Author Response to Both Referee Comments:

Response: We thank the two reviewers for thoughtful suggestions and constructive criticism that have helped us improve our manuscript. Below we provide responses to reviewer concerns and suggestions in blue font.

Reviewer 1:

General comments: This paper presents a new dataset of stratocumulus cloud clearings off the California coast derived from satellite observations, and examines this dataset with a variety of perspectives, including composites of satellite and reanalysis data, aircraft case studies, and a machine learning-based examination of clearing growth rates. The multitude of approaches is thorough and effective at providing a very in-depth characterization of clearing events. The paper is well-written, the text well-supported by the provided figures, and related work is sufficiently cited and referenced.

With regards to interpretation, there are a few areas where I feel the authors can improve and clarify the message of this paper. The most general is in the interpretation of how the large-scale conditions relate to cloud clearings (mainly sections 3.2, 3.3). For a clearing event to take place and be manually identified as described in section 2.1, two conditions must be met: there must be a cloud deck present, and then there must be a coastal clearing that occurs. In other words, the environment must be initially great for a cloudy MBL, and also eventually (at least coastally) poor for a cloudy MBL. The authors spend much of their interpretation arguing (and convincingly so) why certain factors (e.g. offshore winds) would be detrimental to clouds and result in a clearing, but not much on the first condition. For example, when it comes to interpreting the link between clearing days and enhanced stability (Fig 9b), I would expect that it is not so much that the stability is causing a clearing, but rather the link between strong LTS and cloudiness that allows there to be a cloud deck to erode in the first place. Whether a particular environmental factor is predictive of there being a cloud deck, or predictive of it being eroded, is something that can help understand some of the less explained results in the paper, in particular when comparing clearing vs non-clearing days. An obvious one would be the overall higher cloud fraction on clearing days. Presumably, a day with no stratocumulus deck in which to identify a clearing would be classified as "non-clearing day" (if this is incorrect and non-cloudy days are discarded, this should be clarified in section 2.1), and therefore days in which the large-scale conditions in the NEP were unfavourable for clouds would be mixed together with cases which were very favourable to clouds and no clearing occurred in the 'non-clearing day' category. While it would be sufficient to see this discussed in the interpretation with no additional figures, for their own interest the authors might consider splitting their 'non-clearing days' (of which there are approximately twice as many as clearing days anyways) into two sets, based on some criteria of overall cloudiness, and a three-way comparison between 'overall clear days', 'cloudy days-with clearing' and 'cloudy days-no clearing' might prove more interpretable.

Response:

According to the reviewer's comment, we decided to split non-clearing events into two sub-categories of clear and non-clear based on an overall cloud fraction threshold 0.5. Based on this criterion, 529 cases out of total 614 non-clearing days were further classified as cloudy non-clearing cases. As a result, the influence of events with unfavorable large scale conditions for low-level cloud formation are minimized. Then, we constructed the climatology comparisons of important large scale parameters between clearing and non-clearing (cloudy) conditions similar to Fig.7 in the manuscript. The results are shown in the following figure:

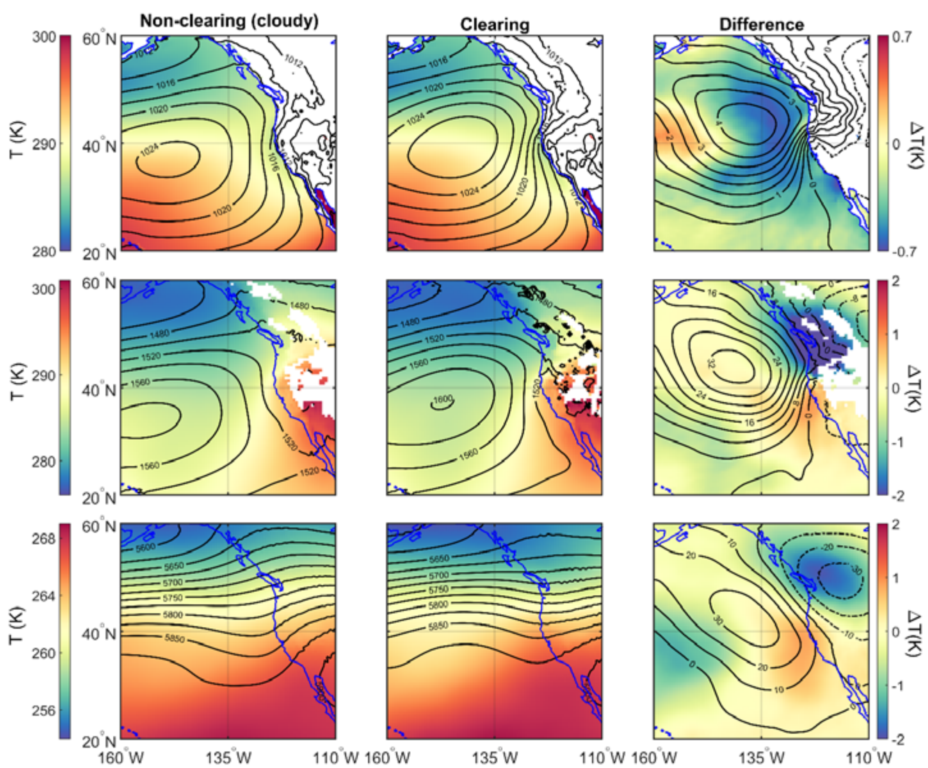

Figure: Climatology of non-clearing (cloudy with CF > 0.5 for study region between 135-115° W and 30-50° N) and clearing days as well as their differences (clearing minus non-clearing) during the summers (JJA) between 2009 and 2018 for a) mean sea level pressure (contours in hPa) and air temperature (color map) at sea surface, b) 850 hPa geopotential heights (contours in m) and air temperature (color map), and c) 500 hPa geopotential heights (contours in m) and air temperature (color map). The data were obtained from MERRA-2 reanalysis. Differences (clearing minus non-clearing) are shown in the farthest right column with separate color scales. White areas indicate no data were available.

As it turns out, the general features were preserved after subcategorizing non-clearing events based on cloud fraction. This result convinced us that the general mechanisms including the displacement/enhancement of the Pacific high associated with clearing events stem from the nature of clearings and not from our analysis method. We have decided to not include this analysis in the manuscript as it might distract the discussion presented in the body of the paper. However, we revised the discussion of Section 3.2 to address reviewer's comment regarding clarifying if certain parameters (like greater *LTS*) are responsible for clearing formation. We refer the reviewer to edits in Section 3.2 for the concern raised in this comment.

This same point is also relevant for the growth rate discussion. The authors show that the initial growth rate is strongest. A high growth rate would obviously correlate with a larger final clearing area, and this perspective is taken throughout the discussion of growth rate influences, but also a high growth rate may be associated with initially smaller clearings (this is supposition, though the authors could easily investigate in their dataset by examining whether the fastest growing clearings tended to have smaller-than-average initial sizes). Figures 4a supports this however; the presence of a longer lower tail on 9 a.m. size and absence of a longer upper tail on 12 p.m. size (though the log scale might be overemphasizing this) indicates that small initial clearings and not large final clearings are more likely to be the result of a high growth rate. In this case, it would be equally valid to explain why certain predictors of growth rate might be associated with enhanced nighttime cloudiness (again, such as the 1 parameter, T850 or possibly LTS), and therefore a well (re-)formed initial deck that is then subsequently susceptible to breakup. Again, this point can largely be addressed in the discussion of results or by author rebuttal and does not require additional figures.

Response:

We addressed this comment by computing the average initial size of clearings (at the time relevant to image 1) which had growing rates (between image 1 and 2) faster than the 95th percentile of all growth rates. This analysis reveals that in fact the average initial size of the aforementioned subset of clearings is 239,100 km^2, while the average size of all clearings is 118,150 km^2. This suggests that the reviewer's speculation is not the case as the fastest growing clearings did not tend to have smaller than average initial sizes. Thus, we have decided to not change any part of manuscript based on this comment.

Specific comments:
Section 2.1, line 119: Can you describe in slightly more detail what was necessary for the visual identification of a clearing event? Approximately how large, how distinct, how much cloud had to be adjacent to the clearing? Were days when the Sc deck was completely detached from the coast or absent considered?

Response:

We added the following description in Section 2.1 in response to this comment:

(i) "Each day's sequence of GOES images were visually inspected to identify if a clearing event was present. This involved utilizing the following general guidelines: (i) There had to be sufficient cloud surrounding the clearing area that the clearing's borders could be approximately identified, which excluded cases with highly broken cloud deck; (ii)

Clearings that were not connected to land between 30°-50° N in any of daily images were excluded; (iii) Days with the cloud deck completely detached from the coast between 30°-50° N were not considered; and (iv) Only clearings with a maximum daily area of greater than 15,000 km^2 (which translates to a clearing length on the order of 100 km) were considered. Consequently, the statistics presented in Section 3.1.1 represent a lower limit of clearing occurrence in the study region. However, it is expected that the qualitative trends discussed in Section 3.1.1 are representative of clearing behavior in the study region."

Section 3.2 (Clearing vs Non-Clearing)
The difference in subsidence between clearing and non-clearing days seems stark and geographically well-matched to the clearing locations, and yet it comes out as minimally important in the PD analysis. Is the only effect of subsidence to lead to a drier lower FT and therefore all it its signal is captured in T850? The w700 discussion seemed very brief.

Response: The influence of subsidence on clearing growth is further explained in Section 3.3 as follows:

"The relationship between ω at 700 hPa and PD_{GRArea} is complex. Brueck et al. (2015) suggested that enhanced ω_{700} promotes cloudiness due to its link to higher *LTS*. Myers and Norris (2013) further showed that stronger subsidence can reduce *CF* (at fixed inversion strength) by pushing down the top of the MBL, which is also supported by Bretherton et al. (2013). The PD_{GRArea} profile of ω_{700} exhibited a minimum point near a value of 0 – 0.2 Pa s^{-1}, with increases in GR_{Area} below and above that range. The increase in PD_{GRArea} with ω values above 0.2 Pa s^{-1} can be attributed to the negative influence of subsidence on lower *CF* (via pushing down the top of the MBL) as discussed by Myers and Norris (2013). Conversely, the increase in GR_{Area} with decreasing ω values below 0 Pa s^{-1} can be due to upward motion reducing the strength of the inversion capping the MBL, which is important to sustain the cloud deck. Vertical motions represented by the ω_{700} parameter could also induce dynamical circulations affecting cloud top processes such as shear and entrainment."

The difference in AOD (low AOD on clearing days, mainly from 43N and up) may be explainable by the circulations shown in figure 8, with anomalously northerly and westerly flow bringing in relatively cleaner air from the marine midlatitudes. That being said, there is no obvious connection between the AOD and Nd maps (low AOD but high Nd on clearing days, though not collocated) that would suggest that the AOD anomalies are having any significant microphysical effect in terms of increasing available CCN, even north of the clearing region. One remedy would be backtrajectory analysis from the low AOD anomaly region, or else looking at the species of aerosol in MERRA-2 to see whether summertime wildfires (which have a large effect on AOD) are impacting the AOD results. The authors state that this may be left for future work, which I would agree with.

Response: This could be subject of future work. Too much for this current paper in our view.

Section 3.3 (Growth Rates): It's not clear to me that the condition of requiring only that $r2 < 0.5$ is a sufficient independence constraint to allow for accurate interpretation of the PD results. For true independence, the authors could have performed an EOF decomposition of all mentioned variables, including those that would clearly correlate strongly with other variables (e.g. LTS, EIS, which as the authors point out are crucial MBL cloud variables), perform the GBRT regression and PD analysis, and additionally the correlation of leading EOFs with input variables. I admit that this would add a level of interpretation, but it would more effectively deal with the tricky problem that so many of these variables are correlated. As it stands the selection of variables seems a little arbitrary, and it is not clear that the resulting ranking of the variables in Figure 11 is physically meaningful. It might be helpful to see another relative ordering of the importance of these variables in accurately determining the growth rate, such as permutation feature importance. Machine learning results are inherently difficult to interpret and the authors have done a more thorough job than many, but one way to improve robustness of interpretation is using multiple evaluation methods.

Response:

We revised the test regarding r^2 criterion to emphasize that the threshold value of 0.5 is chosen based on trial and error and it will only reduce the negative impact of correlated variables and will not completely remove undesired effects:

"While *PD* plots are not flawless in capturing the influence of each variable in the model, especially if the input variables are strongly correlated, they provide useful information for interpretation of GBRT results (Friedman and Meulman 2003; Elith et al., 2008). To decrease the undesired influence of correlated variables on *PD* profiles, an arbitrary r^2 threshold of 0.5 was used based on the linear regressions between prospective input parameters. For instance, there were three choices of air temperature (i.e., at 950, 850, and 700 hPa), but based on the r^2 criterion, only one (T_{850}) was used in the model to minimize the unwanted impact of dependent input parameters. Lower tropospheric stability (*LTS*: defined as the difference between the potential temperature of the free troposphere (700 hPa) and the surface) is the stability parameter that has been widely used as a key factor controlling the coverage of stratocumulus clouds. However, in this study, the effects of stability were examined by putting T_{850} and *SST* into the model without explicitly including *LTS*. The correlation between *LTS* and T_{850} prevented them to be used as input parameters simultaneously. Using T_{850} and *SST* instead of *LTS* is advantageous because the results can be more informative by revealing different impacts of the two individual parameters on the model's output rather than just one parameter in the form of *LTS*. In addition, the mean sea level pressure anomaly ($MSLP_{anom}$) was used as an input parameter, which was calculated in reference to the average values of *MSLP* for the summer months for the study period. In the end, the following 11 predicting variables from MERRA-2 were used as input parameters for the GBRT simulations, with data product details summarized in Table 1: *AOD*, T_{850}, q_{950}, q_{850}, q_{700}, *SST*, $MSLP_{anom}$, U_{850}, V_{850}, *PBLH*, and ω_{700}. It is important to note that the results of extensive sensitivity tests led to the selection of the set of parameters presented in this study. Also, theses sensitivity tests confirmed that the general conclusions presented here were preserved regardless of using different sets of the input parameters.

To train, test, and validate the statistical models, the dataset was split into random parts. The training set was comprised of 75% of the data points, 30% of which were randomly selected for validation. This process helped reduce variance and increase model robustness. The remaining 25% of the data points comprised the test dataset. The model setup was tuned using training data, for which different scenarios were tested that were specified by a parameter grid through a 10-

fold cross-validated search. The model was run on the dataset 30 times to achieve robust results. To qualitatively rank the input parameters based on their influence on growth rates, two scoring metrics were calculated over 30 runs: (i) differences between the maximum and minimum of *PD* (ΔPD); and (ii) the relative feature importance following the method developed by Friedman (2001), which is determined by the frequency that a variable is chosen for splitting, weighted by the gained improvement due to each split and averaged over all trees (Friedman and Meulman 2003; Elith et al., 2008)."

We have also calculated the relative feature importance in addition to the range of *PD* provide in Fig. 10. As the reviewer suggested, this may help to make a more robust conclusion regarding the relative importance of input variables in the GBRT model. We updated Fig. 10 and discussion related to that figure as follows:

"The range of *PD*s for each individual environmental parameter and the relative feature importance are used here as two proxies for the sensitivity of clearing growth rates to that specific parameter. Higher *PD* ranges translate to a higher sensitivity of GR_{Area} to that specific parameter, indicating that it is likely a major influential factor. In addition, the relative feature importance indicates how useful each parameter was in building the GBRT model. The range of *PD* of clearing growth rates and relative feature importance for all the parameters included in the GBRT model are provided in Fig. 10, moving from left to right in order of highest to lowest influence in the model. While it is expected that the results of these two methods of rankings do not match entirely (Fig. 10a and 10b), certain characteristics are similar between these two proxies: 1- using both proxies, T_{850} and ω_{700} appeared as the top and lowest ranking parameters, respectively; 2- q_{950} comes out among top the most important parameters as second and third place according to the range of *PD* and relative feature importance proxies, respectively; 3- *AOD* and q_{700} emerged among the four lowest-ranking parameters; 4- *SST* and V_{850} appear next to each other in the ranking using both scoring proxies. There are some distinct differences among the ranking of parameters as shown in Fig. 10. For instance, while $MSLP_{anom}$ appeared as a moderately influential parameter in GR_{Area} according to *PD* proxy, this parameter turned out to be the second most important variable using relative feature importance proxy. In another example, q_{850} has the second least important rank according to relative importance feature proxy, but it is moderately important based on the range of *PD* (Fig. 10a). The observed discrepancies between the results of two proxies can stem from underlying differences in the methods used to quantify the relative significance of each parameter. Moreover, the relative feature importance proxy may be less susceptible to the unwanted influence of highly correlated input predictors on the ranking outcome (Hastie et al., 2009)."

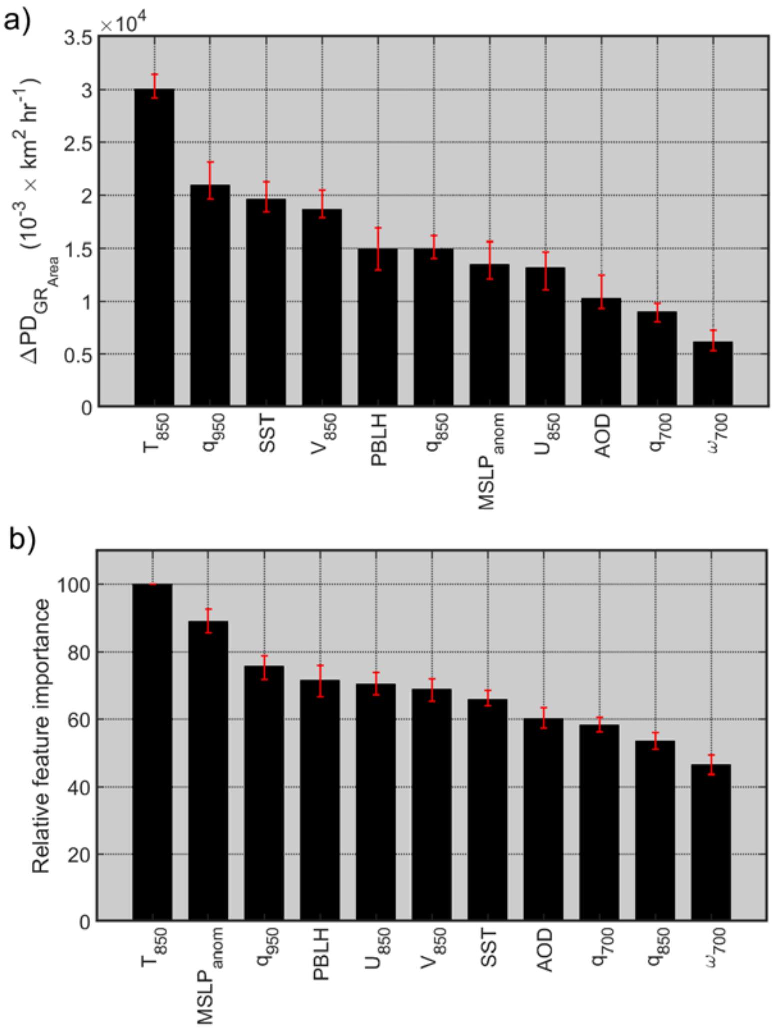

Figure 10. Two scoring methods used for measuring the relative influence of input variables in the GBRT model: a) the median difference of maximum and minimum partial dependence (*PD*) of clearing growth rate (GR_{Area}), and b) the median of relative feature importance calculated based on the method developed by Friedman (2001). Error bars represent the range of variability in 30 model runs. Note that GBRT simulations were performed using clearing growth rates obtained from the analysis of first and second GOES images (~09:00 – 12:00 PST) for all 306 clearing events examined.

One area where I think the authors may have stretched the interpretation past the limits of PD analysis is lines 546-558, for instance with the discussion of MSLP and GR. The problem with using PD and correlated variables is that you risk simulating completely nonphysical states which produce nonsensical results. The high and low tails of the PD sensitivity to MSLP could be a result of the breaking of assumed independence. This could be ameliorated with the addition of a rug plot/histogram to each Figure 12 subplot, showing some kind of likelihood or frequency of occurrence of that particular state (how often a -500 Pa MSLP anomaly occurred in the region affects the degree to which the interpretation of that portion of the PD plot is nonphysical), or the addition of some ICE (individual conditional expectation) plots, both of which are commonly used to help with the interpretation of PD plots.

Response:
To address this comment, we updated Fig. 11 with the information about the distributions of data by marking the various percentiles (5th, 25th, 50th, 75th, and 95th) of input data as blue markers.

