18 Abstract

19 As one of the intense anthropogenic emission regions across the relatively high
20 latitude ($> 40^{\circ}\text{N}$) areas on the Earth, Northeast China faces serious problem on regional
21 haze during long winter with half a year. Aerosols in polluted haze in Northeast China
22 are poorly understood compared with the haze in other regions of China such as North
23 China Plain. Here, we for the first time integrated bulk chemical measurements with
24 single particle analysis from transmission electron microscopy (TEM), nanoscale
25 secondary ion mass spectrometer (NanoSIMS), and atomic force microscopy (AFM)
26 to obtain morphology, size, composition, aging process, and sources of aerosol particles
27 collected during two contrasting regional haze events (Haze-I and Haze-II) at an
28 urban site and a mountain site in Northeast China, and further investigated the causes
29 of regional haze formation. Haze-I evolved from moderate (average $\text{PM}_{2.5}$: 76-108
30 $\mu\text{g}/\text{m}^3$) to heavy pollution (151-154 $\mu\text{g}/\text{m}^3$), with the dominant $\text{PM}_{2.5}$ component
31 changing from organic matter (OM) (39-45 $\mu\text{g}/\text{m}^3$) to secondary inorganic ions
32 (94-101 $\mu\text{g}/\text{m}^3$). Similarly, TEM observations showed that S-OM particles elevated
33 from 29% to 60% by number at urban site and 64% to 74% at mountain site and
34 75-96% of Haze-I particles included primary OM. Change of wind direction induced
35 that Haze-I rapidly turned into Haze-II (185-223 $\mu\text{g}/\text{m}^3$) with the predominant OM
36 (98-133 $\mu\text{g}/\text{m}^3$) and unexpectedly high K^+ (3.8 $\mu\text{g}/\text{m}^3$). TEM also showed that K-OM
37 particles increased from 4-5% by number to 50-52%. Our study revealed a contrasting
38 formation mechanism of these two haze events: Haze-I was induced by accumulation
39 of primary OM emitted from residential coal burning and further deteriorated by
40 secondary aerosol formation via heterogeneous reactions; Haze-II was caused by
41 long-range transport of agricultural biomass burning emissions. Moreover, we found
42 that 75-97% of haze particles contained tarballs, but only 4-23% contained black
43 carbon and its concentrations were low at 2.7-4.3 $\mu\text{g}/\text{m}^3$. The results highlight that
44 abundant tarballs are important light-absorbing brown carbon in Northeast China
45 during winter haze and further considered in climate models.

46 **1. Introduction**

47 Haze pollution is mainly caused by high levels of fine particulate matter (PM_{2.5})
48 and it has widely spread over the globe such as Mexico city (Adachi and Buseck,
49 2008), Paris, France (Fortems - Cheiney et al., 2016), North India (Chowdhury et al.,
50 2019), North China (Huang et al., 2014), and the Arctic (Frossard et al., 2011). In the
51 past twenty years, regional haze episodes with high concentrations of PM_{2.5} have
52 frequently occurred in China following rapid economic development. Various studies
53 on regional haze in China have been conducted by many scientists (e.g., Bennartz et
54 al., 2011; Guo et al., 2014; Li and Shao, 2009; Lin et al., 2017; Liu et al., 2017b; Ren
55 et al., 2016; Shi et al., 2017; Zhang et al., 2018b). Current hot issues on haze pollution
56 concentrate on the formation processes of regional haze in various atmospheric
57 environments and their potential optical and health influences (Chen et al., 2017a;
58 Gao et al., 2017).

59 Many of these studies reported that haze particles can adversely affect human
60 health, ecological environments, and regional climate (Ding et al., 2016; Huang et al.,
61 2013; Lelieveld et al., 2015; Li et al., 2017a; Liu et al., 2019; Liu et al., 2016;
62 Mahowald et al., 2018; Shi et al., 2019; Xie et al., 2019; Zhang et al., 2013). For
63 example, exposure to high levels of ambient PM_{2.5} cause or contribute to a variety of
64 human diseases (e.g., stroke, ischemic heart disease, chronic obstructive pulmonary
65 disease, and lung cancer) (Chen et al., 2019; Liu et al., 2016) and lead to ~1.3 million
66 premature deaths per year in China (Lelieveld et al., 2015). Abundant anthropogenic
67 metal, ammonium, and phosphorus-containing particles are transported into remote
68 regions of oceans, where they promote plankton growth and further influence ocean
69 ecology (Li et al., 2017a; Mahowald et al., 2018; Shi et al., 2019). High
70 concentrations of fine aerosols suspended in haze layers not only influence regional
71 climate through absorbing (e.g., black carbon (BC) and brown carbon (BrC)) and
72 scattering (e.g., sulfates and nitrates) solar radiation (Huang et al., 2013; Liu et al.,
73 2019; Xie et al., 2019), but also depress the planetary boundary layer development

74 (Ding et al., 2016; Li et al., 2017c; Zhang et al., 2013) and reduce crop yields (Tie et
75 al., 2016) in China. Therefore, understanding haze formation mechanisms and sources
76 of haze particles in different regions of China is crucial to provide feasible control
77 strategies for reducing regional PM_{2.5} concentration and protecting ecosystems.

78 In China, regional heavy hazes frequently occur in the North China Plain (NCP)
79 (Zhao et al., 2013) and Northeast China (Ma et al., 2018) during winter. In the past
80 decades, the regional haze formation mechanisms in the NCP have been intensely
81 investigated (Chen et al., 2017b; Cheng et al., 2016; Li et al., 2015; Liu et al., 2017c;
82 Tao et al., 2014; Tian et al., 2015; Wang et al., 2016; Wang et al., 2019; Wang et al.,
83 2014; Xing et al., 2019; Zheng et al., 2015b; Zhong et al., 2019). Adverse
84 meteorological conditions (e.g., low wind speeds and stable atmospheric boundary
85 layer) can induce preliminary formation of hazes during winter (Zheng et al., 2015b;
86 Zhong et al., 2019). Massive numbers of primary particles from industries,
87 households, and vehicular exhaust emissions (e.g., fly ash, metal, primary organic
88 matter, and soot particles) are the major aerosols in winter hazes (Chen et al., 2017b;
89 Tian et al., 2015; Wang et al., 2019). Rapid production of secondary aerosols (e.g.,
90 sulfates, nitrates, and secondary organics) via heterogeneous reactions under high RH
91 mainly elevates haze levels and causes regional hazes (Liu et al., 2017c; Wang et al.,
92 2016; Xing et al., 2019). The two-way feedback between accumulation of air
93 pollutants and depression of the atmospheric boundary layer also aggravate haze
94 pollution (Wang et al., 2014; Zhong et al., 2019). Moreover, regional transport of air
95 pollutants is one of the important factors for the long duration of regional haze (Li et
96 al., 2015; Tao et al., 2014; Zheng et al., 2015b). These studies well revealed formation
97 mechanisms of regional winter hazes in the NCP.

