1999). During this study, the HTDMA-ATOFMS

208 system detected 547 biomass particles which account for 2.9% of total analyzed particles.
209 Despite the small number, the hygroscopicity of biomass particles is low in that the majority of
210 biomass particles (87%) were detected in GF <1.2 range. On average the biomass particle type
211 contribute 2.9% of analyzed particle numbers in this GF range, with peak number fraction
212 occurred at GF 1.1 (19%), as shown in Figure 2 (a). Similar hygroscopicity pattern of biomass
213 particles is reported previously (Rissler et al., 2006; Martin et al., 2013).

214 EC type particles are characterized by a series of elemental carbon peaks at C_n ($n=1, 2, 3 \dots$) in
215 the negative and positive spectra. EC is a dominant particle type which accounts for 37.5%
216 (7020 particles) of the analyzed particle number in this study. EC particles distributed broadly
217 from NH to MH range. However, the particle compositions are different in NH and MH
218 hygroscopicity range, where fresh and aged EC dominate, respectively (Figure 2 b-c). Fresh
219 EC particles have not experienced significant aging, with weak or no secondary peaks ($-62NO_3^-$,
220 $-97HSO_4^-$, $18NH_4^+$) in their spectra. Therefore, most of them were in hydrophobic mode
221 (Weingartner et al., 1997). The mass spectra of aged EC showed the internal mixing of
222 secondary matters (nitrate, sulfate, ammonium), which is consistent with their hygroscopic
223 property. The peak intensity variations ($-62NO_3^-$, $-97HSO_4^-$, $18NH_4^+$ and other relevant peaks)
224 in EC spectra were a function of GF. A gradual increase of secondary peak intensities in GF 0.9
225 - 1.2 range was observed (Figure S2).

226 Dust/ash type particles have inorganic peaks of salts and metals oxides (Wang et al.,
227 2019; Zhang et al., 2009; Dall'Osto et al., 2008). About 7.4% of analyzed particles were
228 classified into this type. Most of dust/ash particles (>85%) were detected in hygroscopic range
229 (GF > 1.3). However, Dust/ash particles with Al-Si signals were clearly enriched in NH mode

230 (Wang et al., 2014), with the highest detection probability at GF 1.1, as shown in Figure S3.

231 The Al-Si particles are assumed to be soil dusts according to their reported low hygroscopicity

232 (Koehler et al., 2009).

233 The spectra of HMOC type particles contain organic peaks in higher m/z range (>150). This

234 type accounts for 2.6% of total number of analyzed particles. Within the HMOC type, 10%

235 particles have identifiable polycyclic aromatic hydrocarbons (PAH) peaks in their positive

236 spectra and 7% produce high mass signals in negative spectra (Denkenberger et al., 2007). Most

237 of HMOC particles (95%) showed low hygroscopicity ($GF < 1.2$), with peak number fractions

238 of 15% at GF 1.0.

239 Amine-rich type particles produce amine peaks at $+59(C_3H_9N)$, $+86(C_5H_{12}N)$ and $+101(C_6H_{15}N)$

240 (Angelino et al., 2001; Pratt et al., 2009). About 20% of analyzed particles are classified in this

241 type. As found previously (Wang et al., 2014), Amine-rich particles are generally very

242 hydrophilic with the highest detection probability occurred within GF > 1.5 range. Short alkyl

243 chain aliphatic amines are basic and have relatively high vapor pressures, therefore their

244 presence in particles most likely occur in the form of aminium salts, whose formation is greatly

245 favored in the presence of particulate water (Angelino et al., 2001; Chen et al., 2019). It is found

246 that 77% Amine-rich particles were internally mixed with sulfate or nitrate.

247 Ammonium/OC type particles demonstrate some similarities to biomass particles, since a

248 strong, dominant potassium peak ^{39}K exist in positive spectra and organic peaks present in

249 lower mass range (45-80). However, this type of particles also produced much more intense

250 ammonium peak at $^{18}NH_4^+$ and significant sulfate peak ($^{-97}HSO_4$). In addition, the ^{-26}CN or

251 ⁴²CNO peaks, which are present in biomass particles, were absent or very weak, suggesting that
252 biomass burning is not their source. The hygroscopicity pattern of ammonium/OC particles was
253 quite unique. As shown in Fig. 2 (g), ammonium/OC particles are contributing significantly to
254 moderate hygroscopicity range (GF 1.1-1.3), with maximum number contribution of 25% at
255 GF 1.2, a GF at the trough between NH and MH mode. Based on their mass spectral signature
256 and the published ATOFMS characterizations, it is possible that the ammonium/OC particles
257 might be from coal burning sources (Healy et al., 2010). The organics in ammonium/OC
258 particles could be probably produced from inefficient combustion of coal (Wang et al., 2013).
259 The strong ammonium peak in this particle type may be generated in SCR denitration process
260 since the ammonia is usually added in such process. These particles were not likely to be deeply
261 aged particles, because their hygroscopicity was only moderate.