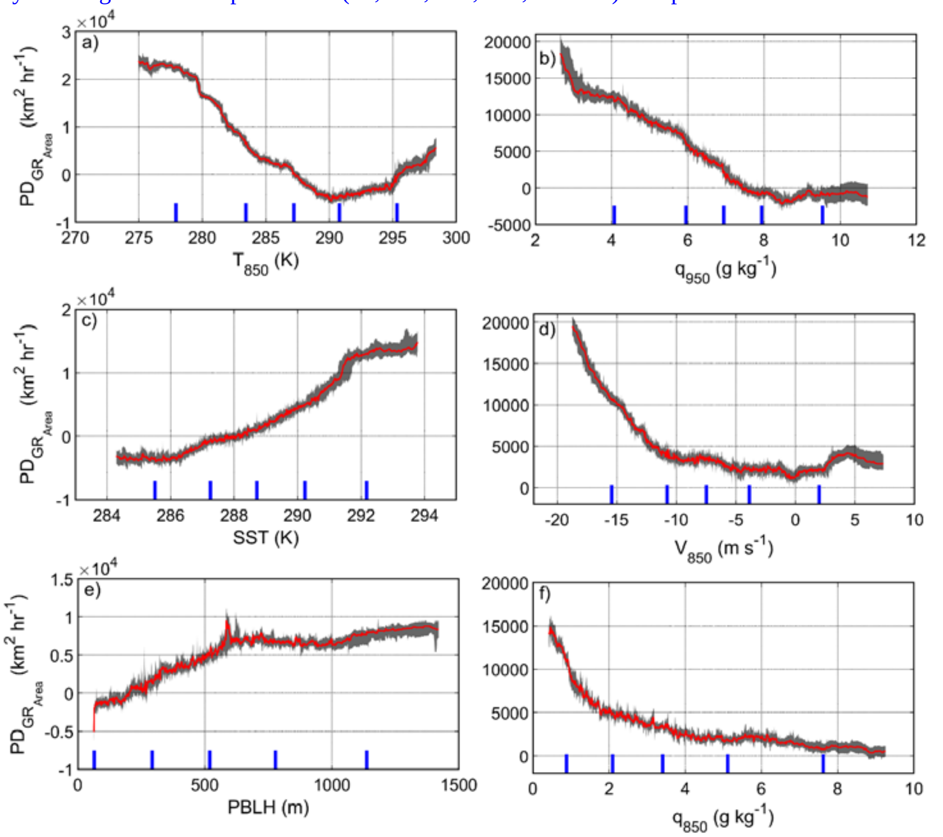

Figure 11. The median partial dependence (*PD*) of clearing growth rate (GR_{Area}) on the following parameters: a) air temperature at 850 hPa (T_{850}), b) air specific humidity at 950 hPa (q_{950}), c) sea

surface temperature (*SST*), d) meridional wind speed at 850 hPa (V_{850}), e) planetary boundary layer height (*PBLH*), f) air specific humidity at 850 hPa (q_{950}), g) mean sea level pressure anomaly ($MSLP_{anom}$), h) zonal wind speed at 850 hPa (U_{850}), i) aerosol optical depth (*AOD*), j) air specific humidity at 700 hPa (q_{700}), and k) vertical pressure velocity at 700 hPa (ω_{700}). Grey Shaded areas represent the range of variability of *PD* for 30 model runs. Blue lines represent the values of the (left to right) 5th, 25th, 50th, 75th, and 95th percentiles of the input parameter. GBRT simulations were performed using clearing growth rates obtained from the analysis of first and second GOES images (09:00 – 12:00 PST) for all 306 clearing events examined.

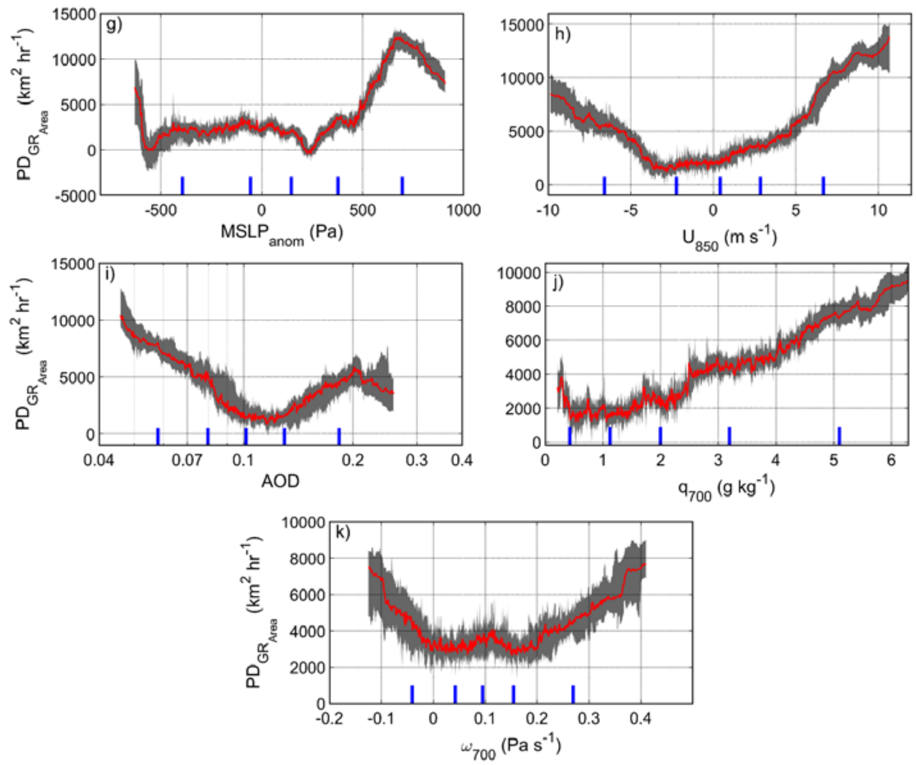

Figure 12 (continued).

Technical corrections/suggestions:
Figure 12 caption (line 1250): grey shaded areas, not red.

Response: Fixed.

Figure 13: It would be helpful to see the inversion levels from Table 3 marked on these plots.

Response: We think adding the inversion heights to Fig. 13 may confuse readers as they can easily find them in Table 3 and their values are different for cloudy and clear columns. Also, readers can spot the base of inversion according to the cloud top marked in Fig. 13.

Reviewer 2:
Review of "Stratocumulus cloud clearing: Statistics from satellites, reanalysis models, and airborne measurements" by Dadashazar et al.

Using several data sources and a machine learning technique, this paper examines the topic of marine boundary layer stratiform cloud clearings over the northeastern Pacific Ocean. The study uses a holistic approach by considering spatial scales ranging from the synpoptic-scale to the microscale. The authors' do a nice job of utilizing satellite retrievals, reanalysis grids, and airborne measurements to highlight the complexity of the problem which involves interactions between the western United States coastline and the marine environment – a region which has historically received much attention in the literature.

I think that the results stemming from this work are certainly interesting and worthy of publication. Because the authors' cover so many topics, I do have several major comments and many minor comments. The major comments concern one of thetechniques used for the MODIS processing in addition to interpretation of some of the results. Overall, I recommend that the paper be accepted for publication once the authors' address my comments.

Major/general comments:
1. I am slightly concerned about the methods used to estimate cloud droplet number concentration, Nd. Because the authors' compare plots of Nd between clearing and non-clearing days, certainly there are differences in cloud base temperature and pressure (as implied by several figures shown in this study) that would affect the adiabatic lapse rate of LWC. Therefore, using an average value of the adiabatic lapse rate of LWC, which is derived from measurements concentrated near the central California coastline (Braun et al., 2018), may not be representative of the much larger domain on which the present study focuses. I recommend that the authors' calculate the adiabatic lapse rate of LWC using the MODIS retrievals of cloud top temperature and pressure. I do not mean to sound nitpicky here, but estimation of Nd already carries relatively large uncertainty, so I think that it is only fair that you estimate it as accurately as possible. It will be interesting to see how sensitive the Nd estimate is to this lapse rate calculation.

Response:

Addressing the reviewer concern about using a constant value for adiabatic (Γ_{ad}) lapse rate of *LWC*, we recalculated N_d values for both MODIS-Aqua and Terra using Γ_{ad} that are dependent of cloud top temperature and pressures. Panel d of Figures 9 and S6 are also updated accordingly. It turns out the above modification had negligible effects on the average spatial distribution of N_d over the region of interest on both clearing and non-clearing days. As such, we have decided to not change any discussion regarding Fig. 9 in the manuscript. We have also revised a few lines in Section 2.1 to describe the methodology of estimating N_d from MODIS observations as follow:

"…where ρ_w is the density of liquid water, Γ_{ad} is the adiabatic lapse rate of liquid water content (LWC), and the parameter k is representative of droplet spectral shape as the cube of the ratio between the volume mean radius and the effective radius. Γ_{ad} is a function of temperature and pressure (Albrecht et al., 1990). In this study, cloud top temperature and pressure, provided by

MODIS, are used to estimate Γ_{ad} following the methodology described in Braun et al. (2018). A constant value of 0.8 (Martin et al. 1994) is assigned to *k* in Equation 1."

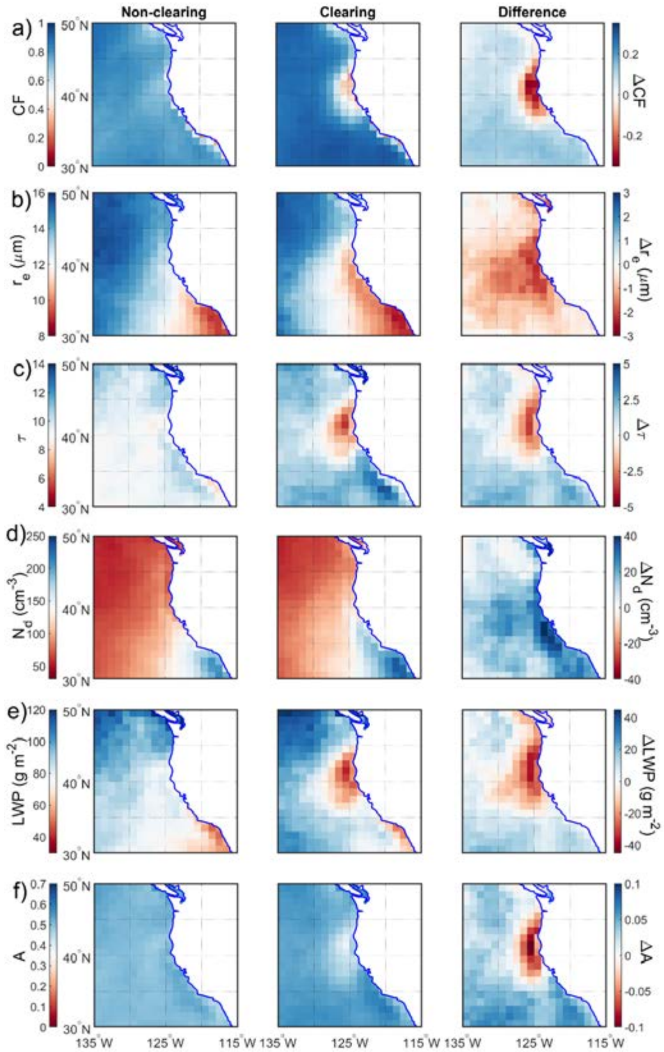

Figure 9. Average cloud parameters for non-clearing and clearing days obtained from MODIS Terra Level 3 (Collection 6.1) data: a) cloud fraction day (*CF*), b) cloud top droplet effective radius (r_e), c) cloud optical thickness (τ), d) cloud droplet number concentration (N_d), e) cloud liquid water path (*LWP*), and f) cloud albedo (*A*). Differences (clearing minus non-clearing) are shown in the farthest right column with separate color scales. Values from any instances of clear pixels

were omitted from the analysis to produce panels b-f. Fig. S6 is an analogous figure based on MODIS Aqua data.

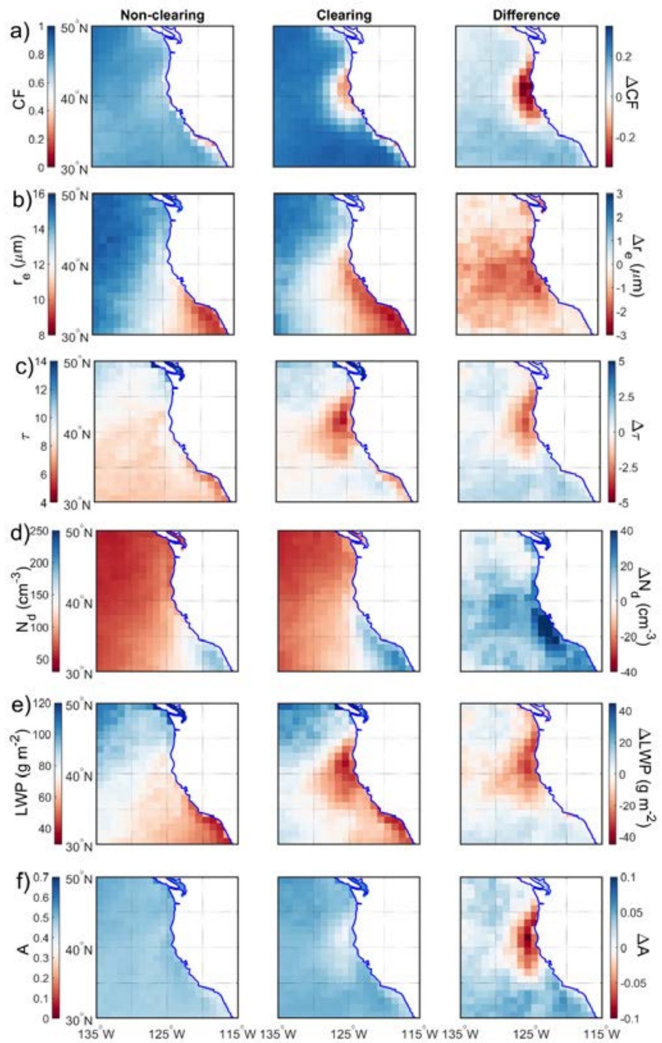

Figure S6. Average cloud parameters for non-clearing and clearing days obtained from MODIS Aqua Level 3 (Collection 6.1) data: a) cloud fraction day (*CF*), b) cloud top droplet effective radius (r_e), c) cloud optical thickness (τ), d) cloud droplet number concentration (N_d), e) cloud liquid water path (*LWP*), and f) cloud albedo (*A*). Differences (clearing minus non-clearing) are shown in the farthest right column with separate color scales. Values from any instances of clear pixels were omitted from the analysis to produce these figures.

2. I think that the arguments presented in Section 3.2 regarding the spatial differences in PBLH (P11, L420-425) require additional explanation. Firstly, citations are needed to support the presented hypotheses. More importantly, why do you think that CF is higher for the broad study region on clearing days? What about the synoptic scale scenarios and the role of offshore flow? Advection of warm air combined with compressional warming near the coastline will increase layer thickness and therefore thin out the MBL below. This seems like a chicken-egg problem. Is it actually cloud processes that are responsible for the shallower PBLHs or are the large-scale dynamics/thermodynamics reducing clouds and therefore causing the shallower PBLHs or perhaps some combination of the two mechanisms?

Response:

We addressed the comment by revising/updating the noted argument presented in Section 3.2 as follows below. We also added new references to support our discussion.

"Another key environmental parameter related to MBL cloud coverage is the *PBLH*. Consistent with previous studies (Neiburger et al., 1961; Wood and Bretherton 2004), regardless of whether clearings were present, *PBLH* generally increases with distance from the coast (Fig. 8d), where warmer *SSTs* lead to deeper MBLs by weakening the inversion (Bretherton and Wyant 1997). The shallowing of the MBL near the California coast is also notable with enhanced gradients in clearing days. The aforementioned MBL shallowing is believed to be a crucial element in development of coastal jet off the California coast (Zemba and Friehe 1987; Parish 2000). Previous studies (Beardsley et al., 1987; Edwards et al., 2001; Parish 2000; Zuidema et al., 2009) also reported MBL height adjustment in the vicinity of coast due to hydraulic adaptation to coastal topography, thermally driven circulation, and geostrophic adjustment in the cross-coast direction in response to the contrast in surface heating between ocean and land. There is also a strong gradient in *PBLH* along the shoreline in the vicinity of Cape Blanco (Fig. 8d). While the presence of a similar gradient in *SST* (Fig. 8a) may partly explain the observed gradient in *PBLH*, coastally induced processes could also play a role.

Comparing clearing with non-clearing days, *PBLH* tends to be higher on clearing days, with the largest differences (~200 m) observed to the north off the coasts of Washington and British Columbia, which re-emphasizes the important role of coastal topography near Cape Blanco and Cape Mendocino in mesoscale dynamics (Beardsley et al., 1987; Haack et al., 2001). Zuidema et al. (2009) suggested that dynamical blocking of the surface winds by the southern Peruvian Andes contributed to boundary layer thickening by encouraging mesoscale convergence. Enhanced dynamical blocking of surface winds by coastal topography near Cape Blanco, as suggested by greater wind speeds on clearing days (Fig. 7a), can lead to a deeper MBL in the coastal regions north and northwest of Cape Blanco. In contrast, coastal areas south of Cape Blanco, exhibit negligible differences in *PBLH* between clearing and non-clearing days. In the aforementioned regions, enhanced hydraulic response (i.e., expansion fan (Parish et al., 2016)) to coastal topography, may cause slightly shallower MBL on clearing days.

Higher MBL depths in the offshore regions of clearing days is noteworthy to discuss. Parameters influencing MBL depth include entrainment rates, vertical velocity at the top of MBL, and horizontal advection of MBL (Wood and Bretherton 2004; Rahn and Garreaud 2010). Although on clearing days there may be greater subsidence rates offshore (Fig. 8c) promoting a shallower MBL, the sum of entrainment and horizontal advection terms counteract the aforementioned effect resulting in a deeper MBL. Wood and Bretherton (2004) showed for the Northeast and Southeast Pacific that entrainment and subsidence were the most influential terms in the MBL prognostic equation, which acted in the opposite manner. It is also likely that entrainment processes resulting from changes in small scale turbulence contributed to elevated *PBLH* on clearing days (Randall 1984, Rahn and Garreaud 2010). The maps of *CF* from MODIS Terra (Fig. 9a) can provide at least one possible explanation for the spatial differences in *PBLH* between clearing and non-clearing days. Cloud fraction is generally higher for the broad study region on clearing days, which leads to more opportunity for cloud top radiative cooling to then fuel turbulence in MBL (Wood 2012). Greater turbulence can lead to a deeper MBL by promoting greater entrainment at the top of MBL (Randall 1984; Wood 2007)."

3. The discussion in Section 3.2 connecting the MERRA-2 and MODIS results raises numerous questions that the authors' should address. For example, on P11, L447-448: This is an interesting yet surprising result. I am wondering how aerosol are treated in MERRA-2. Which aerosol types are included in the reanalysis? Is AOD calculated differently when clouds are present in a column? I must say that I am quite surprised that between clearing and non-clearing days, the MODIS retrievals show a clear difference in microphysical variables suggestive of aerosol influence, but MERRA-2 AOD does not show a clear deference in aerosol loading. While the authors' do provide a possible explanation for this confounding result, I am wondering if it is possible to look at precipitation rates from the MERRA-2 outputs? Or use the MODIS retrievals and the RCB-LWP-Nd relationship derived in Comstock et al. (2004) to estimate cloud base precipitation rate? I think that some general investigative work here would be nice to help shed light.

Response: This is an excellent point and gets a bit more into the weeds of the critical details of how MERRA-2 and MODIS compare. We share here a bit more about MERRA-2:

The MERRA-2 aerosol reanalysis (Buchard et al., 2017; Randles et al., 2017) relies on the GEOS-5 Goddard Aerosol Assimilation System (Buchard et al., 2015) where the Goddard Chemistry, Aerosol, Radiation, and Transport (GOCART) (Chin et al., 2002) model is used to simulate 15 externally mixed aerosol tracers including hydrophobic and hydrophilic black carbon and organic carbon, dust (five size bins), sea salt (five size bins), and SO_4^{-2}. Sea salt and dust emissions are driven by wind speed in the GOCART model. Other species are treated using various emissions from combustion, biomass burning, biogenic sources, and volcanic emissions. The dominant removal mechanisms for aerosols include gravitational settling, dry deposition, and wet scavenging. MERRA-2 assimilates AOD from ground and satellite-based remote sensors, including AVHRR, AERONET, MISR, and MODIS.

J.: The MERRA-2 Aerosol Reanalysis, 1980 Onward. Part I: System Description and Data Assimilation Evaluation, J Climate, 30, 6823-6850, 10.1175/Jcli-D-16-0609.1, 2017.

We added the following text to the paper based on the lengthier description above, which we feel is adequate to articulate how MERRA-2 handles aerosols:

“Of note is that the MERRA-2 aerosol reanalysis relies on the GEOS-5 Goddard Aerosol Assimilation System (Buchard et al., 2015) for which the Goddard Chemistry, Aerosol, Radiation, and Transport (GOCART) model (Chin et al., 2002) simulates 15 externally mixed aerosol tracers including sulfate, dust (five size bins), sea salt (five size bins), and hydrophobic and hydrophilic black carbon and organic carbon. Of relevance to this study, GOCART applies wind-speed dependent emissions for sea salt. Furthermore, the dominant removal mechanisms for aerosols include gravitational settling, dry deposition, and wet scavenging.”

Also, we feel as though deeper examination into precipitation rates is best left for future work. We did not want to get too deep in this current manuscript into the aerosol-related aspects but believe that there are enough compelling results to investigate the aerosol-related aspects in subsequent work.

Minor/specific comments:

1. P2, L41: Do you mean model simulations from this study or previous studies? Please clarify.

Response: This study. Revised sentence:

“Measurements were compared on both sides of the clear-cloudy border of clearings at multiple altitudes in the boundary layer and free troposphere, with results helping to support links suggested by this study’s model simulations.”

2. P3, L54-56: This statement deserves citations; please cite some papers here.

Response: Added:

"Stratocumulus clouds also play an important role in the global radiation budget due to their high albedo contrast with the underlying ocean surface (Hartmann and Short, 1980; Herman et al., 1980; Stephens and Greenwald, 1991)."