98 Among different regions or cities in China, the haze formation mechanisms
99 would most likely differ due to different emissions and meteorological conditions (Li
100 et al., 2019; Zhang et al., 2017; Zheng et al., 2015b). The air quality in Northeast
101 China, a region with a long heating period (mid October-mid April), is mainly

102 influenced by abundant inefficient combustion activities (e.g., coal and biomass
103 burning in residential stoves and coal burning in small boilers for household heating
104 and cooking) (Yang et al., 2017; Zhang et al., 2017). Extremely high concentrations of
105 organic aerosols have been observed in Northeast China during winter haze that
106 coincide with crop growing and harvest periods (Cao et al., 2017; Chen et al., 2015;
107 Zhang et al., 2017). Because of the influences of the regional haze in winter, annual
108 aerosol optical depth in urban areas was ~ 3.7 times higher than that in rural areas in
109 Northeast China (Zhao et al., 2018b). In the past five years, some studies have
110 focused on the physicochemical properties of haze particles collected in Northeast
111 China (Cao et al., 2017; Chen et al., 2015; Li et al., 2017b; Miao et al., 2018; Zhang et
112 al., 2017; Zhao et al., 2018b). However, studies on regional haze evolution and haze
113 formation mechanisms in Northeast China are rare. This limited information
114 precludes the comparison of regional hazes in Northeast China with other regions in
115 China. Furthermore, it is difficult to adopt some reasonable regional haze pollution
116 control strategies from the NCP to apply to the air pollution in Northeast China.

117 Northeast China is only one intense anthropogenic emission region besides
118 Mongolia across the relatively high latitude ($> 40^\circ\text{N}$) areas on the Earth (van
119 Donkelaar et al., 2016). This region is significantly influenced by the Siberian cold
120 high pressure systems in winter. The Siberian anticyclone transports air pollutants
121 from Northeast China to Korea, Japan, and even the Arctic, and further causes
122 large-scale influences in the global climate (Jung et al., 2015; Rodo et al., 2014;
123 Sobhani et al., 2018; Zhang et al., 2016). Therefore, understanding the
124 physicochemical characteristics of anthropogenic fine particles in regional haze and
125 regional haze formation mechanisms over Northeast China has to be considered of the
126 utmost importance.

127 In this study, we conducted a field experiment in the south part of Northeast
128 China from 31 October to 6 November 2016. Two contrasting regional heavy haze
129 episodes occurred there during the sampling period. We investigated the types and

130 mixing states of individual aerosol particles and $PM_{2.5}$ composition during these two
131 episodes. Finally, we elucidated the formation mechanisms of two regional haze
132 events and the main sources of fine haze particles.

133

134 **2. Experimental Methods**

135 **2.1 Sampling sites and sample collections**

136 There are three provincial capital cities (i.e., Shenyang, Changchun, and Harbin)
137 in Northeast China that are surrounded by the Greater Khingan Mountains, the Lesser
138 Khingan Mountains, and the Changbai Mountains (Figure 1a). In this study, we
139 selected an urban site (41.8°N, 123.35°E) and a mountain site (41.92°N, 123.65°E) in
140 Shenyang city (Figure 1b). The urban site is located in the center of Shenyang city. The
141 mountain site on top of Qipan Mountain (224 m) is located ~30 km northeast of the
142 urban site (Figure 1b). There are only a few villages around Qipan Mountain, so its air
143 quality well represents the regional transport in the south part of Northeast China.

144 The $PM_{2.5}$ samples were collected on 90 mm quartz filters (Whatman, UK) using
145 two medium volume samplers (Wuhan Tianhong Inc., TH-150A, 100 L/min) at the
146 urban and mountain sites. Individual particle samples were collected on transmission
147 electron microscopy (TEM) grids and silicon wafers using two DKL-2 samplers
148 (Genstar Inc., 1 L/min) equipped with a 0.5 mm jet nozzle impactor at two sampling
149 sites. The quartz filters provided mass concentrations and the chemical composition of
150 ambient $PM_{2.5}$. The TEM grids and silicon wafers were used for microscopic
151 observations of individual particles. To better explore the variation of $PM_{2.5}$
152 composition and individual particles, we collected the daytime (DT, 8:30-20:00 (local
153 time)) $PM_{2.5}$ and nighttime (NT, 20:30-8:00 (next day)) $PM_{2.5}$ as well as individual
154 particle samples four times a day (i.e., 0:00-3:00, 6:00-9:00, 12:00-15:00, and
155 18:00-21:00). To avoid individual particles overlapping on the substrate, the sampling
156 duration of individual particles was varied from 30 s to 10 min depending on the $PM_{2.5}$
157 concentrations. After individual particles samples were collected, we immediately

158 used a portable optical microscope to check the particle distribution on the substrate,
159 which guaranteed the sample to be suitable for microscopic analyses. After the
160 sampling, the quartz filters were put into a -20 °C refrigerator and the TEM grids and
161 silicon wafers were stored in the dry, clean, and airtight containers until laboratory
162 analyses were performed.

163 Meteorological data (i.e., wind speed and wind direction, temperature, relative
164 humidity (RH), and pressure) at the urban and mountain sites were simultaneously
165 collected by two automated weather instruments (Kestrel 5500, USA) at five minute
166 intervals.

167

168 **2.2 PM_{2.5} analyses**

169 The quartz filters are weighed with a high-precision digital balance (Sartorius ME
170 5-F, 0.001 mg of reading precision) after being equilibrated for 24 h under stable
171 conditions (TP: 20±1 °C; RH: 48±2%) before and after sampling. The PM_{2.5} mass
172 concentrations at the urban and mountain sites are calculated based on the weight
173 difference and sampling volume of each quartz filter.

174 Each quartz filter collected at two sampling sites can be used to analyze chemical
175 composition (i.e., water-soluble ions, organic carbon (OC), and elemental carbon
176 (EC)) of PM_{2.5}. In this study, we use an ion chromatography system (Dionex ICs-90,
177 USA) to obtain mass concentrations of water-soluble ions (i.e., Ca²⁺, Mg²⁺, K⁺, Na⁺,
178 NH₄⁺, NO₃⁻, SO₄²⁻, Cl⁻, and F⁻) and an OC/EC analyzer (Sunset Laboratory Inc., USA)
179 to obtain mass concentrations of OC and EC. Concentrations of organic matter (OM)
180 were further calculated through multiplying OC concentrations by a factor of 1.4
181 reported by Guinot et al. (2007). The experimental details about water-soluble ions
182 analysis and OC/EC analysis have been provided in our previous study (Zhang et al.,
183 2017).