262 Cooking is a significant source of primary organic aerosol (POA) in urban regions (Crippa et
263 al., 2013; Robinson et al., 2006). Zhang et al. estimated that up to 35% of POA are attributed to
264 cooking aerosol during meal hours (Zhang et al., 2007). Cooking particles around the site was
265 likely to be significant considering that the Fudan campus is located in a heavily populated area.
266 The ATOFMS characterization of cooking particles have been performed previously (Silva,
267 2000; Dall'Osto et al., 2013). The markers at -255(C₁₆H₃₂O₂, palmitic), -281 (C₁₇H₃₄O₂, oleic
268 acid) in the negative spectra were used to identify Cooking type of particles (Dall'Osto and
269 Harrison, 2012; Silva, 2000). We identified 861 (%4.6 of total) cooking particles. As shown in
270 Figure 2(h), this particle type had extreme low hygroscopicity and 99% of them were detected
271 in GF<1.1 range. Based on the ATOFMS particle number, cooking particles contribute 19%
272 particle concentrations of NH mode, with its peak contribution occurred at GF 0.9 (49%). It is

273 noted that GF 0.9 does not necessarily indicate a particle shrinkage in diameter. Cooking
274 particles might become more spherical in elevated RH, resulting in smaller mobility diameters.
275 This phenomenon was also observed for other organic particles (Shi et al., 2012). The low
276 hygroscopicity of cooking particles is consistent with their organic composition indicated by
277 the fatty acids (-171, -255, -279,-281) and HOA (+55, +57) peaks in the spectra. The detection
278 of cooking particles in NH mode is a complement to the assumption that combustion sources
279 are the major source of NH particles (Swietlicki et al., 2008;Laborde et al., 2013;Herich et al.,
280 2009).

281 Sea salt particle type is an important type of particles in ambient air in coastal areas(Herich et
282 al., 2009;Gard et al., 1998). Their mass spectra contain a major peak at ^{+23}Na and other peaks
283 at $^{+62}\text{Na}_2\text{O}$, $^{+63}\text{Na}_2\text{OH}$, $^{+81}\text{Na}_2\text{Cl}$. The hygroscopicity of sea salt is of interest since it is critical
284 in the aerosol-cloud interactions in marine and coastal areas (Andreae and Rosenfeld,
285 2008;Massling et al., 2007). Although only 314 sea salt particles (1.7 %) were detected in this
286 study, their hygroscopicity pattern is rather clear that they were mostly present in the largest
287 GF range (>1.5). The large hygroscopicity of sea salt is also indicated by increased number
288 fractions from 2.6% at GF 1.5 to 19% at GF 1.7, as show in Figure 2 (i). The obtained result
289 here is consistent with HTDMA characterizations in marine environment (Swietlicki et al.,
290 2008;Massling et al., 2007), where sea salt particles made up a clear hygroscopicity mode of
291 the largest GF. The hygroscopicity of sea salt in this study is somewhat different compared with
292 the previous characterization in a subarctic region, where sea salt particles were mainly detected
293 in GF 1.3-1.5 range at 82% RH using HTMDA-ATOFMS (Herich et al., 2009). Therefore sea
294 salt particle properties are variant with locations and other factors (organics in seawater, marine

295 microbiological conditions, aging) should be considered (Facchini et al., 2008; Randles et al.,
296 2004).

297 The impact of aging on sea salt hygroscopicity was investigated. Spectra analysis was
298 performed by correlating sea salt peak intensities with GF. It is known that NaCl in fresh sea
299 salt could react with nitric acid in the atmosphere, with the NaNO_3 formed in particles and HCl
300 released (Gard et al., 1998). This chemical transformation is reflected in corresponding change
301 in the sea salt mass spectra. Fresh sea salt produce stronger peaks of positive peak Na_2Cl^+ and
302 negative peak NaCl_2^- in their spectra. With the atmospheric transformation, NaCl is transformed
303 into NaNO_3 , Na_2NO_3^+ and $\text{Na}(\text{NO}_3)_2^-$ peaks emerge and grow stronger, while NaCl related
304 peaks Na_2Cl^+ and NaCl_2^- decrease or vanish. The statistics of sea salt peak intensities at different
305 GF are shown in Figure 3. Obviously, sea salt particles with smaller GF tend to produce stronger
306 NaNO_3 related peaks and weaker NaCl related peaks. This result is an evidence that aged sea
307 salt have reduced hygroscopicity (Herich et al., 2009). The transformation of NaCl into NaNO_3
308 could not generate the observed reduction in GF. Similar result was observed in the subarctic
309 site (Herich et al., 2009). It is likely that organics condensed on Sea salt particles and lowered
310 their hygroscopicity.