Hartmann, D. L., and Short, D. A.: On the Use of Earth Radiation Budget Statistics for Studies of Clouds and Climate, J Atmos Sci, 37, 1233-1250, Doi 10.1175/1520-0469(1980)037<1233:Otuoer>2.0.Co;2, 1980.

Stephens, G. L., and Greenwald, T. J.: The Earths Radiation Budget and Its Relation to Atmospheric Hydrology .2. Observations of Cloud Effects, J Geophys Res-Atmos, 96, 15325-15340, Doi 10.1029/91jd00972, 1991.

3. P3, L85-86: Introduce abbreviations for cloud fraction and cloud liquid water path here?

Response: Done

4. P4, L110-112: Are there differences in retrieval and/or post-processing techniques between GOES-11 and GOES-15 that could impact interpretation/comparison of their results?

Response: Not to our knowledge.

5. P4, 119-121: Please explain how you identified a clearing event using visual inspection.

Response: We added the following description in Section 2.1 in response to this comment:

"Each day's sequence of GOES images were visually inspected to identify if a clearing event was present. This involved utilizing the following general guidelines: (i) There had to be sufficient cloud surrounding the clearing area that the clearing's borders could be approximately identified, which excluded cases with highly broken cloud deck; (ii) Clearings that were not connected to land between 30°-50° N in any of daily images were excluded; (iii) Days with the cloud deck completely detached from the coast between 30°-50° N were not considered; and (iv) Only clearings with a maximum daily area of greater than 15,000 km^2 (which translates to a clearing length on the order of 100 km) were considered. Consequently, the statistics presented in Section 3.1.1 represent a lower limit of clearing occurrence in the study region. However, it is expected that the qualitative trends discussed in Section 3.1.1 are representative of clearing behavior in the study region."

6. P5, L146: From which wavelength retrieval are you using data?

Response: We added the requested information:

"The key daytime parameters (Table 1) retrieved for this study relevant to liquid clouds included the following, which were retrieved at 2.1 μm and selected based on their importance for marine boundary layer (MBL) cloud studies: *CF* obtained from the MODIS cloud mask algorithm (Platnick et al., 2003), cloud optical thickness (τ), *LWP*, and cloud droplet effective radius (r_e). Detailed information about these MODIS products is described elsewhere (Platnick et al., 2003; Platnick et al., 2017; Hubanks et al., 2019)."

7. P5, L147: Is any day that is not a clearing day lumped in with non-clearing days? Or were some days not considered in the analysis?

Response: A non-clearing day is defined as any summer day between 2009 and 2018 which was not identified as a clearing day. We clarify this in the first paragraph of Section 3.2 as follows:

"Large-scale dynamic and thermodynamic characteristics were contrasted (parameters in Table 1) between clearing and non-clearing days (Fig. 6). Sub-daily data were averaged up to daily resolution for parameters of interest, which were subsequently used to produce a climatology for non-clearing (614 days) and clearing (306 days) cases for the summers between 2009 and 2018. It is important to note that non-clearing cases include those summer days (e.g., June, July, and August) from 2009 through 2018 that were not categorized as clearing days. We further calculated the difference between clearing and non-clearing conditions."

8. P5, L148: Why use 1 deg x 1 deg data rather than the higher resolution data that are available? I imagine that the resolution of the GOES data are much higher than 1 deg x 1 deg.

Response: The reviewer is correct. A decision was made early to use the larger resolution data early in the study and the results we feel are robust and informative. Future work by anyone interested can certainly probe similar phenomena at higher resolution, but we decided not to have to re-do the entire analysis for this comment.

9. P5, L150-153: Why are all of these cloud microphysical properties important in the context of cloud clearings? Some justification in this section would be nice.

Response: Text added:

"The key daytime parameters (Table 1) retrieved for this study relevant to liquid clouds included the following, which were selected based on their importance for marine boundary layer (MBL) cloud studies:"

10. P5, L151-153, L156: Please italicize variables here and throughout the remaining text.

Response: Done

11. P5, L167-170: Does this need to be its own paragraph?

Response: We added the paragraph in question to the previous paragraph to address this issue.

12. P5, Section 2.2: Similar to the previous section, it would be nice to hear some justification as to why you choose the listed parameters/vertical levels. Why are these parameters/vertical levels important to the analysis? Were other variables considered and found to be not useful?

Response: We added text to explain our choice of parameters and levels:

"The parameters were chosen based on their ability to provide a sufficient view of atmospheric conditions in which MBL clouds form, evolve, and dissipate. Various vertical levels were used for some MERRA-2 products as a way of obtaining representative information for different layers of the MBL and free troposphere."

13. Figure 2: The gray shading in panels c and d are a bit deceiving. Is the cloud base/top/depth in panel c truly that horizontally homogeneous? Panel d makes it seem as though cloud extends from the surface to 1000 m. I think that I understand what you are trying to show, but perhaps showing it a bit differently would be less confusing.

Response: We typically show our clouds in this manner in past publications. We find our Fig. 2 caption to be sufficiently clear. And we trust that readers know that the gray box in panel c is meant to be representative of where clouds were, and they are not that clear-cut linear at the edges.

14. P6-7, L222-234: Please explain how all of these turbulence measurements will aid in understanding the physical mechanism(s) that contribute to cloud clearing processes.

Response: We discuss the actual results in the Results section and do not think an exhaustive discussion is needed here in the Methods section. Rather, we revise the first sentence of this paragraph:

"Ten Hz measurements of environmental parameters were used to estimate turbulent variance and covariance flux values, which may be relevant to the understanding of clearing formation and evolution based on past work (Crosbie et al., 2016)."

15. P6, L224: Why use a 2-km wide high pass filter? I imagine this is influenced by the aircraft speed? By the way, what is the typical aircraft speed?

Response: Typical aircraft speed is ~55 m s^{-1}. We add a line about this now: "The typical aircraft speed was 55 m s^{-1}."

We used a 2-km wide high pass filter for detrending signals, which is helpful for flux calculations. It is a common strategy employed in studies of this nature. A 2-km wide high-pass filter is conservatively picked to assure filtering of any signals that does not stem from MBL turbulent eddies (with the typical size being less than MBL depth). Given the aircraft speed of ~55 m s^{-1}, a 2-km wide filter translates to a filter with passband frequency of 0.0275 Hz. No change made for this comment.

16. P7, L236: Is Fig. 2c supposed to show where the inversion sits?

Response: The sentence in question says the inversion base typically coincides with cloud top. Thus, Fig. 2c gives a representative view of where the inversion base sits. No change made for this comment.

17. P7, L236-238: Why use temperature rather than potential temperature?

Response: Both could work. We used temperature as has been done in past work. No change made for this comment.

18. P7, L238-240: This sentence is a bit confusing; please reword.

Response: Revised:

"Inversion top was defined as the highest altitude at which $d\theta_l/dz$ exceeded 0.1 K m^{-1}, where θ_l is liquid water potential temperature and *z* is altitude."

19. P7, L247-248: Please reference the GBRT method for unfamiliar readers.

Response: We already did in the second sentence of the paragraph. But we now added another one to the first sentence if that helps:

"A Gradient Boosted Regression Tree (GBRT) model approach was implemented to investigate the impact of environmental parameters on the evolution of clearing events (Friedman 2001)."

20. P8, L284: How is this r2 threshold determined? Are the results sensitive to this choice?

Response: The r^2 threshold was determined by choice. Sensitivity tests were done with different combinations of parameters and the general conclusions were preserved. We updated some text in the manuscript to address this comment:

"While *PD* plots are not flawless in capturing the influence of each variable in the model, especially if the input variables are strongly correlated, they provide useful information for interpretation of GBRT results (Friedman and Meulman 2003; Elith et al., 2008). To decrease the undesired influence of correlated variables on *PD* profiles, an arbitrary r^2 threshold of 0.5 was used based on the linear regressions between prospective input parameters. For instance, there were three choices of air temperature (i.e., at 950, 850, and 700 hPa), but based on the r^2 criterion, only one (T_{850}) was used in the model to minimize the unwanted impact of dependent input parameters. Lower tropospheric stability (*LTS*: defined as the difference between the potential temperature of the free troposphere (700 hPa) and the surface) is the stability parameter that has been widely used as a key factor controlling the coverage of stratocumulus clouds. However, in this study, the effects of stability were examined by putting T_{850} and *SST* into the model without explicitly including *LTS*. The correlation between *LTS* and T_{850} prevented them to be used as input parameters simultaneously. Using T_{850} and *SST* instead of *LTS* is advantageous because the results can be more informative by revealing different impacts of the two individual parameters on the model's output rather than just one parameter in the form of *LTS*. In addition, the mean sea level pressure anomaly ($MSLP_{anom}$) was used as an input parameter, which was calculated in reference to the average values of *MSLP* for the summer months for the study period. In the end, the following 11 predicting variables from MERRA-2 were used as input parameters for the GBRT simulations, with data product details summarized in Table 1: *AOD*, T_{850}, q_{950}, q_{850}, q_{700}, *SST*, $MSLP_{anom}$, U_{850}, V_{850}, *PBLH*, and ω_{700}. It is important to note that the results of extensive sensitivity tests led to the selection of the set of parameters presented in this study. Also, theses sensitivity tests confirmed that the general conclusions presented here were preserved regardless of using different sets of the input parameters."

21. P8, L298-299: What about the other MERRA-2 variables listed in Table 1 that are not listed here?

Response: Well, they are listed still in Table 1 for completeness to walk readers through our process of analysis to reach the point of Lines 298-299. No harm in doing that in our opinion.

22. P9, L322-323: Please reference a figure here.

Response: Done. Additionally, we now differentiate between Figure 3a and 3b in the text.

23. Figure 5: Because this plot is relatively straightforward, and only two sentences are written about it, I think that it makes more sense to add it to Figure 4, which also shows related variables as a function of time.

Response: We added Figure 5 to the Supplement as adding it to Fig. 4 made this figure hard to read.

24. P9, L354-356: What about near Point Conception? Are similar mechanisms responsible for the reduction of CF here?

Response: We added the following text and added that point to Figure 6a:

"Less pronounced is a centroid of reduced cloud fraction by Point Conception, where similar mechanisms may be at work."

25. P9, L356-361: Is it possible to plot low-level (maybe 100 m) wind arrows over the CF contours in Fig. 6 to support/refute this hypothesis?

Response: Figure 8 shows winds clearly and it would be redundant in our view to put them in Figure 6 too.

26. P9, L361-363: You mention southerly wind, but what about northerly wind along the coastline, which is much more common. Are expansion fan dynamics still present?

Response: The sentences are revised accordingly:

"The significance of these capes is discussed in many previous studies (Beardsley et al., 1987; Haack et al., 2001; Juliano et al., 2019a/b) pointing their ability to alter local dynamics, cloud depth, and various microphysical processes such as entrainment. Cloud thinning in the vicinity of the capes due to an expansion fan effect is reported for both northerly and southerly flow (Beardsley et al., 1987; Juliano et al., 2017)."

27. Figure 7: In the difference plot in panel a, are there truly no regions where the SLP is lower in clearing cases?

Response: This occurred because of the choice of spacing in the contour plot. Figure 7 has been updated to fix this issue.

28. P10, L369: How might using nearly 2 times more non-clearing days influence your results?

Response: It obviously provides more statistics and solidifies the non-clearing results. We do not expect this difference in days to affect the general conclusions.

29. P10, L383: When you reference Fig. 8a, should this instead be a reference to Fig. 8b?

Response: Correct, thanks. Change made.

30. P10, L395-396: A few more citations would be nice for a statement that is "well documented".

Response: Sentence revised as the "well-documented" is unnecessary and seems to be a distraction.

31. P11, L411-413: Can you speculate as to why you observe this?

Response: This paragraph is revised to provide a potential explanation for the observed trend:

"The changes in synoptic-scale conditions, including relocation/strengthening of the Pacific high, on clearing days in comparison to non-clearing days can alter large-scale subsidence. This is indeed confirmed in Fig. 8b using ω_{700} as the proxy variable, with the strongest difference between clearing and non-clearing days (up to ~ 0.1 Pa s^{-1}) off the coast by Cape Blanco and Cape Mendocino and geographically coincident with where the sharpest gradients occur for *MSLP* between clearing and non-clearing cases (Fig. 6). It is interesting to note that the maximum *LTS* values coincide spatially with enhanced values of ω_{700} on non-clearing days, in contrast to clearing days when the peak value of ω_{700} is farther north from where *LTS* peaks (Fig. 8c). Consistent with the results presented here (Fig. 8b), modeling studies (Burk and Thompson 1996; Munoz and Garreaud 2005) reported enhanced subsidence for the entrance regions of the Chilean and California CLLJs in response to coastal features. These studies also reported the generation of a warm layer above the MBL due to coastal mechanisms especially downstream of coastal points and capes. This is also the case in this study where higher air temperature at 850 hPa was observed to the south of Cape Blanco and Cape Mendocino on clearing days (Fig. 5b). In addition, higher

LTS values on clearing days by up to ~2 K (Fig. 8c) are largely associated with the presence of warmer layer above the MBL south of Cape Blanco and Cape Mendocino. It is likely that reduced *SST*s and greater subsidence contributed to generally higher *LTS* on clearing days versus non-clearing days (Fig. 8c). Other works have pointed to the connection between cooler *SST*s, higher boundary layer cloud amount, and increased stability in the lower atmosphere (Norris and Leovy 1994, Klein and Hartman 1993)."

32. P11, L414-415: Why does PBLH exhibit this trend? Is this is a well-known feature of the MBL offshore the western U.S.?

Response: We edited this line to add a few references and to address the suspected reason for the observed trend in PBLH:

"Another key environmental parameter related to MBL cloud coverage is the *PBLH*. Consistent with previous studies (Neiburger et al., 1961; Wood and Bretherton 2004), regardless of whether clearings were present, *PBLH* generally increases with distance from the coast (Fig. 8d), where warmer *SSTs* lead to deeper MBLs by weakening the inversion (Bretherton and Wyant 1997). The shallowing of the MBL near the California coast is also notable with enhanced gradients in clearing days. The aforementioned MBL shallowing is believed to be a crucial element in development of coastal jet off the California coast (Zemba and Friehe 1987; Parish 2000). Previous studies (Beardsley et al., 1987; Edwards et al., 2001; Parish 2000; Zuidema et al., 2009) also reported MBL height adjustment in the vicinity of coast due to hydraulic adaptation to coastal topography, thermally driven circulation, and geostrophic adjustment in the cross-coast direction in response to the contrast in surface heating between ocean and land. There is also a strong gradient in *PBLH* along the shoreline in the vicinity of Cape Blanco (Fig. 8d). While the presence of a similar gradient in *SST* (Fig. 8a) may partly explain the observed gradient in *PBLH*, coastally induced processes could also play a role."

33. P11, L467: Lower LWP values because the clouds are thinner, LWCs are lower, or both?

Response: Presumably both. No change needed to text in our view.

34. Section 3.3: Generally speaking, how do sample sizes influence the interpretation of these results? Many of the steep slopes shown in Fig. 12 occur at the low or high ends of the parameter spaces which is likely where the fewest number of samples lie. Are the results robust in these areas?

Response: Added the following text:

"Note that the 5^{th}, 25^{th}, 50^{th}, 75^{th}, and 95^{th} percentiles of input parameter values are denoted in Figure 12 to caution that sharp slopes in the bottom and top 5^{th} percentiles are based on few data points and that robust conclusions should not stem from those outer bounds."

35. P13, L514-516: Are the local changes in slope of the PD-T850 relationship important? For example, from 275 to 280 K, the slope is relatively small, but from 281 to 282 K, the slope is relatively large.

Response: The best we thought to do was report our method of how these plots were generated and then leave it to readers to conclude using their own criteria how important local changes are. In our view, we are most interested in more macroscopic trends in these plots and also changes in signs of relationships.

36. P13, L524-534: Please reference the various panels in this section to help the reader.

Response: Done.

37. P13, L540-543: Please provide a citation for this phenomenon. An example of previous work in this region may be found in Rahn et al. (2016, Observations of LargeWind Shear above the Marine Boundary Layer near Point Buchon, California, JAS).

Response: Done:

"Stronger northerly flow is associated with offshore flow of dry and warm air that can reside above the cloud top, which can dissipate the cloud layer after entrainment and via enhanced shearing (via Kelvin-Helmholtz instability) and mixing of cloudy parcels with warm and dry air in the FT (e.g., Rahn et al., 2016). As will be shown later, aircraft data showed that typical wind speeds parallel to clear-cloudy interfaces were near or greater than 10 m s^{-1} (Fig. 12)."

38. P14, L557-558: A negative U850 promoting cloud clearing makes sense due to the offshore flow component, but can you hypothesize as to why strong positive U850 values also promote cloud clearing?

Response: We are not sure and make this explicit:

"Clearing growth due to negative zonal winds can be explained by the offshore flow component, however, the reason for growth during periods of positive zonal winds is unclear."

39. P14, L566: Might these vertical motions also induce dynamical circulations and thereby influence shear/turbulence/entrainment processes near cloud top?

Response: Maybe so. We add text to give this idea some attention in the draft:

"Vertical motions represented by the ω_{700} parameter could also induce dynamical circulations affecting cloud top processes such as shear and entrainment."

40. P15, L592: Specific or relative humidity?

Response: Made it clear it is "specific".

41. P15, L614-627: I like this portion of the analysis, and the topic of horizontal wind shear is one that probably does not receive enough attention. I think that perhaps a line plot showing how the horizontal shear changes with distance for each of the vertical levels may be very useful.

Response:
We calculated horizontal shear for constant level legs and displayed it in SI file. Additionally, the paragraph has been updated accordingly:

"To extend upon the possibility of shearing effects, absolute changes in *v* (|*v*|) were calculated for level legs performed at the clear-cloudy border for the three research flights (Table 2). For consistency, these calculations were based on level legs of a constant length of ~40 km with relatively equal spacing on both sides of the clear-cloudy border. |*v*| was calculated by multiplying 40 km by the slope of the linear fit of *v* versus distance from cloud edge, where negative (positive) x values represent distance away from the edge on the clear (cloud) side. The results reveal that the horizontal wind shear was strongest somewhere between mid-cloud and cloud top altitudes, with the lowest values at the FT level. The lowest values in the MBL were observed in the surface legs. This can be attributed to turbulent transport of the momentum (Zemba and Friehe 1987) to the surface and the consequent drop in CLLJ wind speeds in the clear column. In addition, Fig. S7 shows absolute horizontal shear (|d*v*/d*x*|) as a function of distance from the cloud boundary for the parallel component of horizontal wind speed. Horizontal shear profiles for all research flights (Fig. S7) are slightly noisy especially at the surface legs, but they show the presence of the greatest horizontal wind gradient within 5 km length away from clear-cloudy edge. Shear at the clear-cloudy edge, especially at cloud levels, can support clearing growth through enhancing the mixing of cloudy and clear air. Crosbie et al. (2016) also showed using the case of NiCE RF19 that that mixing of cloudy air with adjacent clear air can be an important contributor to cloud erosion and thus expansion of clearings. To probe deeper into the clearing cases, the subsequent discussion compares vertically-resolved data on both sides of the clear-cloudy border based on soundings and level legs."

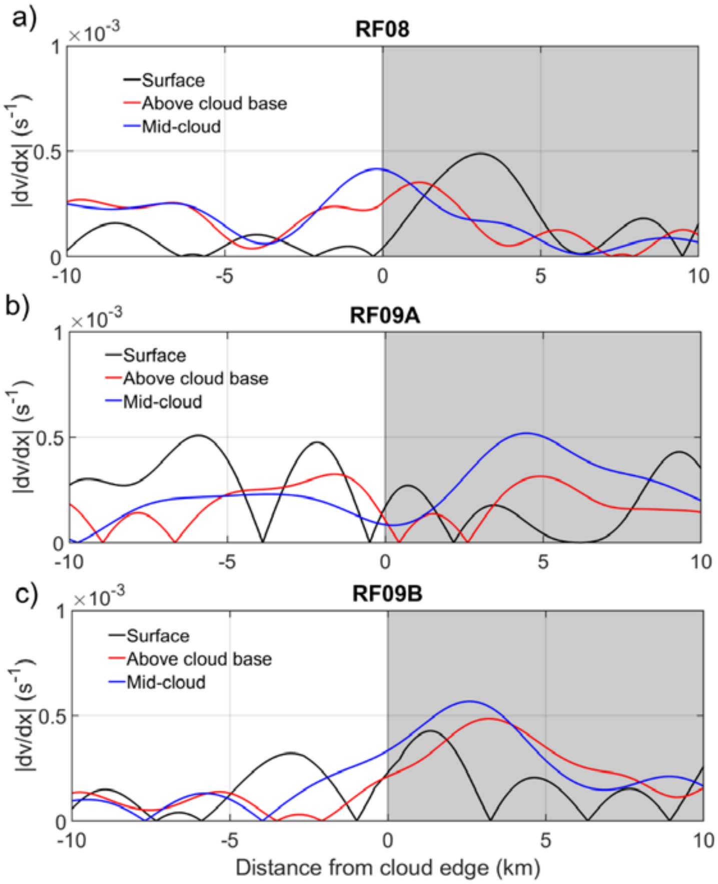

Figure S7. Absolute variations in horizontal shear as a function of distance from the cloud boundary for the parallel component of horizontal wind speed for three case research flights: a) RF08, b) RF09A, and c) RF09B. These variations were shown only for constant altitude legs (surface, above cloud base, and mid-cloud legs). Cloudy columns are highlighted in grey.