184

185 **2.3 TEM/EDS analysis**

186 Individual particles on TEM grids (copper (Cu) grid covered by a carbon (C)
187 reinforcement substrate) are examined using TEM combined with energy-dispersive
188 X-ray spectrometry (EDS) (JEOL, JEM-2100). TEM observation provide the
189 morphology of individual particles and the mixing states of different aerosol
190 components in individual particles on the substrate. EDS determines the elemental
191 composition of individual particles. EDS spectra of individual particles are collected
192 within a maximum time of 30 s to minimize potential X-ray damage and ensure
193 sufficient intensity during EDS analysis. Cu cannot be analyzed for individual particles
194 because the TEM grids are made of Cu. In addition, the C content in EDS spectra of
195 individual particles may be overestimated due to the substrate's contribution.

196 Individual particles are unevenly distributed on TEM grids, with coarser particles
197 in the center of sampling spot and finer particles on the periphery. Therefore, to
198 guarantee that the analyzed particles are representative, five areas are selected from the
199 sampling center to periphery on each TEM grid. After a labor-intensive operation, a
200 total of 3,630 particles at the urban site and 4,281 particles at the mountain site with
201 diameter $< 2.5 \mu\text{m}$ were analyzed by TEM/EDS.

202 The area, perimeter, and equivalent circle diameter (ECD) of individual particles
203 in TEM images are manually or automatically obtained through an image analysis
204 software (iTEM, Olympus soft imaging solutions GmbH, Germany).

205

206 **2.4 NanoSIMS analysis**

207 Based on TEM/EDS analysis, a representative individual particle sample is
208 selected for nanoscale secondary ion mass spectrometer (NanoSIMS, 50L, CAMECA
209 Instruments, Geneviers, France) analysis. In this work, signal intensity mapping of
210 $^{12}\text{C}^{14}\text{N}^-$, $^{12}\text{C}^-$, $^{16}\text{O}^-$, and $^{32}\text{S}^-$ ions are obtained after the Cs^+ primary ion beam ionizes
211 the atoms of particle surface. Ion signal intensity mapping of individual particles with
212 nanometer resolution clearly shows ion distribution in particles. Strong $^{12}\text{C}^{14}\text{N}^-$ and
213 $^{12}\text{C}^-$ signals imply OM in individual particles and eliminate the contribution of C

214 substrate on TEM grids (Chi et al., 2015).

215

216 **2.5 AFM analysis**

217 The surface structure of individual particles collected on silicon wafers are
218 investigated using atomic force microscopy (AFM, Dimension Icon, USA) with a
219 digital nanoscope IIIa in the tapping mode. AFM observations in the tapping mode
220 produce 3-D images of individual particles. The tapping AFM is equipped with a
221 cantilever and a conical tip with a 10 nm radius.

222 Based on the preliminary observations from TEM, we select three typical samples
223 collected during the clean day, Haze-I event, and Haze-II event for the AFM analysis
224 (The naming details for haze events in Section 3.1). To obtain the 3-D morphology of
225 more particles on the basis of keeping images clear, $10 \times 10 \mu\text{m}^2$ of scanning range and
226 0.5-0.8 Hz of scanning rate are selected. 57 particles during the clean day and Haze-I
227 and 29 particles during the Haze-II were carefully analyzed. After obtaining AFM
228 images of individual particles, we use the NanoScope Analysis software to
229 automatically obtain the bearing area (A) and bearing volume (V) of each analyzed
230 particle. The ECD and equivalent sphere diameter (ESD) of individual particles are
231 further calculated according to the following two formulas.

$$232 \quad A = \frac{4}{3}\pi r^2 = \frac{\pi d^2}{3} \rightarrow d = \sqrt{\frac{3A}{\pi}} \quad (1)$$

$$233 \quad V = \frac{4}{3}\pi r^3 = \frac{4}{3} \times \frac{\pi D^3}{8} \rightarrow D = \sqrt[3]{\frac{6V}{\pi}} \quad (2)$$

234 Where d is ECD; D is ESD.

235 The linear correlations between ECD and ESD and typical AFM images of
236 individual particles (clean day & Haze-I: $D=0.5861 \times d$; Haze-II: $D=0.4040 \times d$) are
237 shown in Figures S1a-b. Through the above two linear correlations, we can obtain the
238 ESD of each individual particle analyzed by iTEM software.

239

240 3. Results

241 3.1 Composition of fine particles and meteorology

242 Regional haze pollution was observed in Northeast China during the sampling
243 period from 31 October to 5 November 2016 (Figure S2). Based on the variation of
244 PM_{2.5} mass concentration and visibility at the urban and mountain sites, clean day (31
245 DT October, PM_{2.5} < 75 µg/m³ and visibility > 10 km) and haze days (31 NT October-5
246 NT November, PM_{2.5} ≥ 75 µg/m³ and visibility < 10 km) were identified (Figure 2a). In
247 general, we determined two regional haze events: 31 NT October-4 DT November
248 (Haze-I) and 4 NT-5 NT November (Haze-II), based on the different prevailing wind
249 directions (Haze-I: Southerly; Haze-II: Northerly) (Figures S3a-b) and air mass
250 backward trajectories (Figure S4).

251 To understand haze evolution, we divided Haze-I event into a moderate haze
252 stage (31 NT October-3 NT November) with 75 µg/m³ ≤ PM_{2.5} < 150 µg/m³ and a
253 heavy haze stage (4 DT November) with PM_{2.5} ≥ 150 µg/m³ (Figure 2a). Figure 2a
254 shows that the average mass concentrations of PM_{2.5} increased from 69 µg/m³ to 108
255 µg/m³ at the urban site and from 25 µg/m³ to 76 µg/m³ at the mountain site from the
256 clean day to the moderate Haze-I event. Compared with northerly winds with ~1.4
257 m/s and ~38% of RH on the clean day, the wind directions were from the southerly
258 with 0.7 m/s at the urban site and 3.0 m/s at the mountain site; RH varied from 39% to
259 67% during the moderate Haze-I event (Figures S3a-d). Here the moderate Haze-I
260 event is considered as a general haze pollution that frequently occurs in Northeast
261 China during winter (Zhang et al., 2017). During the moderate Haze-I event, the
262 average mass concentrations of OM, EC, and secondary inorganic ions (i.e., SO₄²⁻,
263 NO₃⁻, and NH₄⁺) in PM_{2.5} were 45 µg/m³, 4.3 µg/m³, and 24 µg/m³ at the urban site
264 and 39 µg/m³, 2.7 µg/m³, and 20 µg/m³ at the mountain site, respectively (Figures
265 2b-c). Following PM_{2.5} concentration exceeding 150 µg/m³, the moderate Haze-I
266 event evolved into the heavy Haze-I event (Figure 2a). During the heavy Haze-I event,
267 mass concentrations of PM_{2.5} were 154 µg/m³ at the urban site and 151 µg/m³ at the

268 mountain site (Figure 2a). RH remained high at 73-80% at the urban and mountain sites
269 during the heavy Haze-I event (Figures S3c-d). Figures 2b-c show that the average
270 concentrations of OM and EC were fairly constant at 39-45 $\mu\text{g}/\text{m}^3$ and 2.7-4.3 $\mu\text{g}/\text{m}^3$
271 from the moderate Haze-I to the heavy Haze-I event. In contrast, secondary inorganic
272 ions rapidly increased from 20-24 $\mu\text{g}/\text{m}^3$ to 94-101 $\mu\text{g}/\text{m}^3$ in the DT of 4 November
273 (Figures 2b-c). Therefore, the variation of chemical composition of $\text{PM}_{2.5}$ clearly
274 reflected the general haze evolution from moderate to heavy in Northeast China.