311 **3.1.2. Particle effective density and hygroscopicity**

312 Simultaneous information on particle effective density and hygroscopicity is rarely reported
313 (Zelenyuk et al., 2008). Fortunately, the particle effective densities and chemical composition
314 can be measured on by HTDMA-ATOMFS system (Figure 4). Obviously, the particles with
315 lower GF had lower effective densities, while the particles with higher GF had a larger effective

316 density, which was finally approaching to $\sim 1.5 \text{ g cm}^{-3}$ and had much smaller range of effective
317 density deviation, suggesting that a main fraction of particles with high GF were more likely to
318 be aged aerosols that mainly comprised of a mixture of secondary species, such as ammonium
319 sulfate (density: 1.77 g/cm^3) and ammonium nitrate (density: 1.73 g/cm^3). Condensation of
320 ammonium sulfate/nitrate on existing organic carbon aerosols and black carbon aerosols would
321 increase their density. In addition, the densities of ammonium sulfate and ammonium nitrate
322 are similar. Thus, particles with higher mass fraction of ammonium sulfate/nitrate tend to have
323 more similar density, consistent with Figure 4, which shows that the effective density of
324 particles with higher GF had smaller deviation of effective densities.

325 **3.2. Estimating hygroscopicity of ambient particles**

326 Prediction of ambient particle hygroscopicity requires that the HTDMA-ATOFMS dataset have
327 good particle representation and coverage. As discussed in the preceding section, particle types
328 which are normally present during ambient ATOFMS sampling have been characterized in this
329 HTDMA-ATOFMS experiment. Therefore, the HTDMA-ATOFMS dataset in this study can be
330 used to estimate particle hygroscopicity for the majority of ambient particles detected by
331 ATOFMS. In this section, we illustrate an estimation of particle hygroscopicity from a period
332 of ambient ATOFMS data (Sep-12 to Sep-28, 2012), which was collected at Fudan campus, the
333 same site for the HTDMA-ATOFMS experiment.

334 **3.2.1 Hygroscopicity modes in estimated GF**

335 There were 538,983 particles chemically analyzed by ATOFMS during Sep-12 to Sep-28, 2012.
336 The mass spectra in this period was utilized to predict the GF (85% RH) of each individual

337 particle based on the previously described method. With the estimated hygroscopicity of
338 individual particles, several hygroscopicity modes were observed. Figure 5 shows the temporal
339 variation of particle estimated GF. Apparently, at least three hygroscopicity modes were present,
340 with their respective GF peaked at ~ 1.05 , 1.42, and 1.6. The temporal variation of
341 hygroscopicity suggested that the entire period can be roughly divided into four distinct periods
342 of P1, P2, P3 and P4 (as indicated in Figure 5) which have different GF distribution patterns.
343 During P1, the particle numbers were dominated by GF 1.42 mode, while during P2, the GF 1.42
344 mode disappeared and GF 1.05 and GF 1.6 modes appeared. The hygroscopicity pattern during
345 P3 is similar to P1, but with more distinct GF 1.05 mode. During P4, all three hygroscopicity
346 modes were present.

347 The three hygroscopicity modes derived from ATOFMS data were compared with the GF
348 distributions that obtained from some HTDMA studies (Ye et al., 2013; Ye et al., 2011; Liu et al.,
349 2011; Swietlicki et al., 2008). Previous HTDMA characterizations of particle hygroscopicity in
350 Shanghai shows a near hydrophobic mode with center GF in 1.05~1.1 range at RH 85% (Ye et
351 al., 2011), which is consistent with our estimated hydrophobic GF mode peaked at 1.05. The
352 more hygroscopic mode measured by HTDMA usually centered at GF at 1.43~1.47, while in
353 the estimated GF data, the maximum number occurred at GF around 1.42. The mass spectra of
354 GF 1.6 mode suggest that they usually have high sodium peaks (Figure S2), which were
355 probably sea salt particles. The sea salt mode were reported to be very hygroscopic, with
356 average GF around 2.0 at 90% RH for freshly generated sea salt particles in marine areas
357 (Swietlicki et al., 2008).

358 Since ATOFMS measured particle aerodynamic diameters simultaneously for each particles,

359 we present particle number as a bivariate function of the estimated GF and particle diameter
360 (aerodynamic diameter measured by ATOFMS) in Figure 6. The three particle modes were also
361 apparent in the GF- d_{va} diagram. We also noticed the gradually increased GF of larger particles,
362 which is very consistent with HTDMA observations (Ye et al., 2011; Ye et al., 2013). Healy et al.
363 have applied a different method to estimate particle hygroscopicity from single particle data
364 using ZSR mixing rule (Healy et al., 2014). In that study particle aerodynamic diameter d_{va} was
365 transformed to equivalent mobility diameter d_m by assuming a particle density. Despite the
366 differences in method, the estimated GF and their distributions are comparable for NH and MH
367 mode particles. However, the presence of sea salt mode was absent in Healy et al., (Healy et al.,
368 2014).