42. P16, L648-650: I do not understand this sentence; please reword.

Response: We revised the sentence:

"The wind maximum in the clearing also enhanced moisture advection, which counteracted the accumulation of moisture caused by mixing induced by vertical shear."

43. P16, L660: How is the cloud base rain rate determined?

Response: Text added:

"Cloud base rain rate was quantified using the size distributions of drizzle drop (D_P > 40 µm) obtained from CIP in the bottom third of clouds along with documented relationships between fall velocity and drop size (Wood 2005b)."

44. P16-17, L677-681: Are you able to hypothesize why, in all three flights, surface PCASP concentrations are higher on the cloudy side even though the surface wind speeds are higher on the clear side? Is it possible that drizzle drops evaporate after the wet scavenging processes and therefore concentrate aerosol near the surface, whereas aerosol are well-mixed in the MBL on the clear side? If available, vertical profiles may help here.

Response: We went ahead and made vertical profiles as shown in the new Figure S8. It is too difficult to reach the speculation above with a high level of confidence provided by the reviewer based on the available dataset in our opinion. Entrainment of free tropospheric aerosol particles is likely a possible explanation too. We added the following text:

"Figure S8 shows vertical profiles of aerosol concentrations on both sides of the clearing border, highlighting differences above cloud top level especially in RF09A and RF09B with higher values in the cloudy column. Higher aerosol concentrations were also observed in the cloud column in the sub-cloud layer even though surface wind speeds were always higher in the clear column for all three flights. Surface winds and thus sea spray production do not exclusively influence the aerosol concentrations. A likely explanation of higher concentrations in the MBL in the cloudy column is that there could be entrainment of more polluted free tropospheric aerosol as has been reported to be a common occurrence during the FASE flights (e.g., Mardi et al., 2019). As also reported during FASE, there can be sub-cloud evaporation of drizzle resulting in droplet residual particles that contribute to the aerosol concentration budget in the cloudy column (Dadashazar et al., 2018)."

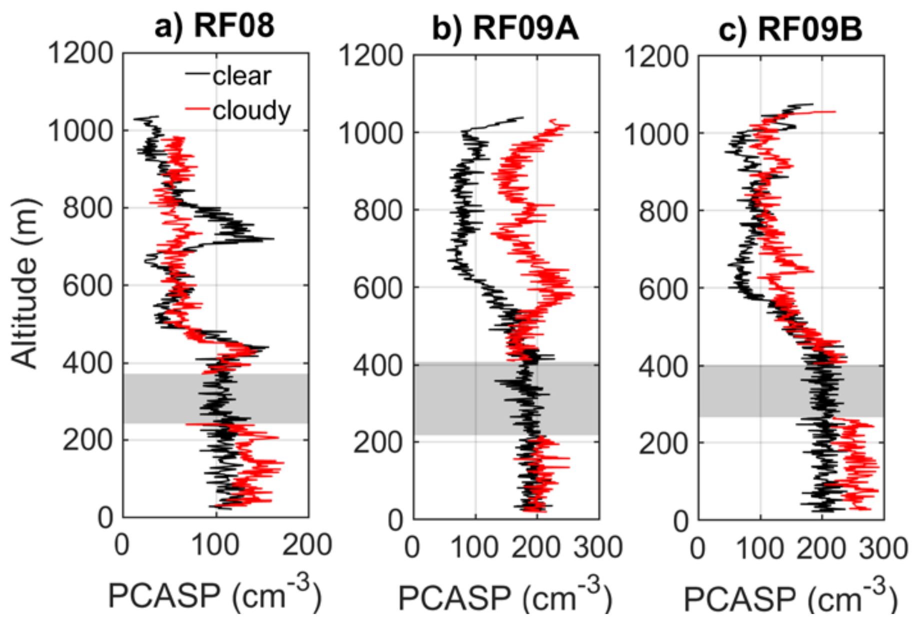

Figure S8. PCASP profiles obtained from soundings performed in clear and cloudy columns for three case research flights: a) RF08, b) RF09A, and c) RF09B. The altitude range where the cloud deck was present is highlited in grey. PCASP data are unreliable in cloud due to droplet shatter artifacts and thus not shown.

45. P17, L683: Do you mean stronger gradients in horizontal wind speed?

Response: Yes, that is correct. Text revised.

"Stronger horizontal wind speed gradients,…"

46. P17, L683-685: What about the role of positive (cyclonic) vorticity that is generated by this horizontal shear? Could this influence cloud properties near the cloudy-clear interface?

Response: We suppose that is a possibility but we felt it was not necessary to address this in the text to avoid having too many speculations without unambiguous support.

47. P18, L749-765: I think that in order for the authors' to argue whether buoyancy or shear production of turbulence is more important, they should calculate the terms according to the TKE equation (e.g., see Eq. 5.1a in Stull, An Introduction to Boundary Layer Meteorology, 1988).

Response: This was in fact attempted already but the data looked noisy and inconclusive; this is mainly a limitation of the aircraft data. We do not feel this is really necessary to respond to as a result.

48. P18, L754-755: Adding vertical profiles of TKE would be very useful.

Response: The vertical profiles of TKE have been added to Fig. 13. We also updated the text as follows:

"Profiles of $\overline{u'^2}$ and $\overline{v'^2}$ exhibited downward trends with increasing altitude for RF09A and RF09B, in general agreement with the findings for RF08. One contrasting aspect was the comparison of $\overline{v'^2}$ between clear and cloudy columns, which mirrored RF08 during RF09A, while in RF09B, the values of $\overline{v'^2}$ for the clear side were substantially lower. In addition, $\overline{w'^2}$ profiles during RF09A and RF09B are substantially enhanced in the cloudy column as compared to RF08, with maxima in the cloud layer. There is an accompanying increase in the buoyancy flux for these profiles suggestive of a more significant contribution of buoyancy to *TKE* production (Fig. 13e). Although more subtle, $\overline{u'^2}$ values also showed an increase in the cloudy column of RF09A and RF09B relative to the clear column, also supportive of the role of buoyancy in these cases. In addition, *TKE* profiles (Fig. 13d) were largely influenced by variances in the horizontal component of wind speed ($\overline{u'^2}$ and $\overline{v'^2}$) which led to overall greater *TKE* values in the clear column except for RF09B."

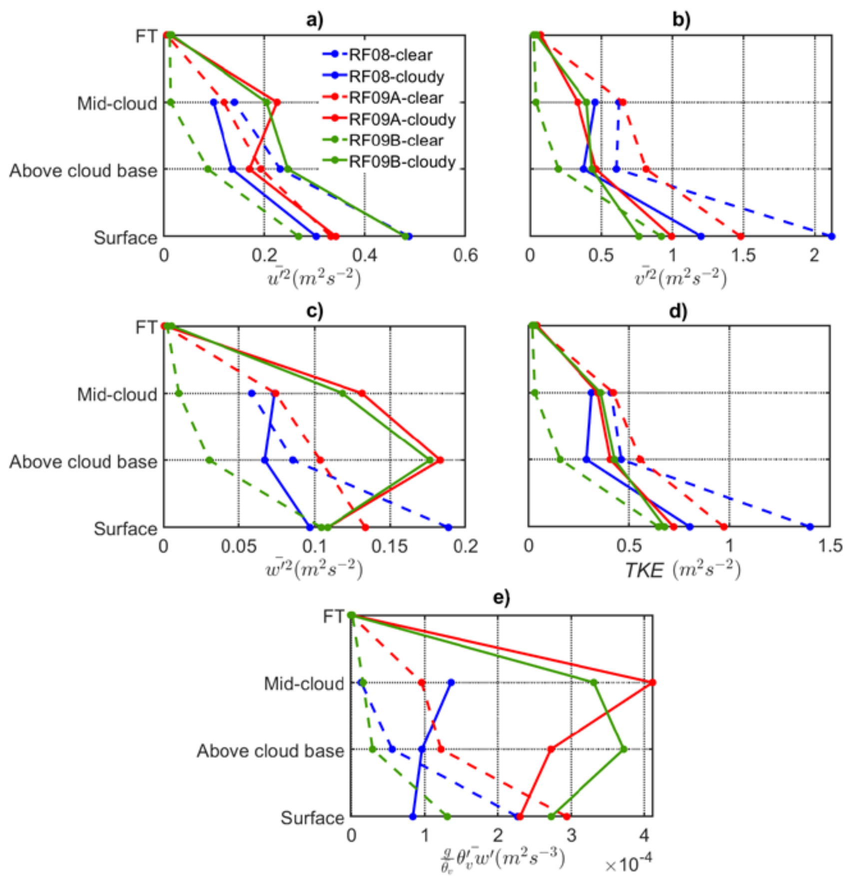

Figure 13. Selected dynamic parameters for the clear (dash lines) and cloudy (solid lines) parts of the legs performed at different altitudes for three FASE case research flights: Panels a-c) exhibit squared average velocity fluctuations of wind speeds components (*u* and *v* horizontal components, w vertical component). Horizontal wind speeds are decomposed into two components, (*u*) perpendicular and (*v*) parallel, relative to the cloud edge. Panels d) and e) display turbulent kinetic energy and buoyancy flux profiles, respectively, for the three flights.

49. P18, L759: What do you mean by "stabilizing effect"?

Response: Those words were removed.

50. P19, L803-805: Can new remote sensing platforms, such as GOES-16/17, help with the diurnal analysis of cloud properties?

Response: Yes. Text added:

“More data such as those provided by GOES platforms can help understand processes occurring at the microscale that scale up to more climatologically relevant scales.”

Grammatical/wording recommendations:
1. P6, L198: Please change “Of the relevance to this study” to “Of relevance to this study”.

Response: Edited.

2. P7, L254: Please change “or each of the 306 events.” to “for each of the 306 days.”.

Response: Fixed.

3. P8, L313: Please change “between 2009 and 2018” to “from 2009 through 2018”.

Response: Fixed.

4. P10, L366: Please change “Large-scale characteristics of a dynamic and thermodynamic nature were contrasted” to “Large-scale dynamic and thermodynamic characteristics were contrasted”.

Response: Edited.

5. P10, L401: Please change “likely contribute” to “likely contributes”.

Response: Edited.
6. P11, L410: Please change “geographical coincident” to “geographically coincident”.

Response: Edited.

7. P12, L494: Consider changing “GBRT model to model clearing” to “GBRT model to reproduce clearing”.

Response: Changed.

8. P12, L500: Please remove “partial dependence” as this acronym has already been defined.

Response: Edited.

9. P16, L656: Please change “lesser effect” to “reduced effect”.

Response: Edited.

10. P19, L780-781: Consider changing “clearings visible from space” to “clearings as suggested by satellite retrievals”.

Response: Changed.

11. P19, L782: Please change “centroid of clearings is centered” to “centroid of clearings is located”

Response: Edited.

12. P19, L808: Please change “sea spray fluxes, which subsequently can impact clouds” to “sea spray fluxes and can subsequently impact clouds”.

Response: Edited.

Stratocumulus Cloud Clearings: Statistics from Satellites, Reanalysis Models, and Airborne Measurements

Abstract

This study provides a detailed characterization of stratocumulus clearings off the U.S. West Coast using remote sensing, reanalysis, and airborne in situ data. Ten years (2009-2018) of Geostationary Operational Environmental Satellite (GOES) imagery data are used to quantify the monthly frequency, growth rate of total area (GR_{Area}), and dimensional characteristics of 306 total clearings. While there is interannual variability, the summer (winter) months experienced the most (least) clearing events with the lowest cloud fractions being along coastal topographical features along the central to northern coast of California including especially just south of Cape Mendocino and Cape Blanco. From 09:00 to 18:00 (PST), the median length, width, and area of clearings increased from 680 to 1231 km, 193 to 443 km, and ~67,000 to ~250,000 km^2, respectively. Machine learning was applied to identify the most influential factors governing the GR_{Area} of clearings between 09:00-12:00 PST, which is the time frame of most rapid clearing expansion. The results from Gradient Boosted Regression Tree (GBRT) modeling revealed that air temperature at 850 hPa (T_{850}), specific humidity at 950 hPa (q_{950}), sea surface temperature (SST), and ~~meridional wind speed at 850 hPa (V_{850}~~anomaly in mean sea level pressure ($MSLP_{anom}$) were probably most impactful in enhancing GR_{Area} using two scoring schemes. Clearings have distinguishing features such as an enhanced Pacific high shifted more towards northern California, offshore air that is warm and dry, stronger coastal surface winds, enhanced lower tropospheric static stability, and increased subsidence. Although clearings are associated obviously with reduced cloud fraction where they reside, the domain-averaged cloud albedo was actually slightly higher on clearing days as compared to non-clearing days. To validate speculated processes linking environmental parameters to clearing growth rates based on satellite and reanalysis data, airborne data from three case flights were examined. Measurements were compared on both sides of the clear-cloudy border of clearings at multiple altitudes in the boundary layer and free troposphere, with results helping to support links suggested by this study's model simulations. More specifically, airborne data revealed the influence of the coastal low-level jet and extensive horizontal shear at cloud-relevant altitudes that promoted mixing between clear and cloudy air. Vertical profile data provide support for warm and dry air in the free troposphere additionally promoting expansion of clearings. Airborne data revealed greater evidence of sea salt in clouds on clearing days, pointing to a possible role for, or simply the presence of, this aerosol type in clearing areas coincident with stronger coastal winds.

1. Introduction

Stratocumulus clouds play an important role in both global and regional climate systems. Stratocumulus clouds are the dominant cloud type over marine environments based on annual mean of area covered (Warren et al., 1986; Hahn and Warren, 2007). In coastal areas, these clouds can impact industries such as agriculture, transportation (e.g., aviation), military operations, coastal ecology, and biogeochemical cycles of nutrients. Stratocumulus clouds also play an important role in the global radiation budget due to their high albedo contrast with the underlying ocean surface~~.~~ (Hartmann and Short, 1980; Herman et al., 1980; Stephens and Greenwald, 1991). Challenges in accurately simulating the presence and properties of stratocumulus clouds include the difficulty in separating the influence of microphysical and dynamical factors and the existence of multiple feedbacks in cloud systems (Brunke et al., 2019). Therefore, accurate characterization of cloud formation and evolution is critical.

Numerous studies have examined the behavior of clouds off the United States (U.S.) West Coast (e.g., Coakley et al., 2000; Durkee et al., 2000; Stevens et al., 2003; Lu et al. 2009; Painemal and Minnis, 2012; Modini et al., 2015; Sanchez et al., 2016). The persistence of the cloud deck in this region, especially during the summer, makes it a key location for studying marine stratocumulus clouds. Furthermore, the prevalence of freshly-emitted aerosols from ships provides an optimal setting for field measurements of aerosol-cloud-precipitation interactions because of the relative ease of finding strong aerosol perturbations, from which cloud responses can be robustly quantified (e.g., Russell et al., 2013). Over the decades of research conducted in the aforementioned study region and two other major stratocumulus regions (Southeast Pacific Ocean off the Chile-Peru coasts and Southeast Atlantic Ocean off the Namibia-Angola coasts), one feature that has not received sufficient attention is large scale stratocumulus clearings that are easily observed in satellite imagery and often exceed 100 km in width (Fig. 1). Perhaps the most obvious impact of these clearings is the change in albedo as an otherwise cloudy area would be highly reflective. Improving understanding of factors governing clearings has implications for modeling of marine boundary layer clouds and for operational forecasting of weather and fog along coastlines.

Previous studies have documented the existence of large scale cloud clearings off the U.S. West Coast (e.g., Kloesel, 1992). During the 2013 Nucleation in Cloud Experiment (NiCE), three case study flights with the Center for Interdisciplinary Remotely-Piloted Aircraft Studies (CIRPAS) Twin Otter examined clearings off the California coast, with a focus on diurnal behavior and contrasting aerosol and thermodynamic properties across the cloud-clearing interface (Crosbie et al., 2016). Based on a multi-day event, they showed that a clearing expanded during the day and contracted at night towards the coast with oscillations between growth and decay over the multi-day clearing lifetime. They observed that small scale processes (~1 km) at the clearing-cloud border are influential in edge dynamics that likely upscale to more climatologically influential scales, which is why reanalysis data cannot accurately replicate the spatial profile of cloud fraction (CF) and cloud liquid water path (LWP) when compared to satellite data. One of their three events was associated with a so-called "southerly surge", also referred to as a coastally-trapped disturbance (CTD). CTD events were recently characterized off the U.S. West Coast by Juliano et al. (2019a,b). Clearing events have been examined over the southeast Atlantic Ocean with the catalyst for cloud erosion shown to be atmospheric gravity waves (Yuter et al., 2018). While these aforementioned studies have explained details associated with clearings in different coastal regions, there are many unanswered questions remaining and a need for more statistics associated with clearings to build more robust conclusions.

The goal of this work is to build upon cloud clearing studies over the U.S. West Coast to provide a more comprehensive analysis using the synergy of data from satellite remote sensors, reanalysis products, and airborne in-situ measurements. We first examine a decade of satellite data to report on statistics associated with the temporal and spatial characteristics of clearings. These characteristics are then studied in conjunction with environmental properties from reanalysis products and machine learning simulations to identify factors potentially contributing to the formation and evolution of clearings. Lastly, airborne in situ data are used to validate findings from the aforementioned analyses and to gain more detailed insight into specific events that otherwise would not be possible with reanalysis and satellite products. The most significant implications of our results are linked to modeling of fog and boundary layer clouds, with major implications for a range of societal and environmental issues such as climate, military operations, transportation, and coastal ecology.

2. Experimental Methods

2.1 Satellite Datasets

Long-term statistics associated with clearings were obtained using Geostationary Operational Environmental Satellite (GOES) visible band (~0.6 μm) images. Visual imagery data were obtained from GOES-11 for 2009 through 2011 and from GOES-15 between 2012 and 2018 (data products summarized in Table 1). Images were analyzed for the spatial domain bounded by 115°-135° W and 30°-50° N. The following steps led to the identification of individual clearings using GOES images, of which a total of 306 were identified between 2009 and 2018:

(ii) GOES-11 and GOES-15 visible images were obtained from the National Oceanic and Atmospheric Administration (NOAA) Comprehensive Large Array-data Stewardship System (CLASS) database (http://www.class.noaa.gov).

(iii) Each day's sequence of GOES images were visually inspected to identify if a clearing event was present. This involved utilizing the following general guidelines: (i) there had to be sufficient cloud surrounding the clearing area that the clearing's borders could be approximately identified, which excluded cases with highly broken cloud deck; (ii) clearings that were not connected to land between 30°-50° N in any of daily images were excluded; (iii) days with the cloud deck completely detached from the coast between 30°-50° N were not considered; and (iv) only clearings with a maximum daily area of greater than 15,000 km^2 (which translates to a clearing length on the order of 100 km) were considered. Consequently, the statistics presented in Section 3.1.1 represent a lower limit of clearing occurrence in the study region. However, it is expected that the qualitative trends discussed in Section 3.1.1 are representative of clearing behavior in the study region.

(iv) For each clearing event, four images were selected to both quantify clearing properties and characterize diurnal variability: (i) Image 1 after sunrise, between 14:15 UTC (7:15 Pacific Standard Time (PST)) and 16:45 UTC (09:45 PST) with a median at ~16:00 UTC (09:00 PST); (ii) Image 2 at a time relevant to the *Moderate* Resolution Imaging Spectroradiometer (MODIS) Terra overpass over the study region, between 18:45 UTC (11:45 PST) and 20:45 UTC (13:45 PST) with a median at ~19:00 UTC (~12:00 PST); (iii) Image 3 at a time relevant to the MODIS Aqua overpass over the study region, ranging from 19:45 UTC (12:45 PST) to 22:15 UTC (15:15 PST) with a median at ~22:00 UTC (~15:00 PST); and (iv) Image 4 before sunset, ranging from 22:45 UTC (15:45 PST) to

02:15 UTC (19:15 PST) with a median at ~01:00 UTC (~18:00 PST). For the purposes of subsequent discussion, local times (PST) will be used.

(v) A custom-made cloud mask algorithm was applied consisting of the following steps: (i) each visible image was converted to an 8-bit integer gray-scale image with values assigned to each pixel ranging from 0 (black) to 255 (white); (ii) continental areas were masked from the analysis (i.e., green regions in Fig. 1), meaning that their values were not included in subsequent steps; (iii) a histogram of values for all pixels over the ocean was calculated for each image obtained in the previous step and then Otsu's method (Otsu 1979) was applied on the obtained histogram to compute a global threshold to categorize each pixel as either clear or cloudy; (iv) a MATLAB image processing toolbox was used to extract the clearing as an object, including the pixels at the clearing-cloud border and pixels inside the clearing; (v) information contained within the clear pixels was then used to estimate clearing dimensions such as width, length, area, and centroid for the spatial domain bordered by 115°-135° W and 30°-50° N; and (vi) a MATLAB application was written to automate all of the aforementioned steps to process data for a decade (2009-2018).