275 With the prevailing wind changing from southerly with ~ 0.8 m/s to northerly
276 with ~ 3.9 m/s (Figures S3a-b), the Haze-I event turned into the Haze-II event. The
277 average $\text{PM}_{2.5}$ concentrations remained at high levels and reached 223 $\mu\text{g}/\text{m}^3$ at the
278 urban site and 185 $\mu\text{g}/\text{m}^3$ at the mountain site (Figure 2a). RH were consistently high in
279 the range of 65-87% during the Haze-II event (Figures S3c-d). In addition, we noticed
280 that hourly concentrations of $\text{PM}_{2.5}$ and CO rapidly climbed from 209 $\mu\text{g}/\text{m}^3$ and 1.3
281 ppm at 6:00 A.M. to 669 $\mu\text{g}/\text{m}^3$ and 1.9 ppm at 8:00 A.M. on 5 November, respectively
282 (Figures S5a-b). Although $\text{PM}_{2.5}$ concentrations during the Haze-II event were close to
283 those of the heavy Haze-I event, we found large differences between aerosol
284 chemistry in these two heavy haze episodes besides the prevailing wind direction
285 (Figures 2a-c). From the heavy Haze-I to the Haze-II events, secondary inorganic ions
286 significantly decreased from 62-66% of the total $\text{PM}_{2.5}$ mass (94-101 $\mu\text{g}/\text{m}^3$) to 31-35%
287 (65-70 $\mu\text{g}/\text{m}^3$); but OM markedly increased from 27-30% (42-45 $\mu\text{g}/\text{m}^3$) to 53-60%
288 (98-133 $\mu\text{g}/\text{m}^3$) (Figures 2a-c). In addition, K^+ average concentrations unexpectedly
289 increased from 1.4 $\mu\text{g}/\text{m}^3$ during the heavy Haze-I event to 3.8 $\mu\text{g}/\text{m}^3$ during the
290 Haze-II event (Figures 2b-c). As a result, the difference between $\text{PM}_{2.5}$ composition
291 before and after 4 November again proved that there were two different haze episodes
292 under the different prevailing wind directions. These two regional haze episodes
293 might have different formation mechanisms (details in Section 4.1).

294

295 3.2 Characteristics of individual haze particles

296 TEM/EDS did an excellent job of determining the morphology and composition
297 of individual particles as shown in Figures 3a-j. NanoSIMS was used to further
298 identify OM particles through ions ($^{12}\text{C}^{14}\text{N}^-$, $^{12}\text{C}^-$, $^{16}\text{O}^-$, and $^{32}\text{S}^-$) signal mappings in
299 order to exclude the interfere of C substrate on TEM grids to EDS (Figure 3k). Figure
300 3k shows high $^{12}\text{C}^{14}\text{N}^-$ and $^{12}\text{C}^-$ signals but low $^{32}\text{S}^-$ signal, which strongly confirms
301 the OM particle. As a result, six basic types of aerosol components were classified
302 based on their morphology, composition, and ion signal mapping: mineral, OM, soot
303 (also known as EC and BC), fly ash/metal, S-rich, and K-rich (Figures 3a-k).

304 Mineral particles mainly contain O, Si, Al, and Fe elements and present irregular
305 shape (Figures 3a-1 and 3a-2). Mineral particles mainly occurred in the coarse size
306 range ($> 1 \mu\text{m}$) (Figures S6a-b), and they were often externally mixed with other
307 types of particles (i.e., OM, soot, fly ash/metal, S-rich, and K-rich particles) (Figure
308 3a-1). OM particles are mainly composed of C, O, and Si (Figures 3b-2, 3c-2, and
309 3i-2). OM particles were further classified into spherical OM (Figure 3b-1), domelike
310 OM (Figure 3c-1), and OM coating (Figures 3i-1 and 3j) based on their morphology.
311 TEM observations showed that most OM particles were internally mixed with S-rich
312 (Figure 3f-1), soot (Figure 3g), and K-rich (Figures 3i-1 and 3j) particles. Soot
313 particles mainly include C and O elements and are aggregates of carbonaceous
314 spheres (Figures 3d-1 and 3d-2). Figures S6a-b show that soot particles mainly
315 occurred in the fine size range ($< 200 \text{ nm}$). TEM observations showed that a majority
316 of soot particles were internally mixed with S-rich or OM particles, which were
317 classified as soot-S/OM particles (Figure 3g). Fly ash/metal particles with spherical
318 morphology are mainly comprised of O, Si, and metallic elements (e.g., Al, Fe, Mn,
319 and Pb) (Figures 3e-1 and 3e-2). Fly ash/metal particles were mainly in the ultrafine
320 size range ($< 100 \text{ nm}$) (Figures S6a-b) and internally mixed with S-rich or OM
321 particles, which were called fly ash/metal-S/OM particles (Figure 3h). S-rich particles
322 are mainly composed of O, S, and N (Figure 3f-2) and formed from the oxidation of
323 SO_2 , NO_x , and NH_3 . S-rich particles normally represent the mixtures of $(\text{NH}_4)_2\text{SO}_4$

324 and NH_4NO_3 (Li et al., 2016). TEM observations showed that abundant S-rich
325 particles were internally mixed with OM particles, called S-OM particles (Figure
326 3f-1). K-rich particles mainly contain K, O, S, and N elements (Figure 3i-3). All
327 K-rich particles were internally mixed with OM particles, and were called K-OM
328 particles (Figures 3i-1 and 3j). To compare number fractions of OM particles during
329 the haze evolution, here we considered the particles including OM as OM-containing
330 particles. In the same way, soot-containing and fly ash/metal-containing particles were
331 also defined.