369 As illustrated in Figure 5, different mixing states were observed during P1-P4 periods. Taking
370 the P4 period as an example, the sea salt mode in this period was persistent during this period,
371 while the concentrations of NH mode particles were intermittent with abrupt changes in
372 temporal trend, consistent with the characteristic of local emissions. The number concentrations
373 of MH mode particles increased during nighttime (Figure 5), which probably related to the
374 mixing layers fluctuations. These facts indicate that the estimated hygroscopicity could help to
375 investigate particles' sources, formation mechanisms, and their possible atmospheric aging
376 pathways (Healy et al., 2014; Li et al., 2018; Laborde et al., 2013; Kamilli et al., 2014; Swietlicki
377 et al., 2008).

378 **3.2.2 Hygroscopicity and visibility**

379 Particles with different hygroscopicity have different liquid water content and optical properties.

380 This fact can be demonstrated by correlating the concentrations of particles having different
381 hygroscopicity with atmospheric visibility (Liu et al., 2012; Qu et al., 2015; Chen et al., 2012).
382 We use the visibility data (<https://www.wunderground.com/>) logged in the Hongqiao airport
383 (31°12'N, 121°20'E) and Pudong airport (31°9.3'N, 121°49'E) during Sep-12 to Sep-28, 2012
384 (see the map in Figure S5). The contemporary visibility data of the two airports correlated
385 strongly (Figure S5), despite the 45 kilometers distance between the two airports. Fudan
386 campus locates roughly between the two airports, so that the average visibility between the two
387 airports was used to represent the visibility at Fudan site. We discriminated the particles into
388 less and more hygroscopic groups at splitting GF of 1.2, with their number concentrations
389 calculated with the same resolution of visibility data, as shown in the upper panel in Figure 5.
390 Except for P2 and P4 periods, when visibility were typically above 10km, an anti-correlation
391 was observed between visibility and particle numbers of more hygroscopic group than less
392 hygroscopic group. The fact could be further demonstrated by splitting particles into finer bins
393 of GF 0.9-1.1, 1.1-1.3, 1.3-1.55, whose number concentrations correlated with visibility (Figure
394 7). For particles in GF 0.9-1.1, there were actually no correlation between their concentrations
395 and visibility ($R^2=0.08$). For moderate hygroscopic particles (GF 1.1-1.3), the correlation
396 became stronger ($R^2=0.34$). MH mode particles (GF 1.3-1.55) were found to best anti-correlated
397 with visibility with $R^2=0.58$. Thus, these results clearly demonstrated that aerosol particles with
398 higher hygroscopicity could play more important role in affecting visibility.

399 **3.2.3 Sea salt type particles**

400 Sea salt type particles show a unique mode in the GF- d_{va} diagram (Figure 6). We further
401 investigated the relation between characteristics of sea salt particles and the back trajectories of

402 airmass (Figure 8) during period P1-P4 using HYSPLIT mode (Draxler, R. R. and Rolph, G.
403 D.,2003). During period P1, the airmass were relatively stable, and the airmass movement were
404 relatively slow. The local circulation of airmass brought regional aerosol pollution to the
405 sampling site, which was consistent with the elevated concentrations of more hygroscopic (MH)
406 mode particles (Figure 5). During P2, the history of airmass exclusively passed over yellow sea
407 without continental influence. The MH mode particles disappeared and only NH and GF 1.6
408 mode were detected in the predicated GF. Similar as P1, the back trajectories during P3 mainly
409 stayed over continental regions in the mainland of China, resulting regional aerosol pollutions
410 in MH particles to the site and GF 1.6 mode were barely present. During P4, the airmass mainly
411 originated from northeastern part of East China Sea and GF 1.6 mode emerge again.
412 Consequently, the back trajectories support the attribution of GF 1.6 mode to sea salt particles.

413 Figure 9 shows the differential mass spectra between sea salt particles during P1&P3 and during
414 P2&P4, indicating that the sea salt particles, detected in P2 and P4, were relatively fresh, while
415 sea salt particles detected in P1 & P3 period were more aged. Clearly, sea salt particles in P1 &
416 P3 show stronger peaks of $\text{Na}(\text{NO}_3)_2^-$, Na_2NO_3^+ , NO_3^- , while sea salt particles in P2 & P4 show
417 stronger NaCl related peaks (Figure 9). This result indicates that sea salt in P1&P3 experienced
418 more aging in the atmosphere. The right panel in Figure 9 compares the hygroscopicity
419 distributions of sea salt particles during P1&P3 and during P2&P4. As expected, the
420 hygroscopicity distribution during P1&P3 shifted slightly ($\Delta\text{GF}=-0.02$) to lower GF, suggesting
421 more aged sea salt particles had reduced hygroscopicity, consistent with the trend discussed
422 previously. These results also demonstrate that the hygroscopicity estimation method is
423 sufficiently sensitive to reflect the minor changes in particle mass spectra to the estimated

424 hygroscopicity.