Data were used from the MODIS on the Terra and Aqua satellites to characterize cloud ~~and aerosol~~ properties on clearing and non-clearing days in the spatial domain of analysis defined above. Daily Level 3 ~~Collection 6.1~~ data (Hubanks et al., 2019) with spatial resolution 1°×1° were downloaded from the LAADS DAAC distribution system (https://ladsweb.modaps.eosdis.nasa.gov/). The key daytime parameters (Table 1) retrieved for this study relevant to liquid clouds included the following~~:~~, which were retrieved at 2.1 µm and selected based on their importance for marine boundary layer (MBL) cloud ~~fraction (~~studies: *CF*~~)~~ obtained from the MODIS cloud mask algorithm (Platnick et al., 2003), cloud optical thickness (τ), ~~cloud liquid water path (*LWP*),~~, and cloud droplet effective radius (r_e). Detailed information about these MODIS products is described elsewhere (Platnick et al., 2003; Platnick et al., 2017; Hubanks et al., 2019).

Although MODIS Level 3 data parameters do not include cloud droplet number concentration (N_d), previous studies estimated N_d using retrievals of τ and r_e with assumptions (Bennartz, 2007; Painemal and Zuidema, 2010; McCoy et al., 2017). We use the following equation from Painemal and Zuidema (2010) to estimate N_d:

$$N_d = \frac{(\Gamma_{ad})^{\frac{1}{2}}}{k} \frac{10^{\frac{1}{2}}}{4\,\pi \rho_w^{\frac{1}{2}}} \frac{\tau^{\frac{1}{2}}}{r_e^{\frac{5}{2}}} \quad (1)$$

where ρ_w is the density of liquid water, Γ_{ad} is the adiabatic lapse rate of liquid water content (*LWC*), and the parameter k is representative of droplet spectral shape as the cube of the ratio between the volume mean radius and the effective radius. ~~While Painemal~~Γ_{ad} is a function of temperature and ~~Zuidema (2010)~~pressure (Albrecht et al., 1990). In this study, cloud top temperature and pressure, provided by MODIS, are used ~~a Γ_{ad} value equal to 2.0×10^{-4} g m^{-4}~~ to estimate ~~N_d for~~Γ_{ad} following the ~~southeast Pacific region, we use the average value of $\Gamma_{ad} = 2.3 \times 10^{-4}$ g m^{-4} reported by~~ methodology described in Braun et al. (2018~~) for the northeast Pacific.~~). A constant value of 0.8 (Martin et al. 1994) is assigned to k in Equation 1.

Similar to our previous study on clearings (Crosbie et al., 2016), cloud top albedo (*A*) was quantified using τ in the following relationship (Lacis and Hansen 1974):

$$A = \frac{\tau}{\tau + 7.7} \quad (2)$$

2.2 Reanalysis Data

Various products from Modern-Era Retrospective analysis for Research and Applications, Version 2 (MERRA-2; Gelaro et al., 2017) were used to gain insight into possible mechanisms influencing the formation and evolution of clearings off the U.S. West Coast. MERRA-2 data were downloaded from the NASA Goddard Earth Sciences Data and Information Services Center (GES DISC; https://disc.gsfc.nasa.gov/). Table 1 summarizes MERRA-2 parameters used in this work, including detailed information such as their product identifier and temporal resolution. –The parameters were chosen based on their ability to provide a sufficient view of atmospheric conditions in which MBL clouds form, evolve, and dissipate. Various vertical levels were used for some MERRA-2 products as a way of obtaining representative information for different layers of the MBL and free troposphere (FT). Of note is that the MERRA-2 aerosol reanalysis relies on the GEOS-5 Goddard Aerosol Assimilation System (Buchard et al., 2015) for which the Goddard Chemistry, Aerosol, Radiation, and Transport (GOCART) model (Chin et al., 2002) simulates 15 externally mixed aerosol tracers including sulfate, dust (five size bins), sea salt (five size bins), and hydrophobic and hydrophilic black carbon and organic carbon. Of relevance to this study, GOCART applies wind-speed dependent emissions for sea salt. Furthermore, the dominant removal mechanisms for aerosols include gravitational settling, dry deposition, and wet scavenging.

2.3 Airborne In-Situ Data

Motivated by the three case study research flights (RFs) probing clearings during the NiCE campaign (Crosbie et al., 2016), the Fog and Stratocumulus Evolution Experiment (FASE) was carried out with nearly the same payload on the Center for Interdisciplinary Remotely-Piloted Aircraft Studies (CIRPAS) Twin Otter between July and August 2016 (Sorooshian et al., 2018). Data were used from three case RFs examining clearings: RF08 on 2 August 2016, and RF09A/RF09B on 3 August 2016. The back-to-back flights on 3 August afforded an opportunity to examine the evolution of clearing properties at the clear-cloudy interface over a span of a few hours. Figure 2 shows GOES imagery and the flight pattern for RF09A, which is representative of the other two shown in Figs. S1-S2. The same flight strategy from NiCE (Crosbie et al., 2016) was used in the FASE RFs and included the following set of maneuvers (Fig. 2c): (i) spiral profiles on both sides of the clear-cloudy interface; (ii) level legs extending on both sides of the clear-cloudy interface near the ocean surface (~30 m; called "surface leg"), above cloud base, and mid-cloud; (iii) a series of sawtooth maneuvers up and down between ~60 m below and above the cloud top on both sides of the clear-cloudy interface; and a (iv) level leg in the free troposphere (FT) at ~1 km altitude. The typical aircraft speed was 55 m s^{-1}.

Commonly used instruments provided dynamic, thermodynamic, and navigational data (Crosbie et al., 2016; Dadashazar et al., 2017; Sorooshian et al., 2018). Of the relevance to this study are 10 Hz measurements of wind speeds, air temperature, and humidity. Setra pressure transducers attached to a five-hole gust probe radome provided three components of wind speeds after correction for aircraft motion, which was obtained by a C-MIGITS-III GPS/INS system. Ambient air temperature was measured by a Rosemount Model 102 total temperature sensor. Also, humidity data were collected with an EdgeTech Vigilant chilled mirror hygrometer (EdgeTech Instruments, Inc.).

Cloud micro/macrophysical parameters were measured at 1 Hz with various instruments. Size distributions of cloud droplets and rain droplets were characterized using the Forward Scattering Spectrometer Probe (FSSP; D_p ~ 2-45 μm) and Cloud Imaging Probe (CIP; D_p ~ 25-1600 μm). Cloud base rain rate was quantified using the size distributions of drizzle drop (D_P > 40 μm) obtained from CIP in the bottom third of clouds along with documented relationships between fall velocity and drop size (Wood 2005a). *LWC* data were obtained using a PVM-100 (Gerber et al., 1994), which were vertically integrated during sounding profiles to quantify cloud *LWP*. Aerosol concentration data are reported here from the passive cavity aerosol spectrometer probe (PCASP; D_p ~ 0.11–3.4 μm; Particle Measuring Systems (PMS), Inc.; modified by Droplet Measurement Technologies, Inc.) at 1 Hz time resolution. Cloud water composition data were obtained using a modified Mohnen slotted-rod collector (Hegg & Hobbs, 1986) that was manually placed out of the aircraft during cloud passes to collect cloud water. The collected samples were analyzed for water-soluble ions using ion chromatography (IC; Thermo Scientific Dionex ICS-2100 system) and water-soluble elements using triple quadrupole inductively coupled plasma mass spectrometry (ICP-QQQ; Agilent 8800 Series). Liquid-phase concentrations of species were converted to air-equivalent units (μg m^{-3}) via multiplication with the sample-averaged *LWC*. The reader is referred to other works for more extensive discussion about cloud water collection and sample analysis from FASE and other recent CIRPAS Twin Otter campaigns (Crosbie et al., 2018; Prabhakar et al., 2014; Sorooshian et al., 2013a; Wang et al., 2016; Youn et al., 2015).

Ten Hz measurements of environmental parameters were used to estimate turbulent variance and covariance flux values~~.~~, which may be relevant to the understanding of clearing formation and evolution based on past work (Crosbie et al., 2016). To perform the aforementioned calculations, collected data for wind speed and temperature were de-trended using a 2-km wide high pass filter that utilizes a minimum order-filter with a stopband attenuation of 60 dB and transition band steepness of 0.95. Friction velocity (u^*) was calculated from the surface leg following the method provided in Stull (1988) and Wood (~~2005~~2005b). In addition, convective velocity (w^*) was estimated by implementing the buoyancy integral method (Nicholls and Leighton, 1986). Turbulent kinetic energy (*TKE*) in the ~~marine boundary layer (MBL)~~MBL is generated by two main mechanisms, specifically shear and buoyancy generation. Following Wood (~~2005~~2005b), the ratio of the MBL depth (z_i) to the Monin–Obukhov length (L_{MO}) was estimated as a way to determine the relative influence of shear versus buoyancy in values of *TKE*. Large positive values of the ratio ($-z_i/L_{MO}$) are associated with the turbulence in the MBL governed more with buoyancy production, while small or negative values are associated with the dominance of shear production.

Properties relevant to the inversion layer were estimated from sawtooth maneuvers above and below the cloud top, which typically coincided with the inversion base altitude (Fig. 2c). The inversion base height was defined as the altitude where the ambient temperature first reached its minimum above the sea surface (Crosbie et al., 2016). Inversion top was defined as the highest altitude ~~with the gradient in~~at which $d\theta_l/dz$ exceeded 0.1 K m^{-1}, where θ_l is liquid water potential temperature ~~over~~and z is altitude~~ in the inversion layer ($d\theta_l/dz$) exceeding 0.1 K m^{-1}~~. $d\theta_l/dz$ was calculated from linear fits over a moving window of 75 points from 10 Hz data. The following characteristics were estimated and reported for the inversion layer: (i) inversion base height; (ii) inversion top height; (iii) inversion depth; (iv) jump in liquid water temperature ($\Delta\theta_l$); (v)

maximum gradient of the potential temperature ($(d\theta_l/dz)_{max}$); (vi) drop in the total moisture (Δq_t); and (vii) change in the horizontal wind speed (ΔU).

2.4 Clearing Growth Modeling Using Machine Learning

A Gradient Boosted Regression Tree (GBRT) model approach was implemented to investigate the impact of environmental parameters on the evolution of clearing events~~.~~ (Friedman 2001). GBRT models have been successfully used in past work to study low-level clouds (Fuchs et al., 2018). The Scikit-Learn library (Pedregosa et al., 2011) was used for careful parameter tuning in order to accurately represent the data and desired relationships without overfitting the model (Fuchs et al., 2018).

We apply the GBRT model to analyze clearing growth rates of total area (GR_{Area}) obtained from the comparative analysis between GOES Image 1 (~9:00 PST) and Image 2 (~12:00 PST) ~~or~~for each of the 306 events. As will be shown, the most rapid clearing growth occurs between 9:00 and 12:00 PST among the three time increments between Images 1-4 (i.e., 09:00 - 18:00 PST). Here we describe how the predictor values were obtained. A rectangular box was placed around the larger of the clearing areas from Image 1 or 2 for each clearing event using the maximum and minimum values of both latitude and longitude. The same size rectangular box was then placed on the other image using identical latitude and longitude bounds. MERRA-2 data were then obtained for each 0.5° × 0.625° grid within the rectangular area for the two images, and then averaged for the pair of images. Each grid was also assigned the value of the clearing GR_{Area} for the entire clearing (i.e., each grid had the same value of GR_{Area} assigned to it). Parameters used in the modeling included those relevant to aerosol (aerosol optical depth (*AOD*)), thermodynamics (air temperature (*T*), air specific humidity (*q*), and sea-surface temperature (*SST*), and dynamic variables (mean sea level pressure anomaly ($MSLP_{anom}$), zonal wind speed (*U*), meridional wind speed (*V*), planetary boundary layer height (*PBLH*), and vertical pressure velocity (ω)). Most of the aforementioned variables were first analyzed at different vertical levels including the surface, 950 hPa, 850 hPa, and 700 hPa in order to then filter variables out to keep only the most appropriate input parameters.

Model simulation results are reported in terms of a parameter termed 'partial dependence' (*PD*) following methods in earlier works (e.g., Friedman, 2001; Fuchs et al., 2018). *PD* plots represent the change of the clearing GR_{Area} relative to a selected parameter by marginalizing over the remaining predictors. For each given value of a selected parameter (x_s), partial dependence ($PD(x_s)$) can be obtained by computing the average of model outputs using the training data as shown in Equation 3:

$$PD(x_s) = \frac{1}{n}\sum_{i=1}^{n} \hat{f}(x_s, {x_R}^{(i)}) \quad (3)$$

where $\hat{f}$ is the machine learning model, x_R are the remaining parameters, and *n* is the number of instances in the training data. *PD* profiles were computed between the 1^{st} and 99^{th} percentile of each selected parameter.

~~To correctly interpret the model output using the PD criterion and gradient boosting, it was required that the model input parameters not be correlated. Thus, the input parameters were chosen so as to have the least correlation among them. Two input parameters were determined to be independent if a linear regression between the two parameters yielded an r^2 value of less than 0.5.~~While *PD* plots are not flawless in capturing the influence of each variable in the model, especially if the input variables are strongly correlated, they provide useful information for interpretation of GBRT results (Friedman and Meulman 2003; Elith et al., 2008). To decrease the

undesired influence of correlated variables on *PD* profiles, an arbitrary r^2 threshold of 0.5 was used based on the linear regressions between prospective input parameters. For instance, there were three choices of air temperature (i.e., at 950, 850, and 700 hPa), but based on the r^2 criterion, only one (T_{850}) was used in the model~~, as it proved~~ to ~~be an independent~~minimize the unwanted impact of dependent input ~~parameter~~parameters. Lower tropospheric stability (*LTS*: defined as the difference between the potential temperature of the ~~free troposphere~~FT (700 hPa) and the surface) is the stability parameter that has been widely used as a key factor controlling the coverage of stratocumulus clouds. However, in this study, the effects of stability were examined by putting T_{850} and *SST* into the model without explicitly including *LTS*. The correlation between *LTS* and T_{850} prevented them to be used as input parameters simultaneously. Using T_{850} and *SST* instead of *LTS* is advantageous because the results can be more informative by revealing different impacts of the two individual parameters on the model's output rather than just one parameter in the form of *LTS*. In addition, the mean sea level pressure anomaly ($MSLP_{anom}$) was used as an input parameter, which was calculated in reference to the average values of *MSLP* for the summer months for the study period. In the end, the following ~~eleven~~11 predicting variables from MERRA-2 were used as input parameters for the GBRT simulations, with data product details summarized in Table 1: *AOD*, T_{850}, q_{950}, q_{850}, q_{700}, *SST*, $MSLP_{anom}$, U_{850}, V_{850}, *PBLH*, and ω_{700}. It is important to note that the results of extensive sensitivity tests led to the selection of the set of parameters presented in this study. Also, these sensitivity tests confirmed that the general conclusions presented here were preserved regardless of using different sets of the input parameters.

To train, test, and validate the statistical models, the dataset was split into random parts. The training set was comprised of 75% of the data points, 30% of which were randomly selected for validation. This process helped reduce variance and increase model robustness. The remaining 25% of the data points comprised the test dataset. The model setup was tuned using training data, for which different scenarios were tested that were specified by a parameter grid through a 10-fold cross-validated search. The model was run on the dataset 30 times to achieve robust results. To qualitatively rank the input parameters based on their influence on growth rates, ~~differences between the maximum and minimum of PD (ΔPD) were calculated over 30 runs.~~two scoring metrics were calculated over 30 runs: (i) differences between the maximum and minimum of *PD* (ΔPD); and (ii) the relative feature importance following the method developed by Friedman (2001), which is determined by the frequency that a variable is chosen for splitting, weighted by the gained improvement due to each split and averaged over all trees (Friedman and Meulman 2003; Elith et al., 2008).

3. Results and Discussion

3.1 Temporal and Spatial Profile of Clearings

3.1.1 Monthly and Interannual Trends

The frequency of clearing events was quantified for the three summer months (June – July – August, JJA) of each year ~~between~~from 2009 ~~and~~through 2018 (Fig. ~~3~~3a). Note that if a clearing event lasted multiple days as in the case of the 11-day clearing probed by Crosbie et al. (2016), it was counted separately for each individual day rather than assigned a value of one for a multi-day period. There was considerable interannual variability, with clearing events ranging between a minimum of 14 in 2017 and a maximum of 45 in 2011. The relative percentage of total days in the summer season having clearings ranged from 15.2% – 48.9% with a mean ± standard deviation of 33.3 ± 10.9 days. The specific month with the most clearing events varied between years, with August typically having the least number of events among the summer months. The most recent

year of the decade examined, 2018, was used to more closely examine the distribution of clearing events as a function of all 12 months. Daily probabilities of clearing events are shown for each month, with the highest probability between May and September (> 0.2), especially June (~0.42) (Fig. 3b). Daily probabilities were lowest in the winter season, with January having no clearings ~~(0)~~..

To identify if the monthly profile of clearings is biased by the monthly profile of *CF*, Figs. S3-S4 show the mean annual cycle of MODIS *CF* for 2018 and 2009-2018, respectively. The range in *CF*s for 2018 and 2009-2018 were 0.59-0.76 and 0.60-0.74, respectively, with the mean values being 0.69 ± 0.05 and 0.68 ± 0.04. This is indicative of relatively low variability. A reasonable question is if August had the lowest clearing daily probability of the summer months because it potentially had the lowest *CF*. Figs. S3-S4 do not show significant variations in *CF* between the summer months, with mean values in 2018 for June, July, and August being 0.71, 0.72, and 0.72, respectively. Also, the lowest mean daily probability in 2018 was for January and February, but those months do not exhibit the lowest *CF* (January = 0.76, February = 0.67). Rather, September exhibited the lowest *CF* (0.59). Finally, *CF* decreased from 0.72 to 0.59 from August to September 2018, but the daily probability of clearings actually increased slightly. Thus, the systematic changes in *CF* between months are not the primary cause for inter-monthly variation in clearing formation.

3.1.2 Diurnal

Dimensional characteristics of cloud clearings as a function of time of day are summarized here. The median width of clearings was smallest in the morning at 09:00 (193 km), with an increase between 09:00 and 12:00, and then a leveling off in expansion until 18:00 (443 km) (Fig. 4). Clearing length and area followed the same qualitative trend in growth with an initial increase and then leveling off. The median length and area of clearings at 09:00 were 680 km and ~67,000 km^2, respectively, with values at 18:00 being ~1231 km and ~250,000 km^2. The aspect ratio (width:length) was of interest to quantify how long such clearings are relative to their width throughout the day, with results indicating a minor increase that was more linear than asymptotic (from ~0.32 at 09:00 to ~0.37 at 18:00). Although the range in median values was very small, there was significant variability at each of the four time steps shown. Figure ~~5~~S5 quantifies the *GR* of total area, width, and length by comparing 12:00 to 09:00, 15:00 to 12:00, and 18:00 to 15:00. The *GRs* for clearing length, width, and area are expectedly lowest from 15:00 to 18:00 and highest from 09:00 to 12:00.

Figure ~~6~~5 shows ~~cloud fraction~~*CF* maps for the times corresponding to panels 1 – 4 for all 306 events between 2009 and 2018. The spatial maps show that the centroid of the clearings is generally focused on the coastal topographical features along the central to the northern coast of California including especially just south of Cape Mendocino and Cape Blanco. Less pronounced is a centroid of reduced *CF* by Point Conception, where similar mechanisms may be at work. The 09:00 map most clearly shows that those two topographical features potentially serve as 'trigger points' for the majority of clearings, and as a typical clearing day develops, the ~~cloud fraction~~*CF* gets reduced around those points by moving farther south and to the west. ~~Juliano et al. (2019a/b) also discussed the~~The significance of these capes is discussed in ~~their analysis of CTDs~~many previous studies (Beardsley et al., 1987; Haack et al., 2001; Juliano et al., 2019a,b) pointing to their ability to alter local dynamics, cloud depth, and various microphysical processes such as entrainment. ~~Southerly wind during CTDs promotes cloud~~Cloud thinning ~~on~~in the ~~northern~~

~~side~~vicinity of the capes due to an expansion fan effect ~~(~~is reported for both northerly and southerly flow (Beardsley et al., 1987; Juliano et al., 2017).

3.2 Contrasting Clearing and Non-Clearing Cases

Large-scale ~~characteristics of a~~ dynamic and thermodynamic ~~nature~~ characteristics were contrasted (parameters in Table 1) ~~were contrasted~~ between clearing and non-clearing days (Fig. ~~7~~6). Sub-daily data were averaged up to daily resolution for parameters of interest, which were subsequently used to produce a climatology for non-clearing (614 days) and clearing (306 days) cases for the summers between 2009 and 2018. It is important to note that non-clearing cases include those summer days (e.g., June, July, and August) from 2009 through 2018 that were not categorized as clearing days. We further calculated the difference between clearing and non-clearing conditions.