332 Figure 4 shows the variation of number fractions of different particles types at
333 the urban and mountain sites from the clean day to the Haze-I event and to the Haze-II
334 event. At the urban site, these data show that mineral and S-OM were the major
335 particle types, which accounted for 36% and 23% during the clean day. Subsequently,
336 S-OM, OM, and soot-containing particles became major particle types which
337 accounted for 29%, 18%, and 23% at the urban site during the moderate Haze-I event.
338 During the heavy Haze-I event, S-OM particles dominated at 60% at the urban site
339 (Figure 4). Interestingly, we found that S-OM particles remained at very high
340 frequencies (61-74%) at the mountain site from the clean day to the Haze-I event
341 (Figure 4). Furthermore, the pink frames in Figure 4 show that OM-containing (i.e.,
342 S-OM, OM, soot-OM, fly ash/metal-OM, and K-OM) particles accounted for 75-86%
343 at the urban site and 95-96% at the mountain site during the Haze-I event. During the
344 Haze-II event, number fractions of OM-containing particles reached their maximum
345 at 96% at the urban site and 97% at the mountain site (Figure 4). It is noted that
346 K-OM became the predominant particles in the Haze-II event, accounting for 50% at
347 the urban site and 52% at the mountain site (Figure 4). Therefore, individual particle
348 analysis clearly shows large differences of particle types and fractions following the
349 haze evolution, which is consistent with the variation of $\text{PM}_{2.5}$ composition described
350 in Section 3.1.

351

352 3.3 Pollutants change following haze evolution and transformation

353 The analysis of X/EC (e.g., $PM_{2.5}/EC$, OC/EC , SO_4^{2-}/EC , NO_3^-/EC , and K^+/EC)
354 factors not only can exclude the influence of changes in atmospheric boundary layer
355 height on pollutants mass concentrations, but also indicate accumulation (e.g., small
356 changes in X/EC) and secondary formation (e.g., increases of SO_4^{2-}/EC and NO_3^-/EC)
357 of $PM_{2.5}$ during haze evolution (Zhang et al., 2017; Zheng et al., 2015b). Although
358 $PM_{2.5}$ concentrations increased from $69 \mu\text{g}/\text{m}^3$ to $108 \mu\text{g}/\text{m}^3$ at the urban site and from
359 $25 \mu\text{g}/\text{m}^3$ to $76 \mu\text{g}/\text{m}^3$ at the mountain site from the clean day to the moderate Haze-I
360 event, X/EC factors only displayed minor variations (Figures 5a-b). This result shows
361 that accumulation of air pollutants mainly induced the moderate Haze-I formation.
362 Following formation of the heavy Haze-I event with $PM_{2.5}$ concentrations at 154
363 $\mu\text{g}/\text{m}^3$ at the urban site and $151 \mu\text{g}/\text{m}^3$ at the mountain site, SO_4^{2-}/EC , NO_3^-/EC , and
364 $PM_{2.5}/EC$ factors dramatically increased (Figures 5a-b). Figures 5a-b show that
365 SO_4^{2-}/EC and NO_3^-/EC factors reached their maximum values at the two sampling
366 sites during the heavy Haze-I event, suggesting that massive secondary sulfates and
367 nitrates formed during Haze-I evolution. In contrast, SO_4^{2-}/EC and NO_3^-/EC factors
368 began to decrease, but OC/EC , K^+/EC , and $PM_{2.5}/EC$ factors significantly increased
369 during the Haze-II event, although $PM_{2.5}$ concentrations became even further elevated
370 to $223 \mu\text{g}/\text{m}^3$ at the urban site and $185 \mu\text{g}/\text{m}^3$ at the mountain site (Figures 5a-b). This
371 result indicates that large amounts of aerosol including OM and K^+ contributed to the
372 conversion from the Haze-I to the Haze-II events.

373 Individual particle analysis shows consistent results with the variation of X/EC
374 factors described above: the fractions of OM, S-OM, and soot-containing particles
375 only had minor changes at 6-9% (i.e., 9% to 18%, 23% to 29%, and 14% to 23%) at
376 the urban site and at 2-3% (i.e., 9% to 11%, 61% to 64%, and 21% to 18%) at the
377 mountain site from the clean day to the moderate Haze-I event (Figure 4). However,
378 along with the moderate Haze-I evolving into the heavy Haze-I event, S-OM fractions
379 suddenly increased from 29% to 60% at the urban site and from 64% to 74% at the

380 mountain site (Figure 4). When the heavy Haze-I turned into the Haze-II events,
381 S-OM fractions significantly decreased from 60-74% to 30-32% at two sampling sites
382 but K-OM fractions largely increased from 4-5% to 50-52% (Figure 4). As a result,
383 the chemical data of PM_{2.5} samples and individual particle analysis both well reflect
384 the haze evolution and transformation.

385

386 **4. Discussion**

387 **4.1 Sources and formation of two distinctive haze events**

388 Our analyses show that the fractions of OM in PM_{2.5} by mass (35-41%, Figures
389 2a-c) and OM-containing in individual particles by number (> 70%, Figure 4) both
390 were elevated during the Haze-I event at the urban and mountain sites. TEM
391 observations showed two major types of OM particles: spherical OM and domelike
392 OM during the Haze-I event (Figures 6c-d). These OM particles have been considered
393 as primary OM aerosol, which can indicate the direct emissions from residential coal
394 burning (Zhang et al., 2018a) or biomass burning (Liu et al., 2017a). In addition, we
395 noticed that K-OM particles as a tracer of biomass burning (Adachi and Buseck, 2008;
396 Bi et al., 2011; Liu et al., 2017a) were quite low at ~3% by number fraction during the
397 Haze-I event (Figure 4) and had poor correlations with PM_{2.5} concentrations (Figure
398 7a). Therefore, we can exclude biomass burning and conclude that coal burning was
399 the major contribution to emissions during the Haze-I event. During the wintertime
400 with the lowest temperature at about -30 °C in Northeast China, high-intensity coal
401 burning activities for household heating are necessary (Xu et al., 2017; Zhang et al.,
402 2017). Central heating through large boilers equipped with efficient filters are in wide
403 use in the urban areas in Northeast China, but residential stoves without emission
404 controls are still used for household heating and cooking in the rural and suburban
405 areas (Zhang et al., 2017). Through the meteorological data (Figures S3a-b) and air
406 mass backward trajectory (Figure 7c) analyses, we inferred that the air at the two
407 sampling sites during the Haze-I event was mostly influenced by Shenyang city and its

408 nearby surrounding emissions. As a result, we determined that large amounts of fine
409 primary OM aerosol during the Haze-I event were mainly from regional emissions of
410 coal burning in residential stoves for heating and cooking as shown in Figure 8.