425 **3.2.4 Particle type distributions in various hygroscopicity modes**

426 The particles analyzed by ATOFMS during the studied period were classified within the same
427 classification scheme as HTDMA-ATOFMS experiment. With the estimated hygroscopicity of
428 individual particles, Figure 10 shows the number contributions of each particle type as a
429 function of GF. In the GF 0.9-1.1 range, the fresh EC and HMOC particles were dominant with
430 biomass and cooking types. In the GF 1.1-1.3 range, the Ammonium/OC particles is the most
431 abundant type, which contributed to nearly 40% particle numbers in this GF range. The main
432 particle type in the higher GF range (1.3-1.55) was aged EC particles. Sea salt particles were
433 present mainly in the narrower range of GF 1.55-1.65. A previous HTDMA characterization
434 study (Swietlicki et al., 2008) has suggested that ambient submicron particles have four
435 hygroscopicity modes, namely near-hydrophobic (NH), less-hygroscopic (LH), more-
436 hygroscopic (MH) and sea salt modes, with their GFs centered in 1.0-1.1, 1.11-1.33, >1.33
437 and >1.85 ranges, respectively (at 90% RH). These hygroscopicity modes correspond well to
438 the particle types analyzed in this study. Freshly emitted EC particles from combustion sources
439 and organic particles with higher molecular weight were the major contributors of nearly
440 hydrophobic (NH) mode in this study. Consistent with their particle mass spectra (Figure 2,
441 Figure S2), more-hygroscopic particles were hydrophilic due to condensation of nitrate and
442 sulfate. For the chemical composition of less-hygroscopic particles was rarely reported.
443 However, the present study indeed identified a unique particle type that is specifically enriched
444 in less-hygroscopic range. Both the HTDMA-ATOFMS experiment and ambient ATOFMS
445 sampling have suggested that their mass spectra contained many organic, ammonium and

446 sulfate signals. Temporal concentrations of this particle type indicate they were only enriched
447 in specific days in P1 and P3 period, as suggested in Figure 5. Their real sources and production
448 mechanisms deserve further investigations.

449 **4. CONCLUSIONS**

450 The hygroscopicity and composition of submicron particles were simultaneously characterized
451 in urban atmosphere (Shanghai). A single particle mass spectrometer, ATOFMS, was connected
452 to the downstream of HTDMA to analyze composition of hygroscopicity segregated particles.
453 A dataset linking single particle compositions and particle hygroscopicity was obtained.
454 Generally, biomass particles, fresh EC particles, organic particles with high molecular weight
455 (HMOC) were mostly present in NH particle mode. Hydrophilic particle types, including aged
456 EC, amine rich particles, usually have a $GF > 1.3$. Cooking particles were exclusively detected
457 in $GF < 1.1$ range. Sea salt particles were present in very hygroscopic range ($GF > 1.5$).
458 Atmospheric processing was shown to reduce the hygroscopicity of sea salt particles. A unique
459 Ammonium/OC particle type was identified to have a GF mode centered at 1.2, which is
460 assumed to originate from coal combustion.

461 In this study, based on the obtained hygroscopicity-composition relations, we developed a new
462 statistical method to estimate particle hygroscopicity just from its single particle mass spectra.
463 Individual particles were differentiated by the estimated hygroscopicity into various modes.
464 Consistent with the HTDMA hygroscopicity measurements, our estimated hygroscopicity
465 distribution shows three modes, namely near hydrophobic (NH) mode, more hygroscopic mode
466 (MH) and sea salt mode. The temporal profiles of estimated hygroscopicity distributions can

467 explain the variations of visibilities. This method is a novel way of single particle mass
468 spectrometry data analysis, which would provide critical new information on particulate water
469 content, particle source apportionment and aging process.

677 **AUTHOR CONTRIBUTION**

- 678 Xinning Wang designed this study and conducted the experiments. Xiaofei Wang and Xin
679 Yang supervised this study and help with experiment design. Xinning Wang, Xiaofei Wang
680 and Xin Yang wrote the manuscript.

681 **DATA AVAILABILITY**

- 682 All of the observation data and the codes used in this manuscript are available from the
683 corresponding author upon request (xiaofeiwang@fudan.edu.cn).

684 **ACKNOWLEDGMENT**

685 This work was partially supported by the National Natural Science Foundation of China (Nos.
686 91544224, 21906024, 41775150, 41827804) and Shanghai Natural Science Foundation (No.
687 19ZR1404000).