The Pacific high usually sets up ~~a few hundred kms~~~1000 km west of California during the summertime, which promotes northerly flow near the surface along the coastline (e.g., Juliano et al., 2019a). As compared to non-clearing cases, clearing days are characterized by having an enhanced Pacific high shifted more towards northern California (Fig. ~~7).~~6a). The presence of Pacific high over the ocean and thermal low over the land, especially for the summer months, are the main synoptic components contributing to the formation of coastal low-level jets (CLLJs) along the California coast (Beardsley et al., 1987; Parish 2000). California CLLJs are characterized by vertically narrow regions of intensified coast-parallel winds in low altitudes near the MBL top (Burk and Thompson 1996) with an average strength of ~15 m s^{-1} (Lima et al., 2018). In contrast, CLLJs have a relatively large horizontal offshore extent of up to a couple of hundred kms, which is determined by the Rossby radius of deformation (Ranjha et al., 2013). In both cases (clearing and non-clearing), the cross-coast gradient in *MSLP* and 850 hPa geopotential height gradients are the highest in northern California and directed away from the coast. Due to the displacement of the Pacific high towards the northeast part of the study region on clearing days, these gradients are much more profound on clearing days as compared to non-clearing days. The zonal pressure gradient is the main parameter controlling the intensity and occurrence of California CLLJs (Zemba and Friehe 1987; Parish 2000; Lima et al., 2018). The probability of CLLJ incidents is most likely greater on clearing days as a response to the enhanced pressure gradients near the coast. This ~~results in~~is also supported by low level wind fields shown in Fig. 7, which exhibit a 2-5 m s^{-1} increase in northerly surface wind speed (Fig. ~~8a~~7a) between 35°N and 45°N. Looking at the 850 hPa wind field (Fig. ~~8b~~7b), there is also a ~2-5 m s^{-1} increase in wind speed but in this case more in a northeasterly direction, which equates to having offshore flow from the northern California coast. The tightening of the 850 hPa geopotential height gradient on clearing days results in strong offshore flows by Cape Blanco and Cape Mendocino (Fig. ~~8a) where cloud fraction minima are observed (Fig. 6).~~7b) where *CF* minima are observed (Fig. 5). In addition, Beardsley et al. (1987) reported periods of low cloudiness along the California coast as a response to the synoptic scale features, an increase in the pressure gradient along the coast, and enhanced wind speeds. In other studies, over the southeast Pacific (Garreaud and Munoz 2005; Zuidema et al., 2009), dissipation of the coastal stratocumulus cloud deck was observed over the jet regions. Average conditions at 500 hPa indicate mostly westerly flow on both clearing and non-clearing days. Non-clearing days exhibited a weak trough offshore, while during clearing days a ridge is present at 500 hPa farther offshore~~, which can be attributed to~~. Displacement and strengthening of the ~~stronger~~ high-pressure system on clearing days~~.~~ can be associated with the passage of mid-latitude ridges (Garreaud and Munoz 2005).

Formatted: Font: Italic

The difference in air temperature between clearing and non-clearing cases at the surface reaches up to ~0.7 K on the western edge of the study domain (Fig. ~~7a~~6a). Clearing cases exhibited cooler temperatures closer to the coast where the clearings develop and evolve. *SST* shows a similar pattern as air temperature at the surface (Fig. ~~9a~~8a). Faster offshore winds at the surface can promote ocean upwelling and thus cooler *SST*s~~,~~ (Lima et al., 2018), as was also observed for CTD events in the same region (Juliano et al., 2019a). Furthermore, the generally high ~~cloud fractions~~*CF*s during clearing days for the entire spatial domain reduces radiative transfer to the ocean, also acting to reduce *SST* over the broader study region. ~~It is well-documented that cloudiness~~Cloudiness and surface winds play a major role in influencing *SST*s (e.g., Klein et al., 1995). In contrast, air temperatures at higher levels (850 and 500 hPa) are enhanced adjacent to the coastline in clearing cases. Air temperature at 850 hPa is higher (lower) to the south (north) of Cape Blanco and Cape Mendocino (Fig. ~~6~~5) in clearing cases as compared to non-clearing cases, with the difference reaching as high as ~2 K. The enhanced offshore flow of warm and dry air in in the vicinity of Cape Blanco and Cape Mendocino likely ~~contribute~~contributes to why many of the clearings geographically are centered ~~at~~by these coastal topographical features (Fig. ~~6).~~5). It is noteworthy that over the west coast of subtropical South America, cloud dissipation over and upstream of the coastal jet region was reported (Garreaud and Munoz 2005; Zuidema et al., 2009), whereas downstream there was enhanced *CF*, which appears to be analogous to this study.

~~Concomitant with higher cloud fraction and reduced SSTs,~~The changes in synoptic-scale conditions, including relocation/strengthening of the ~~study region also exhibited generally higher LTS by up to ~2 K~~Pacific high, on clearing days ~~versus~~ in comparison to non-clearing days ~~(Fig. 9b). Other works have pointed to the connection between cooler SSTs, higher boundary layer cloud amount, and increased stability in the lower atmosphere (Norris and Leovy 1994, Klein and Hartman 1993). With enhanced LTS values on clearing days, it is expected that there will be simultaneously strong~~can alter large-scale subsidence. This is indeed confirmed in Fig. ~~9c~~8b using ω_{700} as the proxy variable, with the strongest difference between clearing and non-clearing days (up to ~ 0.1 Pa s^{-1}) off the coast by Cape Blanco and Cape Mendocino and ~~geographical~~geographically coincident with where the sharpest gradients occur for *MSLP* between clearing and non-clearing cases (Fig. ~~7).~~ 6a). It is interesting to note that the maximum *LTS* values ~~in LTS~~ coincide spatially with enhanced values of ω_{700} on non-clearing days, in contrast to clearing days when the peak value of ω_{700} is farther north from where *LTS* peaks~~.~~ (Fig. 8c). Consistent with the results presented here (Fig. 8b), modeling studies (Burk and Thompson 1996; Munoz and Garreaud 2005) reported enhanced subsidence for the entrance regions of the Chilean and California CLLJs in response to coastal features. These studies also reported the generation of a warm layer above the MBL due to coastal mechanisms especially downstream of coastal points and capes. This is also the case in this study where higher air temperature at 850 hPa was observed to the south of Cape Blanco and Cape Mendocino on clearing days (Fig. 6b). In addition, higher *LTS* values on clearing days by up to ~2 K (Fig. 8c) are largely associated with the presence of warmer layer above the MBL south of Cape Blanco and Cape Mendocino. It is likely that reduced *SST*s and greater subsidence contributed to generally higher *LTS* on clearing days versus non-clearing days (Fig. 8c). Other works have pointed to the connection between cooler *SST*s, higher boundary layer cloud amount, and increased stability in the lower atmosphere (Klein and Hartman 1993; Norris and Leovy 1994).

Another key environmental parameter related to MBL cloud coverage is the *PBLH*. ~~Regardless~~Consistent with previous studies (Neiburger et al., 1961; Wood and Bretherton 2004), regardless of whether clearings were present, *PBLH* generally increases with distance from the

coast (Fig. ~~9d),~~8d), where warmer *SSTs* lead to deeper MBLs by weakening the inversion (Bretherton and Wyant 1997). The shallowing of the MBL near the California coast is also notable with enhanced gradients on clearing days. The aforementioned MBL shallowing is believed to be a crucial element in development of the coastal jet off the California coast (Zemba and Friehe 1987; Parish 2000). Previous studies (Beardsley et al., 1987; Edwards et al., 2001; Parish 2000; Zuidema et al., 2009) also reported MBL height adjustment in the vicinity of coast due to hydraulic adaptation to coastal topography, thermally driven circulation, and geostrophic adjustment in the cross-coast direction in response to the contrast in surface heating between ocean and land. There is also a strong gradient in *PBLH* along the shoreline in the vicinity of Cape Blanco (Fig. 8d). While the presence of a similar ~~to~~gradient in *SST*~~.~~ (Fig. 8a) may partly explain the observed gradient in *PBLH*, coastally induced processes could also play a role.

Comparing clearing with non-clearing days, *PBLH* tends to be higher on clearing days ~~though~~, with the largest differences (~200 m) observed to the north off the coasts of Washington and British Columbia~~. The smallest~~, which re-emphasizes the important role of coastal topography near Cape Blanco and Cape Mendocino in mesoscale dynamics (Beardsley et al., 1987; Haack et al., 2001). Zuidema et al. (2009) suggested that dynamical blocking of the surface winds by the southern Peruvian Andes contributed to boundary layer thickening by encouraging mesoscale convergence. Enhanced dynamical blocking of surface winds by coastal topography near Cape Blanco, as suggested by greater wind speeds on clearing days (Fig. 7a), can lead to a deeper MBL in the coastal regions north and northwest of Cape Blanco. In contrast, coastal areas south of Cape Blanco, exhibit negligible differences ~~existed where the majority of clearings evolved, specifically off the California coast.~~in *PBLH* between clearing and non-clearing days. In the aforementioned regions, enhanced hydraulic response (i.e., expansion fan (Parish et al., 2016)) to coastal topography, may cause slightly shallower MBL on clearing days.

Higher MBL depths in the offshore regions of clearing days is noteworthy to discuss. Parameters influencing MBL depth include entrainment rates, vertical velocity at the top of MBL, and horizontal advection of MBL (Wood and Bretherton 2004; Rahn and Garreaud 2010). Although on clearing days there may be greater subsidence rates offshore (Fig. 8b) promoting a shallower MBL, the sum of entrainment and horizontal advection terms counteract the aforementioned effect resulting in a deeper MBL. Wood and Bretherton (2004) showed for the Northeast and Southeast Pacific that entrainment and subsidence were the most influential terms in the MBL prognostic equation, which acted in the opposite manner. It is also likely that entrainment processes resulting from changes in small scale turbulence contributed to elevated *PBLH* on clearing days (Randall 1984; Rahn and Garreaud 2010). The maps of ~~cloud fraction~~*CF* from MODIS Terra (Fig. ~~10a~~9a) can provide at least one possible explanation for the spatial differences in *PBLH* between clearing and non-clearing days. Cloud fraction is generally higher for the broad study region on clearing days, which leads to more opportunity for cloud top radiative cooling to then fuel turbulence in MBL~~.~~ (Wood 2012). Greater turbulence can lead to a deeper MBL~~. But in the one area where PBLHs are not enhanced for the clearing days, off the California coast, cloud fractions are reduced, which is why PBLH does not exhibit~~ by promoting greater ~~values and actually has lower PBLH values.~~entrainment at the top of MBL (Randall 1984; Wood 2007).

Figure ~~9e~~8e shows spatial maps of specific humidity at 10 m above the sea surface (q_{10m}), which serves as a proxy of available moisture in MBL. Assuming a shallow and well-mixed MBL, q_{10m} represents moisture levels in ~~that~~the MBL. Similar to *SST*, q_{10m} increases to the south of the

Formatted: Font: Italic
Formatted: Font: Italic

study region with especially reduced values immediately adjacent to the California coast. Comparing clearing and non-clearing days, the former is less humid in the MBL (up to -0.6 g kg^{-1}). This is at least partly attributed to offshore flow and entrainment of dry continental air. Specific humidity was also examined at 850 hPa, which is closer to the vertical layer more relevant to air impacting cloud top close to the coastline. Figure ~~9f~~8f shows that q_{850} was substantially lower (up to ~-1.2 g kg^{-1}) in the clearing cases, especially in the regions where most of the clearings occur. Drier air above cloud top will decrease cloudiness through entrainment processes. It is interesting to note that the area of greatest q_{850} difference (Fig. ~~9f~~8f) corresponds to the area of greatest northeasterly winds in the difference plot of the wind field at 850 hPa (Fig. ~~8b~~7b). These pieces of evidence point to the role of dry continental air in contributing to the formation and sustenance of clearings via offshore flow.

Another important parameter influencing MBL clouds is nuclei of the cloud droplets, specifically the cloud condensation nuclei (*CCN*). *CCN* in the region originate from a blend of sources, including natural ones (sea spray, marine and continental biogenic emissions, terrestrial dust), biomass burning, ship exhaust, and continental anthropogenic sources (Hegg et al., 2010; Coggon et al., 2014; Wang et al., 2014; Maudlin et al., 2015; Mardi et al., 2018). As a representation of the general level of aerosol pollution in the region, spatial maps are shown for Aerosol Optical Depth (*AOD*), which is a columnar measurement of aerosol extinction (Fig. ~~9g~~8g). In general, regions closer to the shore exhibit higher values of *AOD* on non-clearing days, with especially higher levels north of 40° N. It is unclear as to why this is, since stronger winds on clearing days along the coast have the potential for more emissions from marine biogenic sources (via upwelling), sea spray, and offshore continental flow. Although based on speculation, one of many possible explanations could be that stronger fluxes of sea spray on clearing days have the potential to expedite the drizzle formation process in polluted clouds via broadening of cloud droplet size distributions, which leads to wet scavenging of aerosols in the study region (Dadashazar et al., 2017; Jung et al., 2015; MacDonald et al., 2018; Sorooshian et al., 2013b). South of Cape Blanco and Cape Mendocino on clearing days, there were pockets of high *AOD* relative to other coastal locations, which is presumed to be linked to stronger winds and offshore continental flow; this is analogous to how CTD events exhibit more pollution north of these coastal features when there is southerly flow (Juliano et al., 2019a). That the greatest *AOD* differences occur close to the coast ~~warrant~~warrants additional research as ~~they~~such differences may be suggestive of variations in ocean-land-atmosphere interactions that result from the movement and strengthening of the Pacific high during clearing events. Future work should examine if such *AOD* differences on clearing versus non-clearing days are linked to differences in MBL sources and sinks (i.e., wet scavenging), or FT processes.

Spatial maps of cloud microphysical variables provide consensus that clearing days generally have higher N_d and reduced values of r_e, τ, and *LWP* near the California coast where clearings form and evolve (Fig. ~~10~~9). Figure ~~S5~~S6 shows the same qualitative results based on MODIS Aqua data for cloud microphysical parameters. Lower *LWP* values on clearing days near the coast are consistent with offshore flow of dry and warm air eroding clouds. The combination of higher N_d and lower *LWP* by the coastline results in smaller r_e on clearing days. The more polluted clouds along the coastline during clearing days, especially south of major capes, is analogous to CTD clouds being more polluted during southerly wind regimes in the study region (Juliano et al., 2019a~~/~~,b). An intriguing aspect of clearing days was that although a significant section of the study region was cloud-free, the mean cloud albedo (*A*) over the entire study domain was actually slightly higher than on non-clearing days (Fig. ~~10f~~9f). More specifically, the domain-averaged *A* values based on MODIS Terra data (and using Eq. 2) were 0.50 and 0.53 for non-clearing and clearing cases, respectively. The corresponding values using MODIS Aqua data were 0.48 and 0.50, respectively. It is possible that the method used to identify clearing led to the greater *CF* and *A* on clearing days in distant offshore regions. It is difficult to identify the root cause of greater *CF* and *A* on clearing days versus non-clearing days, but Garreaud and Munoz (2005) also demonstrated that the cloud deck tends to dissipate over CLLJ regions in contrast to an increase in cloudiness downstream of the jet core. This is also the case in this study as large scale conditions such as an intensified Pacific high and greater *LTS* on clearing days are in favor of the preservation of cloud deck in the regions except for coastal areas impacted by a CLLJ.

3.3 Modeling of Clearing Growth Rates

It has been already shown (Figs. 4-~~6~~5) that clearings exhibit diurnal variability in dimensional characteristics, with rapid growth between 09:00 and 12:00 PST~~.~~ (Fig. S5). It is of interest now to examine what environmental parameters control the growth within this 3 h period based on the 306 clearing cases between 2009 and 2018. The GBRT modeling method was used to this end based on the method described in Section 2.4.

The coefficient of determination (r^2) between predicted and observed clearing growth rates for the 30 randomly selected testing datasets ranged between 0.52 to 0.77 with an average of 0.65. A multivariate linear regression model using the LASSO method (Tibshirani, 1996) was also applied to the obtained dataset to assess the performance of the GBRT model in comparison to the linear model. The r^2 value of the linear model varied between 0.08 and 0.11 with an average of 0.10, revealing the poor performance as compared to the GBRT model. As noted in at least one previous study (Klein 1997), linear models can explain less than 20% of the variance in low cloud amount on daily time scales. This is in contrast to monthly time scales for which such models perform much better and can explain over 50% of the variance (Klein and Hartmann, 1993; Norris and Leovy, 1994). Part of the success of the GBRT model to ~~model~~reproduce clearing growth rates can be attributed to the complexity of the model, specifically its ability to capture non-linearity between clearing growth rates and environmental parameters.

~~As there is independence between model parameters, the~~The range of *PD*s for each individual environmental parameter ~~is~~and the relative feature importance are used here as ~~a proxy~~two proxies for the sensitivity of clearing growth rates to that specific parameter. Higher *PD* ranges translate to a higher sensitivity of GR_{Area} to that specific parameter, indicating that it is ~~a major influential factor. The range of partial dependence (PD) of clearing growth rates for all the parameters included in the GBRT model is provided in Fig. 11, moving from left to right in order of highest to lowest PD ranges. Figure 12~~likely a major influential factor. In addition, the relative feature importance indicates how useful each parameter was in building the GBRT model. The range of *PD* of clearing growth rates and relative feature importance for all the parameters included in the GBRT model are provided in Fig. 10, moving from left to right in order of highest to lowest influence in the model. While it is expected that the results of these two methods of rankings do not match perfectly (Fig. 10a and 10b), certain characteristics are similar between these two proxies: (i) using both proxies, T_{850} and ω_{700} appeared as the top and lowest ranking parameters, respectively; (ii) q_{950} emerges as one of the most important parameters, being second and third place according to the range of *PD* and relative feature importance proxies, respectively; (iii) *AOD* and q_{700} emerged among the four lowest-ranking parameters; and (iv) *SST* and V_{850} appear next to each other in the ranking using both scoring proxies. There are some distinct differences among the ranking of parameters as shown in Fig. 10. For instance, while $MSLP_{anom}$ appeared as a

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

moderately influential parameter in GR_{Area} according to *PD* proxy, this parameter turned out to be the second most important variable using the relative feature importance proxy. In another example, q_{850} has the second least important rank according to relative importance feature proxy, but it is moderately important based on the *PD* range (Fig. 10a). The observed discrepancies between the results of two proxies can stem from underlying differences in the methods used to quantify the relative significance of each parameter. Moreover, the relative feature importance proxy may be less susceptible to the unwanted influence of highly correlated input predictors on the ranking outcome (Hastie et al., 2009).

Figure 11 shows the profiles of *PD* for GR_{Area} (PD_{GRArea}) relative to each individual parameter tested, where increasing values of PD_{GRArea} indicate that the corresponding change on the x-axis for the value of the specific parameter is conducive to faster clearing growth.

Figure 11 displays the PD of clearing GR_{Area} for the range of change in environmental parameters used in the GBRT model. The top-ranking parameter with the highest PD range was air temperature at 850 hPa (T_{850}). The difference in PD range from T_{850} to the next best parameter (q_{950}) was the greatest between any other consecutive pair of parameters. Note that the 5th, 25th, 50th, 75th, and 95th percentiles of input parameter values are denoted in Figure 11 to caution that sharp slopes in the bottom and top 5th percentiles are based on few data points and that robust conclusions should not stem from those outer bounds. The response of PD_{GRArea} to the changes in T_{850} is shown in Figure 11a. T_{850} is closely linked to inversion strength variables such as *LTS* (Klein and Hartmann, 1993) and estimated inversion strength (*EIS*) (Wood and Bretherton, 2006). At constant *SST*, higher T_{850} translates to higher *EIS* and LTS values. It is well-established that inversion strength plays a key role in controlling MBL cloud coverage (Klein and Hartmann, 1993). It is expected that higher T_{850} decreases (increases) GR_{Area} (cloud amount) by enhancing stability. Figure 12a11a shows that up to 290 K, the profile of *PD* exhibits a downward trend as T_{850} increases. Above 290 K, *PD* of GR_{Area} starts to show the opposite trend with increasing T_{850}. As noted in Brueck et al. 2015, "…increased stability is a necessary but not a controlling factor for cloudiness, especially not when it is already sufficiently large. A further increase in inversion strength may thus further limit cloudiness, because it increases the entrainment of relatively drier and warmer air…". Figure 7b6b showed that T_{850} was enhanced off the California coast on clearing days, pointing to the high potential for warm continental air to impact the underlying cloud deck via entrainment. It is important to note that, when the model was run with the same set of parameters but replacing T_{850} with *LTS*, the *PD* profile of *LTS* exhibited a qualitatively similar trend to what was presented for T_{850} in Fig. 12a11a.

The moisture content at 950 hPa was the second most influential parameter. The PD_{GRArea} profile of q_{950} shows increasing values as q_{950} decreases below 8 g kg^{-1}, (Fig. 11b), coincident with dry air that can dissipate clouds and aid in clearing formation and expansion. FurtherSimilarly, the PD_{GRArea} *PD* profile of growth rate generally decreases as q_{850} showed a sharp decrease below values of 2 g kg^{-1}, whereas PD_{GRArea} leveled off above 2 g kg^{-1}.increases (Fig. 11f). In contrast to the other level heights, the PD_{GRArea} profile of q_{700} exhibits an opposite trend but a smaller influence on GR_{Area} (Fig. 12j11j). This can be partly due to the fact that this layer of the FT is not as close to the cloud layer, which in turn can permit other factors besides the entrainment process to stand out. These various humidity parameters clearly show that conditions of dry air close to the MBL top help clearings form and expand, with the most likely source being continental air. The positive relationship between humidity at the level of clouds and low-level cloud amount was reported in earlier studies (Albrecht 1981; Wang et al., 1993; Bretherton et al., 1995; Wang et al., 1993).

~~Sea surface temperature and V_{850} were the next most influential parameters.~~ As previously explained, lower *SST* values are associated with cloudiness (Fig. 11c) and increased *LTS* (Norris and Leovy 1994, Klein and Hartman 1993). Figure ~~12d~~11d displays the dependence of PD_{GRArea} on V_{850}, which is representative of flow in the FT. As discussed already, clearings coincided with CLLJs and strong northerly flow at 850 hPa, which is consistent with the sharp increase in PD_{GRArea} as northerly wind speeds increased above 10 m s^{-1} while otherwise being flat for lower speeds. Stronger northerly flow is associated with offshore flow of dry and warm air that can reside above the cloud top, which can dissipate the cloud layer after entrainment and via enhanced shearing (via Kelvin-Helmholtz instability) and mixing of cloudy parcels with warm and dry air in the FT~~.~~ (e.g., Rahn et al., 2016). As will be shown later, aircraft data showed that typical wind speeds parallel to clear-cloudy interfaces were near or greater than 10 m s^{-1} (Fig. ~~13~~12).