411 The significant increases of $\text{SO}_4^{2-}/\text{EC}$, NO_3^-/EC , and $\text{PM}_{2.5}/\text{EC}$ factors from the
412 moderate to heavy Haze-I event (Figures 5a-b) suggest that massive secondary
413 production of sulfates and nitrates elevated $\text{PM}_{2.5}$ concentrations. Similar results that
414 secondary aerosol formation causes heavy winter hazes in the NCP have been well
415 documented (Liu et al., 2017c; Sun et al., 2014; Xue et al., 2016; Zheng et al., 2015a).
416 Although photochemical activity is weak because of thick haze layers weakening solar
417 radiation (Zhao et al., 2013; Zheng et al., 2015b), heterogeneous chemical reactions on
418 particle surfaces have been considered as major pathways in the formation of sulfates
419 and nitrates from SO_2 and NO_x whenever RH exceeds 70% (Sun et al., 2018; Wang et
420 al., 2016; Wu et al., 2018). Here, TEM observations did show that large numbers of
421 primary OM particles were coated by S-rich aerosols at 73-80% of RH during the
422 heavy Haze-I event (Figures 6c-d). Obviously, the preexisting particles in the hazes
423 provided large heterogeneous surfaces for the formation of sulfates and nitrates (He et
424 al., 2014; Li et al., 2011; Zhang et al., 2017). When the moderate Haze-I turned into
425 the heavy Haze-I event, we indeed found that secondary inorganic ions (i.e., SO_4^{2-} ,
426 NO_3^- , and NH_4^+) became the predominant species in $\text{PM}_{2.5}$, accounting for 62-66%
427 (Figures 2a-c). Therefore, we conclude that atmospheric heterogeneous reactions
428 under high RH ($> 70\%$) are a critical factor in heavy haze formation in Northeast
429 China.

430 In contrast to the Haze-I event, we found that concentrations of K^+ and OM in
431 $\text{PM}_{2.5}$ both were elevated about twice as much during the Haze-II event (Figures 2b-c).
432 In addition, TEM observations showed that the fraction of K-OM particles
433 explosively increased by 45-48% during the Haze-II event (Figure 4). High levels of
434 K^+ or K-OM particles represent the influences of biomass burning (Bi et al., 2011; Liu
435 et al., 2017a). Indeed, MODIS data during the Haze-II event show that many fire

436 spots occurred in the north part of Northeast China, far away ~580 km from sampling
437 sites, and the air mass backward trajectories at the urban and mountain sites both
438 crossed these fire spots (Figure 7d). MODIS maps further show that these fire spots
439 were in the farming lands instead of the forest areas (Figure 7d). Based on the MODIS
440 data and reports from the local department of ecology and environment
441 (<http://www.hljdep.gov.cn/hjgl/zfjc/jphz/2017/05/15698.html>), these dense fire spots
442 on 4 November were agricultural biomass burning. Open agricultural biomass burning
443 is normally intense during the early winter in Northeast China, a region with abundant
444 agricultural production, because large amounts of agricultural waste need to be
445 cleaned up and their burnt products can be used as fertilizers to increase soil fertility
446 (Cao et al., 2017; Yang et al., 2017). Along with the backward trajectories of air
447 masses, we found sharp $PM_{2.5}$ concentrations occurring from Harbin city ($1281 \mu\text{g}/\text{m}^3$
448 at 18:00 on 4 November) to Changchun city ($658 \mu\text{g}/\text{m}^3$ at 0:00 on 5 November) and
449 to Shenyang city ($669 \mu\text{g}/\text{m}^3$ at 8:00 on 5 November) (Figure S5a). These above
450 analyses well indicated that long-range transport of agricultural biomass burning
451 emissions directly led to the Haze-II formation (Figure 8) and explained why K^+/EC ,
452 OC/EC , and $PM_{2.5}/\text{EC}$ factors together reached their maximum values during the
453 Haze-II event (Figures 5a-b) and $K\text{-OM}$ fractions and $PM_{2.5}$ mass concentrations had
454 strong positive correlation (Figure 7b). Overall, although the Haze-II and Haze-I
455 events both displayed heavy pollution levels, they had contrasting emission sources
456 and formation mechanisms as illustrated in Figure 8.

457

458 **4.2 Comparison: haze in Northeast China vs. NCP**

459 OC/EC ratios in $PM_{2.5}$ of 8.0-10.6 during the Haze-I event and 25.4-27.9 during
460 the Haze-II event were reported in Northeast China in this study (Table S1). The
461 results are much higher than OC/EC ratios in $PM_{2.5}$ during winter haze episodes in the
462 NCP, such as 4.5 in Beijing city (Zhao et al., 2013), 5.5 in Jinan city (Chen et al.,
463 2017b), and 5.3 in Tianjin city (Han et al., 2014). In addition, TEM observations

464 showed that OM-containing particles were dominant by number fraction (e.g., 75-96%
465 during the Haze-I event and 96-97% during the Haze-II event) in Northeast China
466 (Figure 4). The results are higher than 50-70% during regional haze episodes in the
467 NCP which were influenced by residential coal burning (Chen et al., 2017b; Li et al.,
468 2012). These comparisons suggest that the contribution of residential coal burning and
469 biomass burning to winter haze formation in Northeast China is significantly larger
470 than that in the NCP. Moreover, fly ash/metal-containing particles as the tracers of
471 industry emissions frequently occurred in regional hazes in the NCP, such as ~30% by
472 number fraction in Jinan city (Li et al., 2011), 23-29% in Beijing city (Ma et al., 2016),
473 and 13-17% in Xianghe (Zou et al., 2019). These data are much higher than 8%
474 (Haze-I) and 1% (Haze-II) reported in this study (Figure 4), suggesting that the
475 contribution of industrial emissions to regional haze in Northeast China is much
476 smaller than that in the NCP. Many studies have summarized formation mechanisms
477 of general regional haze in North China: regional transport of air pollutants (Zheng et
478 al., 2015b), massive formation of secondary aerosols (Shao et al., 2019), and two-way
479 feedback between adverse meteorological conditions and pollutant accumulation
480 (Zhong et al., 2019). We found that the Haze-I formation in this study can be attributed
481 to these three formation mechanisms (Figure 8). Moreover, the Haze-II formation
482 indicates that the primary emissions from intensive agricultural biomass burning
483 activities can rapidly induce regional heavy haze formation in Northeast China
484 (Figure 8).

485

486 **5. Atmospheric implications**

487 High concentrations of PM_{2.5} in haze adversely affect human health by inducing
488 various respiratory diseases (Cohen et al., 2017; Liu et al., 2016). In China, long-term
489 exposure to high levels of ambient PM_{2.5} has resulted in 1.1-1.35 million premature
490 deaths (Cohen et al., 2017; Lelieveld et al., 2015). The large-scale coal burning for
491 household heating and cooking in Northeast China emits vast numbers of

492 OM-containing particles (discussed in Section 4.1), which include abundant
493 polycyclic aromatic hydrocarbons (PAHs) (Chen et al., 2017b; Chen et al., 2013;
494 Zhang et al., 2008). Based on Ebenstein et al. (2017), people's life expectancy
495 decreases by 0.64 years for every 10 $\mu\text{g}/\text{m}^3$ contributed by residential coal burning
496 emissions. Furthermore, we found that 1-8% of haze particles contained toxic metals
497 (e.g., Pb, Zn, Cr, and Mn) from fly ash/metal particles with sizes smaller than 100 nm
498 in Northeast China (Figures 4 and S6a-b). Oberdorster et al. (2004) indicated that
499 such ultrafine metal particles can exert adverse health impacts via deposition in
500 human lungs and further penetration into the blood. Therefore, these OM-containing
501 and fly ash/metal-containing particles observed by TEM (Figures 6a-f) are harmful to
502 human health in Northeast China in winter.