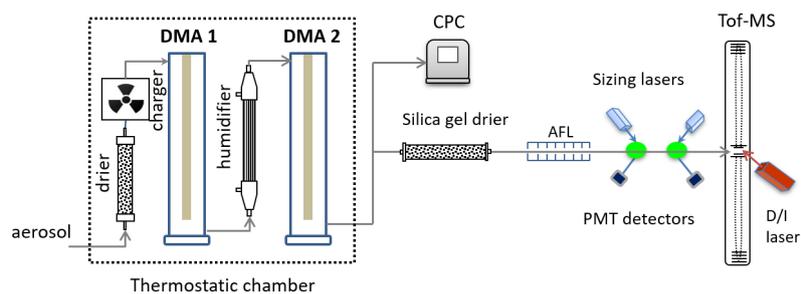

688 **COMPETING INTERESTS**

689 The authors declare that they have no conflict of interest.

690

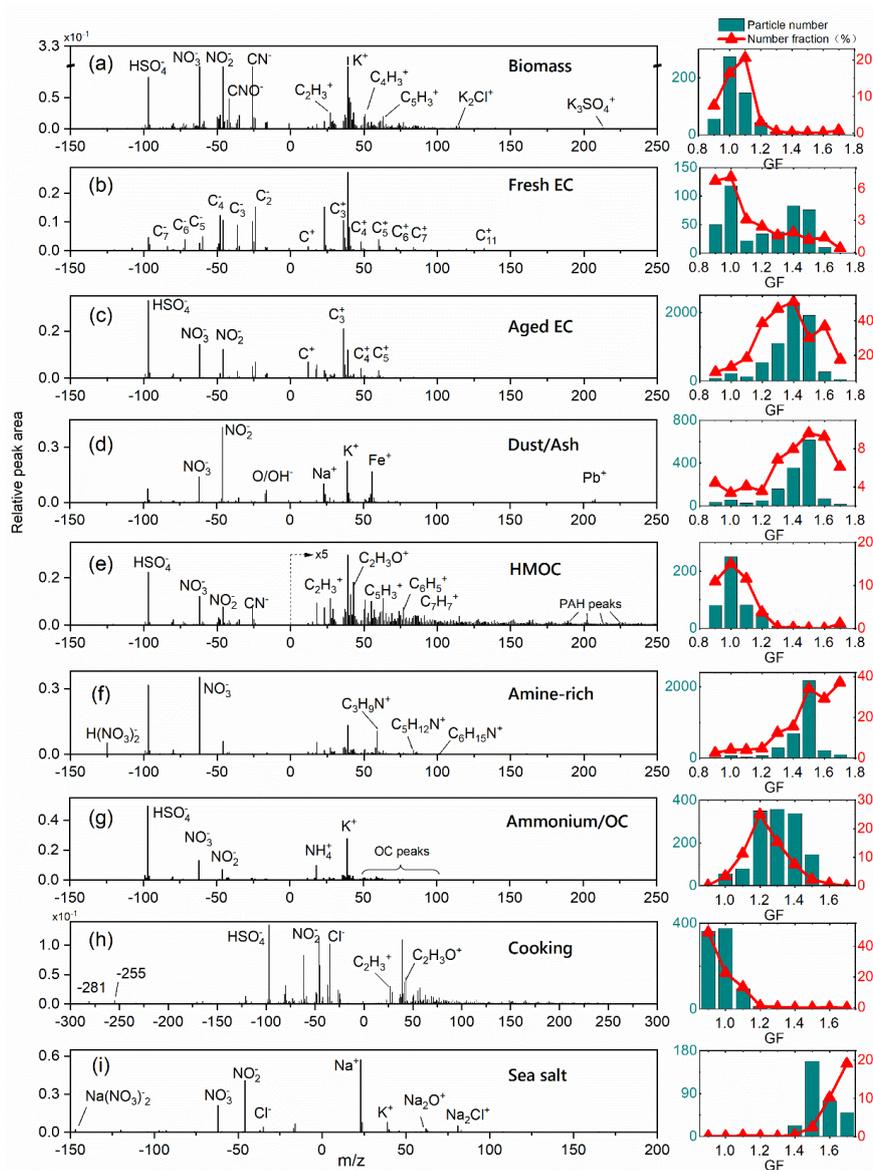

691 **FIGURES**

692

693 Figure 1. The schematic of HTDMA-ATOFMS characterization setup showing the major parts

694 of HTDMA (left), ATOFMS (right). The humidifier in HTDMA was maintained at 85% RH.