~~Several parameters followed V_{850} in ranking with PD_{GRArea} ranges similar to one another: PBLH, q_{850}, $MSLP_{anom}$, and U_{850}. For PBLH, Figure 12e~~For *PBLH*, Figure 11e suggests that above ~600 m, PD_{GRArea} is relatively insensitive to positive perturbations in PBLH, but below ~600 m, the shallower the MBL, the lower the value of PD_{GRArea}. This potentially can be attributed to the fact that a shallower MBL could be more well-mixed and moisture can get transported from the ocean surface to the cloud layer which promotes cloudiness (Albrecht et al., 1995). Figure ~~12g~~11g shows that for $MSLP_{anom}$ between ~ -560 Pa and ~450 Pa, perturbations do not have much impact on GR_{Area}. However, above ~450 Pa, GR_{Area} is more susceptible to positive perturbations in *MSLP*. This confirms that stronger Pacific high conditions in the study region promote the expansion of clearing events during the day. ~~Also, GR_{Area} is highly sensitive to MSLP anomalies below ~ -560; this can be attributed to a decrease in the dominant pressure system in the region, which is not the optimal condition to sustain the cloud layer.~~ Based on the PD_{GRArea} profiles in Fig. ~~12h~~11h, clearings expanded faster as U_{850} increased above 0 m s^{-1} and decreased below -3 m s^{-1}. Clearing growth due to negative zonal winds can be explained by the offshore flow component, however, the reason for growth during periods of positive zonal winds is unclear.

There was low variability in the range of PD_{GR} for the rest of the parameters shown in Fig. ~~11~~10: *AOD*~~, q_{700},~~ and ω_{700}. Figure ~~12i~~11i shows a decrease in PD_{GRArea} as *AOD* increases up to the value of ~0.12, above which PD_{GRArea} increases as a function of *AOD*. While it is expected that stronger northerly winds associated with clearing expansion promote higher sea salt fluxes (i.e., higher AOD), future work is warranted to investigate as to whether this process subsequently depletes cloud water and thins out clouds via expedited drizzle production via broadening of cloud droplet size distributions, as already suggested in Section 3.2.

The relationship between ω at 700 hPa and PD_{GRArea} is complex. Brueck et al. (2015) suggested that enhanced ω_{700} promotes cloudiness due to its link to higher *LTS*. Myers and Norris (2013) further showed that stronger subsidence can reduce ~~cloud fraction~~*CF* (at fixed inversion strength) by pushing down the top of the MBL, which is also supported by Bretherton et al. (2013). The PD_{GRArea} profile of ω_{700} exhibited a minimum point near a value of 0 – 0.2 Pa s^{-1}, with increases in GR_{Area} below and above that range. The increase in PD_{GRArea} with ~~higher~~ ω values above 0.2 Pa s^{-1} can be attributed to the negative influence of subsidence on lower ~~cloud fraction~~*CF* (via pushing down the top of the MBL) as discussed by Myers and Norris (2013). Conversely, the increase in GR_{Area} with decreasing ω values below 0 Pa s^{-1} can be due to upward motion reducing the strength of the inversion capping the MBL, which is important to sustain the cloud deck. Vertical motions represented by the ω_{700} parameter could also induce dynamical circulations affecting cloud top processes such as shear and entrainment.

It is important to caution that the interpretation of results from the GBRT simulations are speculative and rooted in documented physical relationships between the various parameters shown in Figs. 10-11~~-12~~ and low cloud behavior. One way to try to validate some of the conclusions above is with airborne data for case studies. For instance, in situ data can help confirm the nature of factors discussed above during clearing events, including vertically-resolved winds, primary marine aerosol fluxes in different wind regimes, humidity and temperature of air within and above the MBL, and potential for mixing of air above and below the MBL top. The next section is an attempt to conduct this exercise using three airborne case studies.

3.4 Airborne Case Studies

To gain a more detailed perspective on clearings in the study region, three case flights are examined from the 2016 FASE airborne campaign. For context, Crosbie et al. (2016) examined three different case flights during the 2013 NiCE campaign and provided the following insights, which motivated the FASE flights for further statistics: (i) two of the three clearings (RF19 on 1 August 2013, RF23 on 7 August 2013) were immediately adjacent to the coastline and had reduced specific humidity in the MBL on the clearing side, suggestive of dry continental offshore wind laterally mixing into and dissipating clouds; (ii) the latter two cases also had enhanced temperature in the clear column at cloud-relevant altitudes, which help explain the lack of clouds in the clear column; and (iii) the other clearing flight (RF16 on 29 July 2013) had the clearing positioned to the west of a cloud deck, which was associated with a CTD event along the coastline to the east of the clearing (i.e., southerly surge). ~~This~~The latter case exhibited warmer temperatures in the clear column only in the top 100 m of the MBL with similar specific humidity profiles, but with cooler and moister air above the inversion base in the clear column. This case was suspected to be linked to entrainment and mixing of dry air into the cloud deck to produce the clearing, but it was not a case of subsidence/divergence, otherwise the air in the clear column would have been warmer and drier above the inversion base.

For the three FASE case flights, the clearing was always situated to the west of a cloud deck touching the coastline (Figs. 2, S1-S2). This positioning is reminiscent of NiCE RF16, which was less sensitive to lateral entrainment of continental air in comparison to the other two NiCE flights. Wind data were decomposed into *u* and *v* components to represent speeds that are perpendicular and parallel, respectively, to the clear-cloudy interface. Figure 2d illustrates an example of how these two components of winds varied during RF09A. There were substantial changes in *v* on the two sides of the clear-cloud border, with stronger northerly winds on the clear side, reaching as high as 20 m s^{-1}, in contrast to about half that magnitude on the cloudy side. Wind speed with the intensity of as high as 20 m s^{-1} is close to the values reported in previous studies associated with California CLLJs (Parish 2000; Ranjha et al., 2013; Lima et al., 2018). Furthermore, wind profiles obtained from soundings (Fig. 12) exhibit the structure similar to CLLJ on clearing columns with enhanced horizontal wind speed at the altitude near the MBL top. It is noteworthy that the cloud edge tends to reside in the transition region where the near cloud top flow becomes similar to CLLJ (Figs. 2d and 12). The same substantial change in *v* across the

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

interface was also present in RF08 and RF09B with stronger *v* winds always on the clear side. There was no substantial change in the *u* component of wind speed between the two columns in each of the three flights.

To extend upon the possibility of shearing effects, absolute changes in *v* ~~(|v|)~~(|*v*|) were calculated for level legs performed at the clear-cloudy border for the three research flights (Table 2). For consistency, these calculations were based on level legs of a constant length of ~40 km with relatively equal spacing on both sides of the clear-cloudy border. ~~|v|~~|*v*| was calculated by multiplying 40 km by the slope of the linear fit of *v* versus distance from cloud edge, where negative (positive) x values represent distance away from the edge on the clear (cloud) side. The results reveal that the horizontal wind shear was strongest somewhere between mid-cloud and cloud top altitudes, with the lowest values at the FT level. The lowest values in the MBL were observed in the surface legs. This can be attributed to turbulent transport of the momentum (Zemba and Friehe 1987) to the surface and the consequent drop in CLLJ wind speeds in the clear column. In addition, Fig. S7 shows absolute horizontal shear (|d*v*/d*x*|) as a function of distance from the cloud boundary for the parallel component of horizontal wind speed. Horizontal shear profiles for all research flights (Fig. S7) are slightly noisy especially at the surface legs, but they show the presence of the greatest horizontal wind gradient within 5 km length away from clear-cloudy edge. Shear at the clear-cloudy edge, especially at cloud levels, can support clearing growth through enhancing the mixing of cloudy and clear air. Crosbie et al. (2016) also showed using the case of NiCE RF19 that that mixing of cloudy air with adjacent clear air can be an important contributor to cloud erosion and thus expansion of clearings. To probe deeper into the clearing cases, the subsequent discussion compares vertically-resolved data on both sides of the clear-cloudy border based on soundings and level legs.

3.4.1 RF08

RF08 (2 August 2016) represented a case similar to the NiCE RF16 (29 July 2013) case study in Crosbie et al. (2016) where cooler and moister air above the inversion in the clear column was speculated to be due to entrainment and mixing eroding the cloud rather than subsidence and divergence catalyzing cloud dissipation. Of note is that there was rapid infill of cloud the night of the NiCE FR16 flight. FASE RF08 data showed that potential temperature was warmer (~1 K) in the MBL of the clear column as compared to the cloudy column, while in the FT, the air was slightly warmer on the cloudy side (Fig. ~~13~~12). *SST* was also approximately 0.4 K higher in the clear column (Table 3). Specific humidity was almost identical in the MBL on both sides, but air was moister above the inversion base on the clear side. As noted above, vertical profiles of *u* revealed little difference between the two columns, but *v* values were nearly twice as high in the clear column extending from the surface to approximately 200 m above cloud top. Surface wind speeds were also enhanced on the clear side, which resulted in greater friction velocity (u^* = 0.40 m s^{-1} vs 0.15 m s^{-1} on the cloudy side).

An important feature was the wind maximum in and above the inversion layer on the clear side, which resulted in larger vertical shear across the inversion on the clear side (5.44 m s^{-1}) compared with the cloudy side (0.8 m s^{-1}) (see ΔU, Table 3). The strong shear on the clear side likely facilitated mixing of MBL air with drier and warmer FT air. This is supported by a lower temperature gradient $(\Delta\theta_l/\Delta z)_{max}$ in the inversion layer of the clear column (0.32 K m^{-1} ~~vs~~versus 0.38 K m^{-1}), which was thicker than the cloudy column (82 m ~~vs~~versus 55 m). ~~A further effect of the~~The wind maximum in the clearing ~~was to increase~~also enhanced moisture advection, ~~counteracting~~which counteracted the accumulation of moisture caused by mixing induced by

vertical shear.~~ ~~ This was most significant at the cloud top level as seen in the largest difference in the edge-parallel wind |*v*| (Table 2). ~~ ~~In the absence of cloud, the effects of longwave radiative cooling close to the cloud top level would be subdued allowing shear-induced mixing to erode the sharpness of the inversion. Redistribution of moisture into the inversion also serves to insulate lower layers from longwave cooling, further delaying the formation of cloud. The difference in |*v*| was smallest close to the surface, indicating that the wind maximum in the clearing had a (comparatively) ~~lesser~~reduced effect in enhancing surface moisture fluxes. Satellite imagery confirms that later in the day, the cloud layer filled-in partially where the clearing was with the presumed help of nocturnal radiative forcing.

The cloud layer in RF08 was the thinnest (131 m) with the shallowest MBL among all three cases. In addition, the lowest N_d (107 cm^{-3}), largest r_e (6.6 µm), and highest cloud base rain rate (0.48 mm day^{-1}) was measured in RF08 of all three cases. The enhanced rain can likely explain why the surface aerosol concentrations from the PCASP were lowest in RF08 (106-108 cm^{-3} vs 186-236 cm^{-3} for the other two flights) even though surface winds were highest, specifically due to efficient wet scavenging of aerosols. This possibility is at least linked to the speculation reported earlier in Sections 3.2 and 3.3 that stronger northerly winds linked to the growth of clearings result in sea salt expediting rain formation in clouds and thus thinning them out. In support of this notion, cloud water composition results are of relevance as they provide an indication of the relative influence of giant *CCN* (*GCCN*) in the form of sea salt, as previously demonstrated in the region by Dadashazar et al. (2017). The combined concentration of sodium (Na^+) and chloride (Cl^-) was 60 µg m^{-3}, 33 µg m^{-3}, and 64 µg m^{-3} for RF08, RF09A, and RF09B, respectively. In contrast, the average combined sum of Na^+ and Cl^- for all samples collected in FASE was 14 µg m^{-3}. Based on a two-tailed student's t-test with 95% confidence, the means of RF08 and RF09B were significantly different than the mean of all FASE samples. The $Cl^-:Na^+$ mass ratios in all three FASE clearing flights (RF08 = 1.80, RF09A = 1.78, RF09B = 1.79) were very close or matching that of pure sea salt (1.81), providing more confidence that sea salt was impacting these clouds via serving as *CCN*. The cloud water results are in support of *GCCN* enhancing drizzle in RF08 and thus thinning out clouds and removing aerosol underneath the cloud base. It is unclear with this dataset though as to what role the impact of sea salt in depleting clouds of their water had to do with the actual clearing, but at least there is support for this process potentially impacting the cloudy column. ~~Consistent with the NiCE clearing cases, aerosol concentrations were relatively similar on both sides of the clear-cloudy border for all three FASE cases.~~

Figure ~~14~~S8 shows vertical profiles of aerosol concentrations on both sides of the clearing border, highlighting differences above cloud top level especially in RF09A and RF09B with higher values in the cloudy column. Higher aerosol concentrations were also observed in the cloud column in the sub-cloud layer even though surface wind speeds were always higher in the clear column for all three flights. Surface winds and thus sea spray production do not exclusively influence the aerosol concentrations. A likely explanation of higher concentrations in the MBL in the cloudy column is that there could be entrainment of more polluted free tropospheric aerosol as has been reported to be a common occurrence during the FASE flights (Mardi et al., 2019). As also reported during FASE, there can be sub-cloud evaporation of drizzle resulting in droplet residual particles that contribute to the aerosol concentration budget in the cloudy column (Dadashazar et al., 2018).

Figure 13 displays turbulence parameters such as variance in the three components of wind speed (Fig. ~~14a~~13a-c~~)~~), turbulent kinetic energy (Fig. 13d), and buoyancy flux (Fig. ~~14d~~13e). Stronger horizontal wind ~~speeds~~speed gradients, and consequently stronger shear production, near

Formatted: Font: Italic

the surface on the clear side resulted in greater variance in the horizontal wind components at all MBL levels. Both $\overline{u'^2}$ and $\overline{v'^2}$ exhibit a general downward trend with increasing altitude, which is also supportive of shear driven turbulence. On the other hand, $\overline{w'^2}$, which is closely associated with cloud layer properties, exhibits a different trend on the cloudy side as it increases from cloud base to mid-cloud level. For surface and above cloud base levels, $\overline{w'^2}$ is higher in the clear column likely due to the combined influence of shear and buoyancy terms on the turbulence budget. On the other hand, in the mid-cloud layer, $\overline{w'^2}$ is slightly higher (Fig. ~~14c~~13c) in the cloudy column as compared to clear ~~one~~column, which can be attributed to the buoyancy flux (Fig. ~~14d~~13e). It is also interesting to note that RF08 is the only flight with a minimum in $\overline{w'^2}$ being at the level above cloud base in the cloudy column relative to other MBL levels. This is most likely due to lower buoyancy production in the cloud layer of RF08 as compared to the other flights.

To further investigate the relative role of each buoyancy and shear term in the turbulence budget, the $-z_i/L_{MO}$ ratio was compared between the two columns (Table 3). This ratio is an order of magnitude greater in the cloudy column as compared to clear one due to the latter column having stronger shear and reduced buoyancy flux. This confirms that shear is most likely the dominant mechanism for turbulence production in the clear column in the absence of the cloud layer.

3.4.2 RF09A and RF09B

The two flights on 3 August 2016 allowed for an opportunity to contrast clearing properties at two different times on the same day at roughly the same location (~20 km apart). Owing to their similarities, they are discussed together here. The clearing module in RF09A was performed between 11:00 and 12:30 PST, while that during RF09B was performed between 15:00 - 17:00 PST. Similar to RF08, MBL air in the clear column of RF09A and RF09B was slightly warmer than the cloudy column; however, the magnitude of the temperature difference (clear – cloudy) decreased from RF09A (~1.1K) to RF09B (~0.8K). *SST* was also greater by 0.4 K in the clear column of RF09A as compared to the cloud column, while it was slightly cooler by 0.1 K in the clear column of RF09B.

Specific humidity profiles in RF09A/RF09B exhibit more subtle differences as compared to RF08. In contrast to RF08, air in RF09A above the inversion base was drier and warmer in the region immediately above the inversion base and differences above the inversion base are less clear for RF09B. During both RF09A and RF09B, the clear profile exhibited steadily decreasing levels of water vapor with altitude, while the cloudy column was more well-mixed. The *v* component of wind speed again exhibited substantially greater values in the clear column as compared to the cloudy column for both RF09A and RF09B. Looking at the inversion layer properties (Table 3), the temperature gradient was lower and shear was greater in the clear column of RF09A and RF09B. Inversion depth was also greater in the clear column of RF09A, but less so for RF09B.

The sounding data in RF09A qualitatively resemble those from NiCE RF19 on 1 August 2013 where Crosbie et al. (2016) suspected that there was increased local subsidence and divergence in the clear column. Similar to their case, we observed the following in the clear column of RF09A: (i) warmer and drier air above and below the inversion base; (ii) the inversion base height was lower (354 m ~~vs~~versus 375 m) with reduced temperature gradient in the inversion layer (0.33 K km^{-1} ~~vs~~versus 0.41 K km^{-1}); and (iii) potential temperature exhibited warming and drying in the layer equivalent to the top 100 m of cloud. The RF09B case differed in that above the

Formatted: Font: Italic

Formatted: Font: Italic

Formatted: Font: Italic

inversion base, the air in the clear column was not warmer and drier but very slightly cooler and moister, similar to RF08. This potentially is due to the diurnal nature of the clearing system where there is a stronger forcing to dissipate clouds during mid-day with the help of subsidence of dry and warm air from the FT, whereas later in the afternoon that process switches to a scenario where cooler and moister air exists above the inversion base and there is a waiting process for stronger radiative forcing to form a cloud again.

The cloud layer is the thickest in RF09A (191 m) among all three case flights. The cloud layer became thinner (137 m) later in the day during RF09B as a result of a change in the lifting condensation level (*LCL*), where cloud base increased from 217 m to 265 m. Moreover, *LWP* decreased during the day from 32 g m^{-2} to 18 g m^{-2}. It is important to note that the adiabaticity parameter, defined as the ratio of measured *LWP* to *LWP* of an adiabatic cloud, exhibited values of 0.75, 0.76, and 0.83 for RF08, RF09A, and RF09B, respectively. These adiabaticity values are close to the average value of 0.766 for the region reported in Braun et al. (2018). The clouds were quite thin near the interface based on the relatively low values of *LWP* in contrast to typical conditions observed in the region based on airborne measurements in the same campaigns (Fig. 3 of Sorooshian et al., 2019). Other cloud properties such as N_d, r_e, and rain rate were quite similar in both RF09A and RF09B. N_d was greater in RF09A and RF09B as compared to RF08, corresponding to smaller values of r_e and suppressed drizzle. The dataset cannot provide unambiguous evidence as to whether the higher surface aerosol concentrations in RF09A and RF09B, as compared to RF08, were due to (or led to) suppressed drizzle.

Profiles of $\overline{u'^2}$ and $\overline{v'^2}$ exhibited downward trends with increasing altitude for RF09A and RF09B, in general agreement with the findings for RF08. One contrasting aspect was the comparison of $\overline{v'^2}$ between clear and cloudy columns, which mirrored RF08 during RF09A, while in RF09B, the values of $\overline{v'^2}$ for the clear side were substantially lower. In addition, $\overline{w'^2}$ profiles during RF09A and RF09B are substantially enhanced in the cloudy column as compared to RF08, with maxima in the cloud layer. There is an accompanying increase in the buoyancy flux for these profiles suggestive of a more significant contribution of buoyancy to *TKE* production. (Fig. 13e). Although more subtle, $\overline{u'^2}$ values also showed an increase in the cloudy columnscolumn of RF09A and RF09B relative to the clear column, also supportive of the role of buoyancy in these cases. In addition, *TKE* profiles (Fig. 13d) were largely influenced by variances in the horizontal component of wind speed ($\overline{u'^2}$ and $\overline{v'^2}$) which led to overall greater *TKE* values in the clear column except for RF09B.

Drizzle may be an important factor in governing the differences in buoyancy between the cloudy columns of RF09A/B and RF08, by creating a stabilizing effect.. While no obvious decoupling of the RF08 cloudy MBL is observed, this profile may rely more heavily on shear production to maintain a well-mixed state. The clearing persisted following RF08, while there was a rapid infilling of cloud during the night following RF09A/B, similar to the case presented by Crosbie et al. (2016), which was also non-drizzling. While the nocturnal radiative environment has been shown to be conducive to infilling of clearings, we hypothesize that other factors that promote tighter coupling between the cloud layer and the surface (such as a lack of drizzle) may also contribute.

4 Conclusions

This study extends upon recent works interested in large stratocumulus clearings that significantly impact albedo and have implications for fog, cloud, and weather forecasting. We specifically reported on ten years (2009-2018) of satellite and reanalysis data to characterize the temporal behavior, spatial and dimensional characteristics, growth rates, and governing environmental properties controlling the growth of clearings off the U.S. West Coast. We also examined three case flights from the 2016 FASE campaign that probed clearings to gain a deeper insight at finer spatial scales to try to validate speculated links between environmental parameters and clearing growth rates based on machine learning simulations using satellite and reanalysis data. The major results were as follows:

(i) Summertime (wintertime) experiences the highest (lowest) frequency of clearings visible from spaceas suggested by satellite retrievals.