503 The light-absorbing particles (i.e., BC and BrC) have been proved to reduce solar
504 radiation reaching the ground and further influence regional climate and crop
505 production (Alexander et al., 2008; Bond et al., 2013; Tie et al., 2016; Wang et al.,
506 2018). This study shows that concentrations of BC (i.e., EC or soot) were low at
507 2.7-4.3 $\mu\text{g}/\text{m}^3$ during the haze days and only accounted for 1.4-3.9% of $\text{PM}_{2.5}$ in
508 Northeast China (Figures 2a-c). These results are lower than them in other regions of
509 China such as the NCP: 7.6 $\mu\text{g}/\text{m}^3$ and 5.2% in Beijing city (Wu et al., 2016), Yangtze
510 River Delta: 11.8 $\mu\text{g}/\text{m}^3$ and 4.4% in Shanghai city (Zhi et al., 2014), and Pearl River
511 Delta: 9.6 $\mu\text{g}/\text{m}^3$ and 7.7% in Guangzhou city (Tao et al., 2012). These comparisons
512 indicate that BC concentrations are at low levels in Northeast China during winter
513 haze periods, although $\text{PM}_{2.5}$ concentrations are extremely high. Furthermore, TEM
514 observations showed that 75-97% of haze particles were OM-containing particles
515 such as spherical OM and domelike OM, but only 4-23% were soot-containing
516 particles in Northeast China (Figure 4). Previous studies have demonstrated that these
517 spherical and domelike OM particles from coal and biomass burning with low
518 combustion efficiency are tarballs (Chakrabarty et al., 2010; Hand et al., 2005; Pósfai
519 et al., 2004; Zhang et al., 2018a) or precursors of tarballs (Adachi et al., 2019;

520 Sedlacek III et al., 2018; Tóth et al., 2014), respectively. Tarballs as the primary BrC
521 have a wide absorption spectrum from visible to ultraviolet wavelengths (Hoffer et al.,
522 2016). The comparison in Section 4.2 indicates that the highest emission of tarballs in
523 China during winter occurs in Northeast China because of the intense and inefficient
524 residential coal burning and agricultural biomass burning. Therefore, how large
525 numbers of tarballs in regional winter haze influence atmospheric optical radiation
526 and climate in Northeast China should be studied in much greater detail.

527 Implementing suitable policies to encourage cleaner energy use (e.g., natural gas
528 and electricity) instead of coal and biomass for household heating are necessary in
529 Northeast China. Such policies would not only reduce regional haze formation but
530 also reduce the toxic aerosol components in the air. Admittedly, this transition of
531 heating energy would be facing a monumental challenge in Northeast China due to its
532 low economic growth and its low urbanization development rates (Zhao et al., 2018a).
533 Moreover, how to control open agricultural biomass burning should be considered in
534 Northeast China. Over the past decades, agricultural biomass returned to soils and
535 recycling agricultural biomass have both failed in Northeast China. This failure arises
536 because agricultural biomass does not decay throughout the winter with its low
537 temperatures down to $-30\text{ }^{\circ}\text{C}$ and snow or ice covers and its recycling consumes a lot
538 of manpower, material resources, and money (Yan et al., 2006). Therefore, how to
539 deal with agricultural biomass waste in Northeast China should be carefully thought
540 out by the local farmers in concert with the government.

541

542 **6. Conclusions**

543 To understand the formation mechanisms of winter haze in Northeast China, we
544 carried out an aerosol experiment at an urban site and a mountain site in the south part
545 of Northeast China from 31 October to 6 November 2016. Two different regional
546 heavy haze events (Haze-I and Haze-II) were identified during the sampling period.
547 Chemical composition (water-soluble ions, OM, and EC) of $\text{PM}_{2.5}$ were obtained using

548 ion chromatography and OC/EC analysis. Types and mixing states of individual
549 particles were identified using TEM/EDS and NanoSIMS: mineral, fly
550 ash/metal-containing, soot-containing, OM, S-OM, K-OM, and OM-containing.

551 Haze-I event has an evolution process from moderate to heavy pollution. OM was
552 the dominant component in $PM_{2.5}$ and their concentrations were $45 \mu\text{g}/\text{m}^3$ at the urban
553 site and $39 \mu\text{g}/\text{m}^3$ at the mountain site during the moderate Haze-I event. Individual
554 particle analysis also showed that over 70% of particles contained OM during the
555 moderate Haze-I event. Following the Haze-I evolution, secondary inorganic ions (i.e.,
556 SO_4^{2-} , NO_3^- , and NH_4^+) became the dominant components ($94\text{-}101 \mu\text{g}/\text{m}^3$) during the
557 heavy Haze-I event with $PM_{2.5}$ concentrations of $151\text{-}154 \mu\text{g}/\text{m}^3$. Similarly, the number
558 fractions of S-OM increased from 29% to 60% at the urban site and from 64% to 74%
559 at the mountain site from the moderate Haze-I to the heavy Haze-I event. Along with
560 the prevailing wind suddenly changing from southerly with $\sim 0.8 \text{ m/s}$ to northerly with
561 $\sim 3.9 \text{ m/s}$, the heavy Haze-I rapidly turned into the Haze-II events with $PM_{2.5}$
562 concentrations of $185\text{-}223 \mu\text{g}/\text{m}^3$. Meanwhile, OM replaced secondary inorganic ions
563 as the dominant component in $PM_{2.5}$ during the Haze-II event, accounting for 53-60%.
564 Furthermore, K^+ concentration during the Haze-II event was about three times higher
565 than that during the heavy Haze-I event. Individual particle analysis showed
566 consistent results that the number fractions of K-OM significantly increased from 4-5%
567 to 50-52%.

568 Based on our study, the accumulation of primary OM particles, mainly emitted
569 from residential coal burning, induced the moderate Haze-I formation with the onset of
570 stable meteorological conditions. Production of secondary aerosols via heterogeneous
571 reactions at high RH ($> 70\%$), in particular sulfates and nitrates, caused the transition
572 from the moderate Haze-I to the heavy Haze-I. Furthermore, the long-range transport
573 of primary emissions from intense agricultural biomass burning led to the Haze-II
574 formation in the downwind areas in Northeast China. Our study also reveals that the
575 significant light-absorbing particles in Northeast China during winter are tarballs,

576 which is different from other regions in China influenced by serious air pollution.