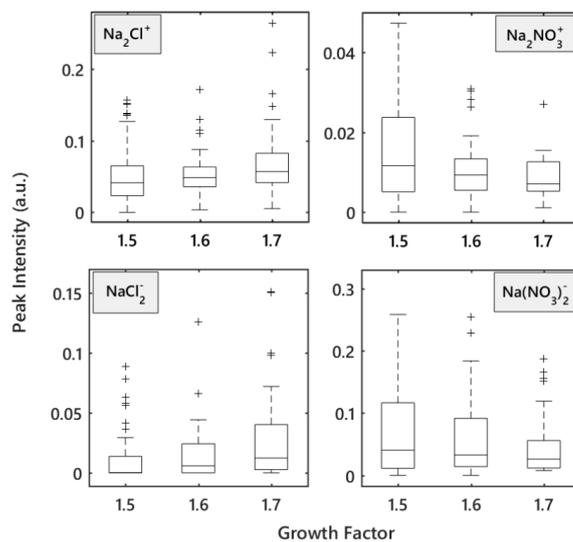

695

696 Figure 2. (Left panel) Averaged particle mass spectra of the major particle types detected in
697 HTDMA-ATOFMS characterization. Peaks of significance were labelled. Right panels show
698 the particle numbers of each type (left-axis) and their relative number fractions in total particles

699 (right-axis) as a function of GF.

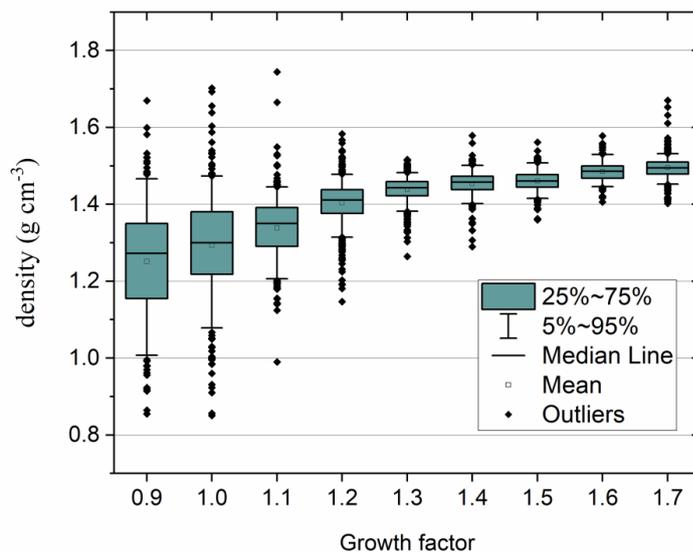

700

701 Figure 3. Statistics of relevant peak intensities in sea salt particle mass spectra detected at GF

702 1.5-1.7 range. The statistics are (from bottom to top): the minimum, 25th percentile, median,

703 75th percentile, maximum and outliers.

704

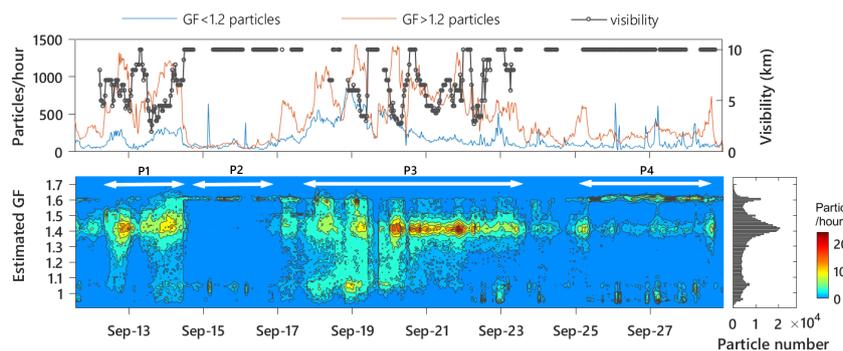

705

706 Figure 4. Particle effective densities of particles as a function of growth factor. The statistics
707 are (from bottom to top): the 5th percentile, 25th percentile, median, 75th percentile, 95th
708 percentile and outliers.