(ii) The centroid of clearings is centeredlocated around coastal topographical features along the California coastline, specifically Cape Blanco and Cape Mendocino.

(iii) The median length, width, and area of clearings between 09:00 and 18:00 (PST) increased from 680 km, 193 km, and ~67,000 km^2, respectively, to ~1231 km, 443 km, and ~250,000 km^2. The most growth occurred between 09:00-12:00.

(iv) The most influential factors in clearing growth rates of total area between 09:00-12:00 were T_{850}, q_{950}, *SST*, and V_{850}.$MSLP_{anom}$ using two different scoring methods. Compared to non-clearing days, clearing days were characterized by having an enhanced Pacific high shifted more towards northern California, offshore air that is warm and dry, faster coastal surface winds, higher lower tropospheric static stability, and stronger subsidence.

(v) Clearing days exhibited higher values of N_d and reduced values of r_e, τ, and *LWP* near the California coast where clearings form and evolve. However, the mean cloud albedo over the entire study domain was actually higher on clearing days.

(vi) Airborne data revealed that extensive horizontal shear at cloud-relevant altitudes, with much faster winds with low-level jet structure parallel to the clearing edge on the clear side as compared to the cloudy side. This helped to promote mixing and thus dissipation of clouds. Differences in sounding profiles reveal that warm and dry air in the free troposphere additionally promoted expansion of clearings.

More research is needed to further characterize clearings and the broader regions they evolve in. For instance, it remains uncertain as to if there is a physical link between the existence of clearings and a higher domain-wide cloud albedo on clearing days. More data such as those provided by GOES platforms can help understand processes occurring at the microscale that scale up to more climatologically relevant scales. The results of this work showed that there are important diurnal features that require additional examination with in situ observations. One of the hypotheses posed in this work requiring more measurements and statistical robustness is the link between sea salt aerosol and the formation and evolution of clearing events. Clearing days are characterized by having stronger northerly winds, which translate into higher sea spray fluxes, which and subsequently can impact clouds via faster onset of drizzle. This chain of events subsequently can thin out clouds via depletion of cloud water. Targeted experiments to examine these types of events will help advance understanding about their nature, which can then be contrasted with clearings along other coastal regions such as the southeastern Atlantic Ocean. Also, the nature of clearings has direct relevance to CTD events that evolve in similar regions as discussed by Juliano et al. (2019a,b).

Data availability

Airborne field data used in this work can be found on the Figshare database (Sorooshian et al., 2017; https://figshare.com/articles/A_Multi-Year_Data_Set_on_Aerosol-Cloud-Precipitation-Meteorology_Interactions_for_ Marine_Stratocumulus_Clouds/5099983). Also, the ~~satellite and reanalysis~~other data used ~~can be obtained from~~in this study are available at websites ~~listed~~provided in ~~Sections 2.1-2.~~Section 2.

Author contributions

EC~~, XZ,~~ and AS designed the study. HJ, AS, EC, and HD conducted the research flights ~~in~~during the FASE field campaign. MSM and HD developed the image analysis tool to analyze GOES images. MP, HD, and MAM ~~conducted~~ran the GBRT model. HD analyzed the collected data. AB, MB, and XZ provided ~~inputs for various part of project~~input on the results and draft. AS and HD wrote the paper. EC, MAM, AB, MB, and XZ revised the manuscript.

Competing interests

The authors declare that they have no conflict of interest.

Acknowledgments

This work was funded by Office of Naval Research grant N00014-16-1-2567 and NASA grants NNX14AM02G and 80NSSC19K0442, the latter of which is in support of the ACTIVATE Earth Venture Suborbital-3 (EVS-3) investigation, which is funded by NASA's Earth Science Division and managed through the Earth System Science Pathfinder Program Office.

We acknowledge Johannes Mohrmann and an anonymous reviewer for their constructive feedback.

Table 2. Absolute changes in the parallel component of horizontal wind speed relative to the cloud edge, |Δ*v*| in units of m s^{-1}, across various legs using FASE aircraft data. Values were calculated based on a 40 km leg distance (approximate length of each leg). Values for the cloud top leg were estimated using the sawtooth leg performed across the cloud top boundary. The free troposphere level leg was not conducted in RF08 and thus left blank.

	RF08	RF09A	RF09B
Free troposphere		0.4	1.6
Cloud top	9.6	6.4	4.8
Mid-cloud	7.2	6.8	6.0
Above cloud base	6.8	5.2	5.2
Surface	3.6	2.4	0.0

Formatted: Font: Italic

Table 3. Summary of thermodynamic, dynamic, and cloud properties on both sides of the clear-cloudy interface for three FASE case research flights (RFs). *U* represents total horizontal wind speed ($U = \sqrt{u^2 + v^2}$) across the depth of the inversion layer.

	Cloudy			Clear		
	RF08	RF09A	RF09B	RF08	RF09A	RF09B
SST (K)	286.6	287.1	287.3	287.0	287.5	287.2

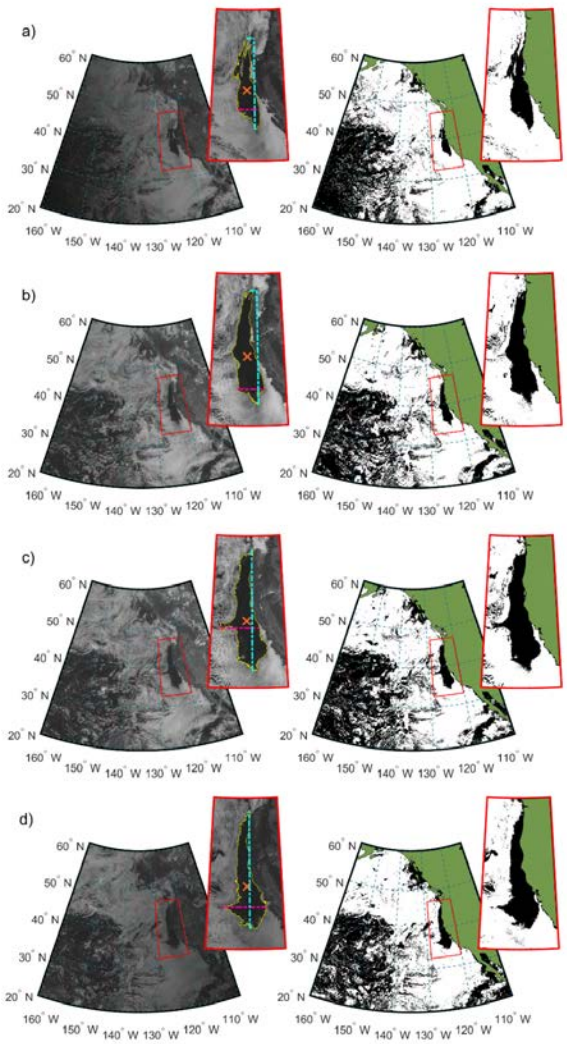

Figure 1. Sequence of data processing with GOES imagery at four times during a day: (i) 16:15 UTC 09 August 2011; (ii) 19:15 UTC 09 August 2011; (iii) 20:45 UTC 09 August 2011; and (iv) 01:15 UTC 10 August 2011. Left panels show visible-band images of a clearing event obtained from GOES-11 data, while the right panel is produced using cloud masking. Note that the clearing border, centroid, and lengths (x and y) are overlaid on the GOES images. Local time (PST) requires subtraction of seven hours from UTC time.

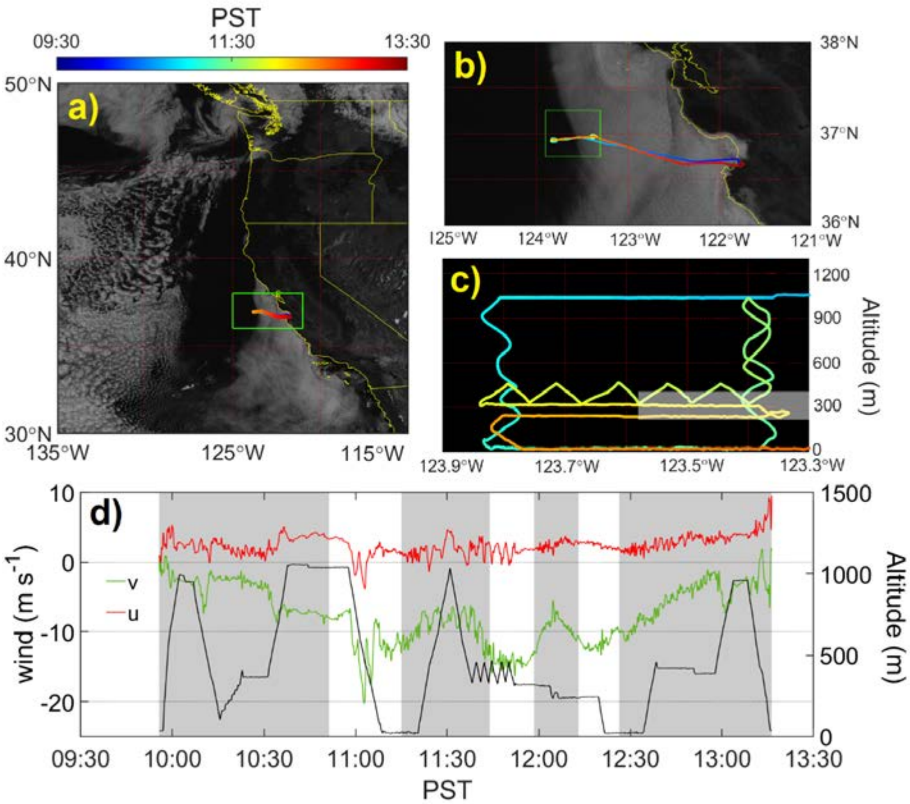

Figure 2. a) GOES 15 visible band image (11:45 (18:45) PST (UTC) on 03 Aug 2016) with the overlaid flight path of FASE RF09A. b) Zoomed-in view of the satellite image to highlight the clear-cloudy border. c) Aircraft flight strategy at the cloudy-clear interface for the green box highlighted in b). Cloud borders are denoted by a shaded box. d) Time series of flight altitude and horizontal wind speed, which is decomposed into two components that are perpendicular (*u*) and parallel (*v*) to the cloud edge. Wind speeds were smoothed using low-pass filtering. Parts of the flight that sampled air on the cloudy side of the clear-cloudy border are shaded in grey.

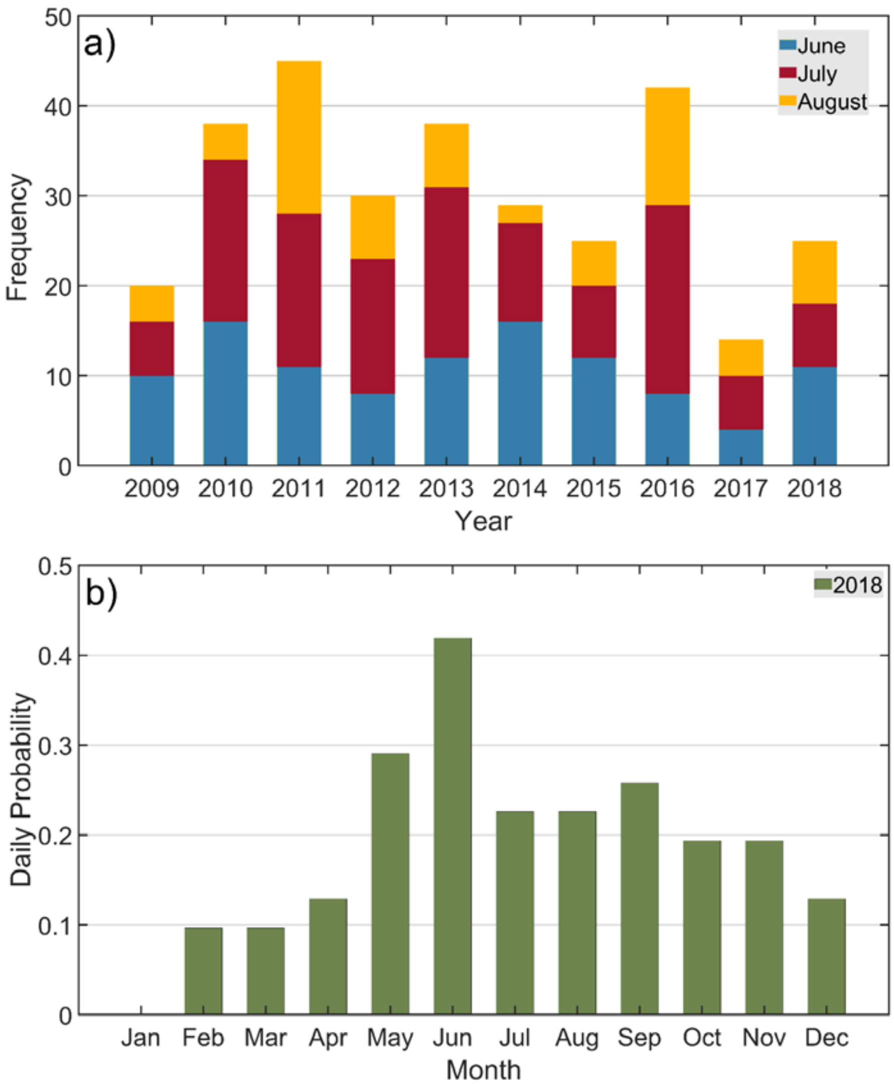

Figure 3. a) Frequency of clearing events in the study region for each summer month between 2009 and 2018. b) Daily probability of clearing events (i.e., days with clearings divided by total days in that month) in each month of a representative year, 2018.

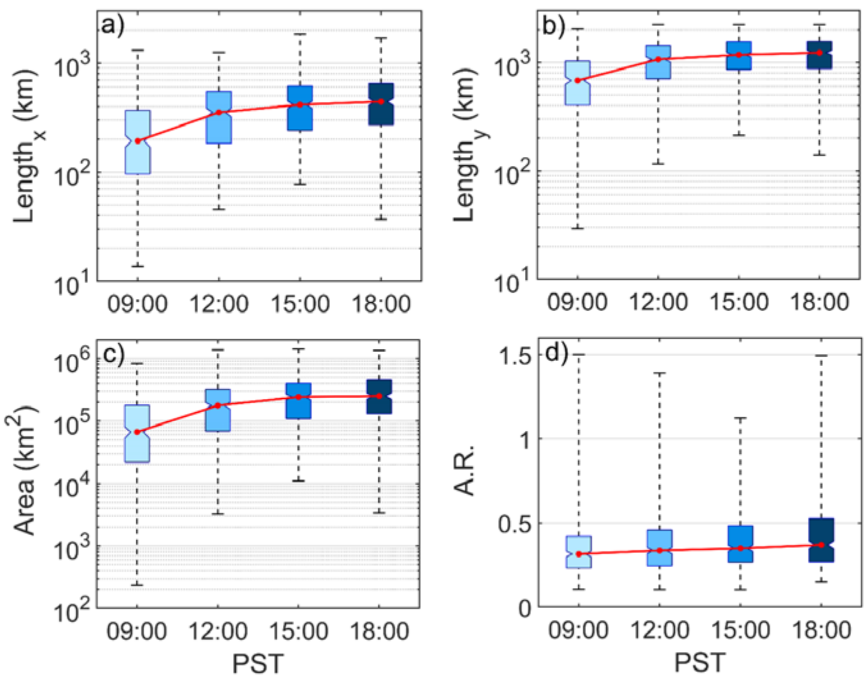

Figure 4. Diurnal profiles of (a) widest point of clearings at a fixed latitudinal value, (b) longest dimension between the maximum and minimum latitudinal coordinates of a clearing regardless of longitudinal value, (c) total clearing area, and (d) aspect ratio of clearing (i.e., width divided by length using the maximum values as described by panels a-b). The box and whisker plots show the median values (red points), the 25th and 75th percentile values (bottom and top of boxes, respectively), and minimum and maximum values (bottom and top whiskers, respectively).

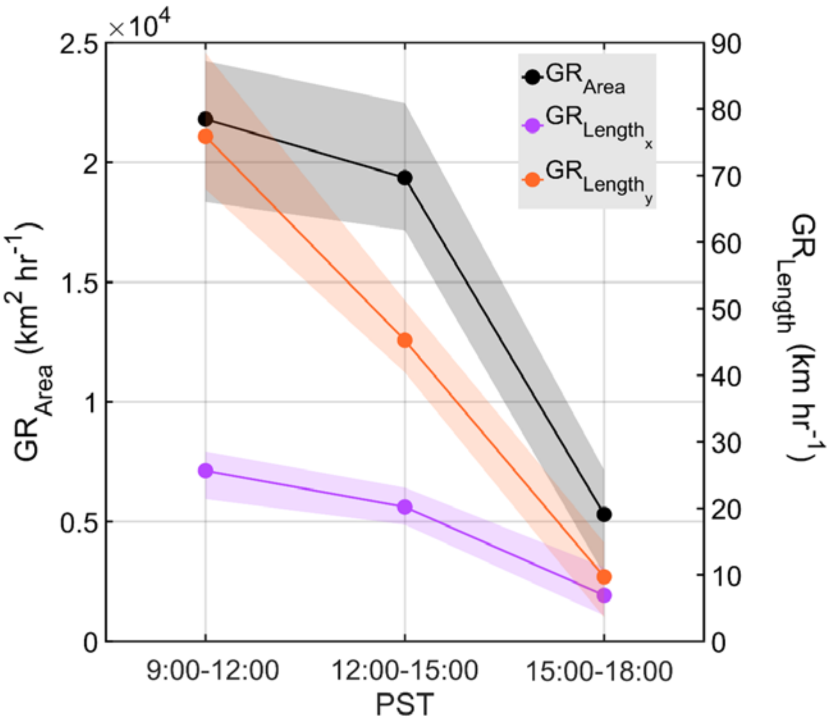

Figure 5. The median growth rate of clearing area (left y-axis) and width and length of clearings (right y-axis) over three hour increments. Shading of curves represents 95% confidence intervals calculated using bootstrapping (n =10,000).

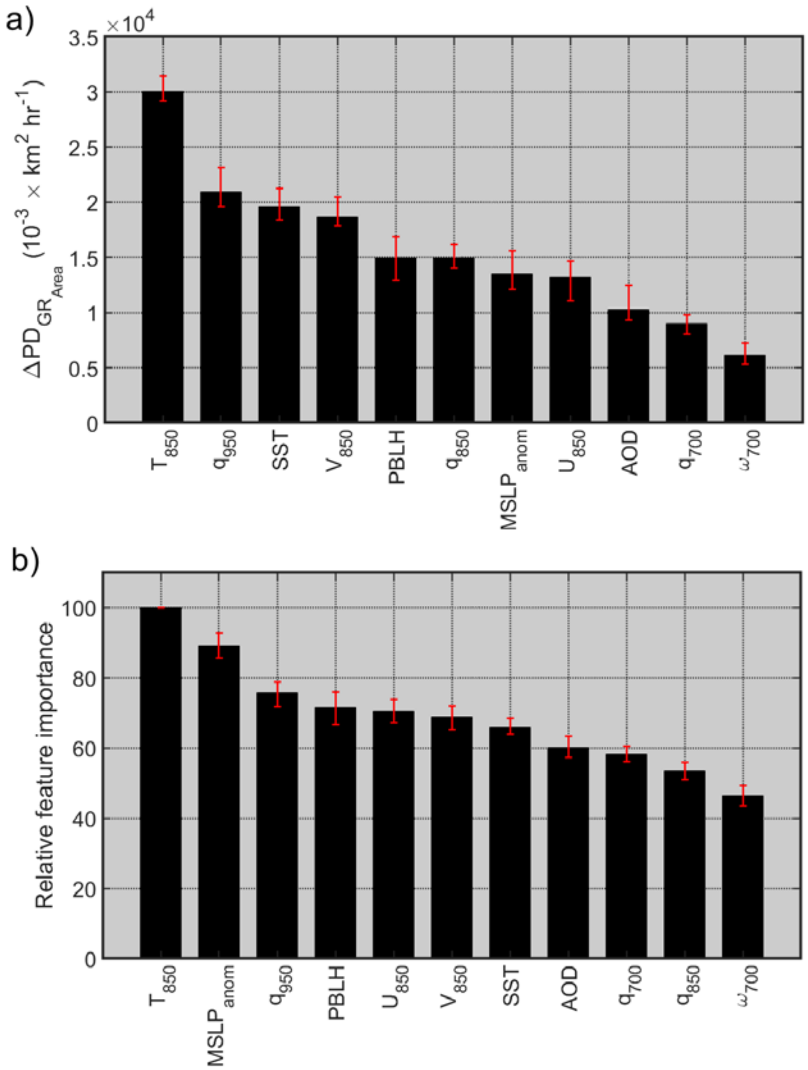

Figure 11. The**10.** Two scoring methods used for measuring the relative influence of input variables in the GBRT model: a) the median difference of maximum and minimum partial dependence (*PD*) of clearing growth rate (GR_{Area}), and b) the median of relative feature importance calculated based on the method developed by Friedman (2001). Error bars represent the range of variability in 30 model runs. Note that GBRT simulations were performed using clearing growth rates obtained from the analysis of first and second GOES images (~09:00 – 12:00 PST) for all 306 clearing events examined.