577 **Author contributions**

578 JZ and WL conceived the study and wrote the manuscript. The field campaign was
579 organized and supervised by JZ and WL, and assisted by LL, LX, and HZ. JZ, LL, LX,
580 and QL contributed the sample analyses. All authors reviewed and commented on the
581 paper.

582

583 **Acknowledgements**

584 We appreciate Peter Hyde's comments and proofreading. We thank Jiaying Sun
585 and Yong Ren for their assistance of sample collections. This work was funded by the

951 **Figure 1. (a)** Topographic features of Northeast China, which is surrounded by the
952 Greater Khingan Mountains, the Lesser Khingan Mountains, and the Changbai
953 Mountains. **(b)** Locations of the urban and mountain sites. The relief map in panel (a) is
954 from OpenStreetMap contributors 2019 distributed under a Creative Commons BY-SA
955 License (<https://maps-for-free.com/>).

956 **Figure 2.** Variation in the concentrations of PM_{2.5}, organic matter (OM), elemental
957 carbon (EC), and water-soluble ions (i.e., Ca²⁺, Mg²⁺, K⁺, Na⁺, NH₄⁺, NO₃⁻, SO₄²⁻, Cl⁻,
958 and F⁻) at the urban and mountain sites from daytime (DT) on 31 October to nighttime
959 (NT) on 5 November 2016: **(a)** PM_{2.5}; **(b-c)** OM, EC, and water-soluble ions. Two
960 regional haze episodes (Haze-I: 31 NT October-4 DT November; Haze-II: 4 NT-5 NT
961 November) were identified.

962 **Figure 3.** Typical transmission electron microscopy (TEM) images and
963 energy-dispersive X-ray spectrometry (EDS) spectra of different types of individual
964 aerosol particles: **(a)** mineral particle; **(b)** spherical OM particle; **(c)** domelike OM
965 particle; **(d)** soot particle; **(e)** Fe-rich particle; **(f)** mixture of S-rich and OM particles; **(g)**
966 mixture of soot, S-rich, and OM particles; **(h)** mixture of Fe-rich and S-rich particles;
967 **(i-j)** mixture of K-rich and OM particles at the urban and mountain sites. The EDS
968 spectra of these particle components are located below their TEM images. **(k)** a
969 typically spherical OM particle and its NanoSIMS ion intensity mappings of ¹²C¹⁴N⁻,
970 ¹²C⁻, ¹⁶O⁻, and ³²S⁻ signals.

971 **Figure 4.** Variation in number fractions of different types of particles at the urban and
972 mountain sites. Analyzed particle numbers are listed on the top of each rectangle.

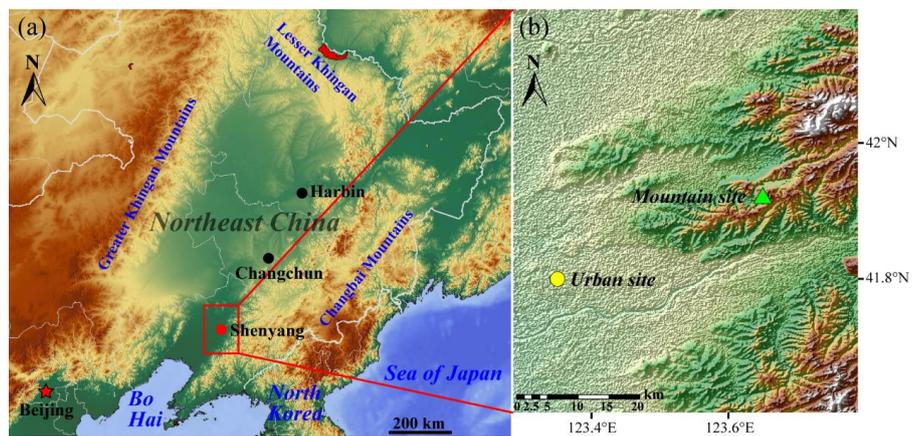

973 **Figure 5.** Variation in PM_{2.5}/EC, OC/EC, SO₄²⁻/EC, NO₃⁻/EC, and K⁺/EC factors at the
974 urban site **(a)** and mountain site **(b)**. These factors are normalized.

975 **Figure 6.** Typical TEM images of individual aerosol particles at low magnification at
976 the urban and mountain sites: **(a-b)** clean day; **(c-d)** Haze-I; **(e-f)** Haze-II.

977 **Figure 7.** Linear correlations between PM_{2.5} mass concentration (x) and K-OM

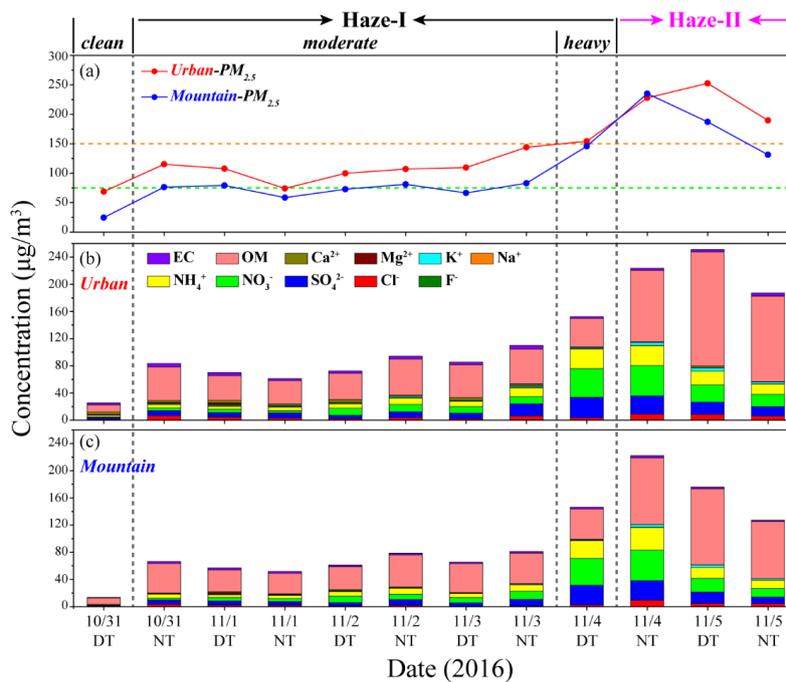

978 number fraction (y) during the Haze-I **(a)** and Haze-II **(b)**. Typical 24-h air mass
979 backward trajectories before arriving at the urban and mountain sites during the Haze-I
980 **(c)** and Haze-II **(d)**. Fire spot data are from the MODIS Collection 6 Active Fire
981 Product provided by the NASA FIRMS (<https://firms.modaps.eosdis.nasa.gov/map/>).
982 **Figure 8.** Schematic diagram of Haze-I and Haze-II formation in Northeast China
983 during winter. The major emission sources and haze formation processes are shown.