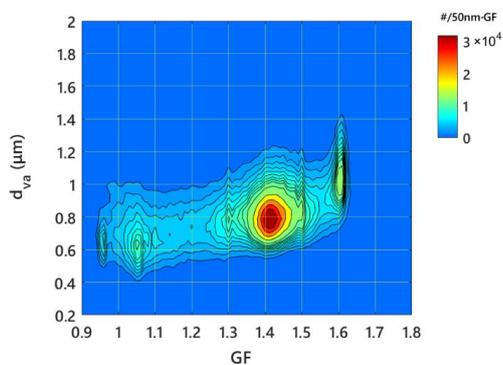

709

710

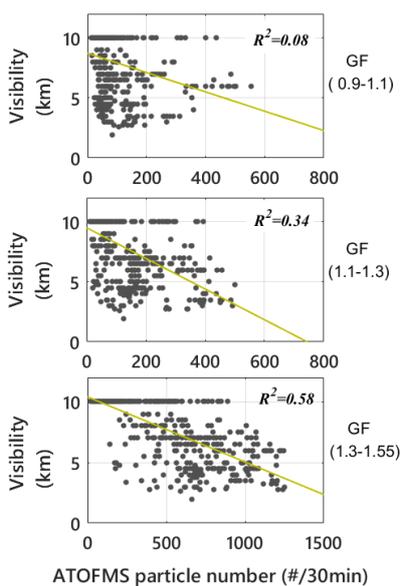

711

712 Figure 5. (Upper) Temporal variation of atmospheric visibility and particle concentrations of
713 Near Hydrophobic (estimated $GF < 1.25$) and More Hygroscopic ($GF > 1.25$) mode. (Lower)
714 The contour plot illustrates the temporal variation of estimated GF from Sep-12 to Sep-28, 2012.
715 The lower-right panel denotes particle number distribution as a function of estimated GF during
716 the period.

717

718 Figure 6. Contour plot of particle number concentrations as bivariate function of estimated GF
719 and aerodynamic diameter measured by ATOFMS.

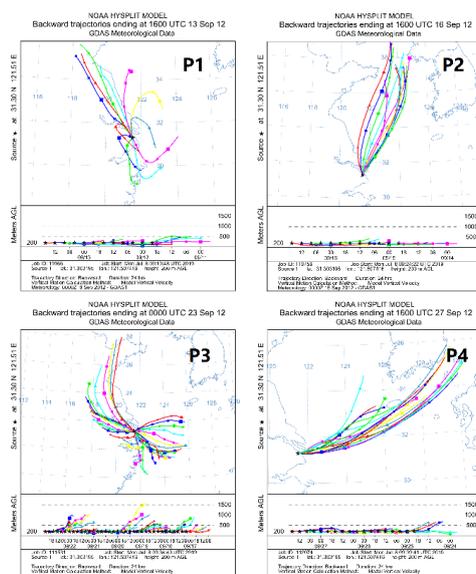

720

721 Figure 7. Correlation plots between visibility and ATOFMS particle numbers with the estimated

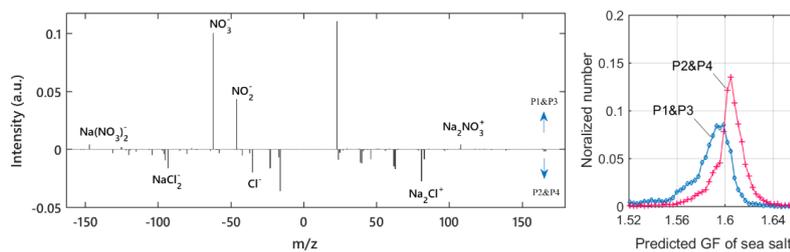

722 GF in 0.9-1.1, 1.1-1.3 and 1.3-1.55 range.

723

724

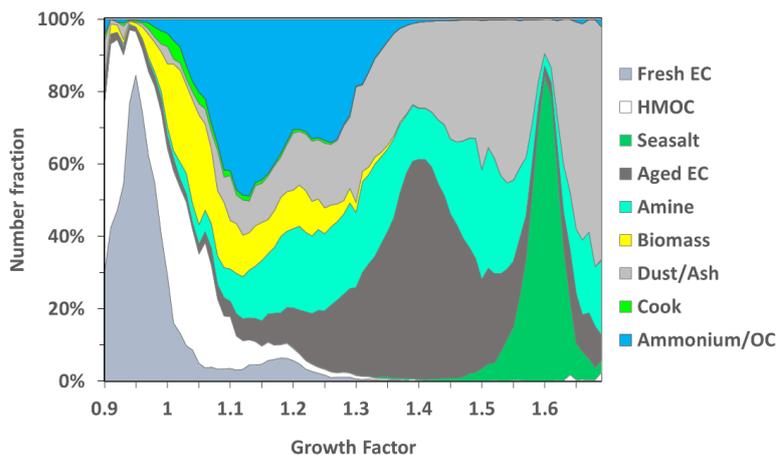

725 Figure 8. The 24-hour backward trajectories during P1 - P4 periods of the sampling site (by
 726 HYSPPLIT model).

727

728 Figure 9. The differential mass spectrum between sea salt particles in (P1&P3) and (P2&P4).
 729 Positive peaks indicate they are larger in P1&P3 than P2&P4. The right figure shows the
 730 distributions of the predicted GF of sea salt in (P1&P3) and (P2&P4). Sea salt numbers were
 731 normalized by their total numbers.

732

733

734 Figure 10. The number fractions of ATOFMS particle types as a function of estimated
735 hygroscopicity during Sep-12 to Sep-28, 2012.

736
