Abstract. The dependence of aerosol acidity on particle size, location and altitude over Europe during a summertime period is investigated using the hybrid version of aerosol dynamics in the chemical transport model PMCAMx. The pH changes more with particle size in northern and southern Europe owing to the enhanced presence of non-volatile cations (Na, Ca, K, Mg) in the larger particles. Differences of up to 1-4 pH units are predicted between sub- and super-micron particles, while the average pH of PM_{1-2.5} can be as much as 1 unit higher than that of PM₁. Most aerosol water over continental Europe is associated with PM₁, while coarse particles dominate the water content in the marine and coastal areas due to the relatively higher levels of hygroscopic sea salt. Particles of all sizes become increasingly acidic with altitude (0.5-2.5 units pH decrease over 2.5 km) primarily because of the decrease in aerosol liquid water content (driven by humidity changes) with height. Inorganic nitrate is strongly affected by aerosol pH with the highest average nitrate levels predicted for the PM₁₋₅ range and over locations where the pH exceeds 3. Dust tends to increase aerosol pH for all particle sizes and nitrate concentrations for supermicron range particles. This effect of dust is quite sensitive to its calcium content. The size-dependent pH differences carry important implications for pH-sensitive processes in the aerosol.

1. Introduction

Acidity is an aerosol property of central importance driving gas-particle partitioning and heterogeneous chemistry (Pye et al., 2020). pH affects the formation of semi-volatile particulate

matter and the nitrogen cycle by modulating $\text{HNO}_3/\text{NO}_3^-$ and $\text{NH}_3/\text{NH}_4^+$ gas-particle partitioning (Meskhidze et al., 2003; Guo et al., 2017; Nenes et al., 2019). Aerosol acidity can influence pH-dependent heterogeneous atmospheric processes, like oxidation of SO_2 to sulfate, formation of secondary organic aerosol and uptake of N_2O_5 on particles (Huang et al., 2011) and also influences aerosol hygroscopicity (Hu et al., 2014). Deposition of acidic particles causes damage on building materials, forests, and aquatic ecosystems (Xue et al., 2011). Aerosol pH can change the solubility of metals, such as iron and copper, which have been linked to aerosol toxicity, and at the same time affects nutrient distributions with impacts on photosynthesis productivity and ocean oxygen levels (Meskhidze et al., 2003; Nenes et al., 2011). Adverse health outcomes have been linked to aerosol acidity, including respiratory diseases (Raizenne et al., 1996), oxidative stress (Fang et al., 2017) and lung and laryngeal cancers (Hsu et al., 2008).

The nitrate partitioning to the aerosol phase is favored when pH exceeds a threshold value (between 1.5 and 3) that depends logarithmically on liquid water content and temperature (Meskhidze et al., 2003; Guo et al., 2016; Nenes et al., 2019). If aerosol pH is high enough (typically above 2.5 to 3), aerosol nitrate formation is favored, as most of the total nitrate formed from NO_x chemistry resides in the aerosol phase. For lower pH values (below 1.5 to 2), formation of aerosol nitrate is not favored and remains in the gas phase as HNO_3 . Between these pH value limits, a sensitivity window (of 1 to 1.5 pH units) exists in which nitrate can be found either as gas or as aerosol (Vasilakos et al., 2018; Nenes et al., 2019). Atmospheric aerosol has often pH values inside this sensitivity window, for which pH errors could translate to importance biases in aerosol composition (Bougiatioti et al., 2016; Guo et al., 2015, 2017; Vasilakos et al., 2018).

Aerosol acidity and partitioning of semi-volatile species, like nitrate, can be modulated by the presence of soluble inorganic cations of sea salt and mineral dust, such as Na^+ , K^+ , Ca^{2+} and Mg^{2+} (Vasilakos et al., 2018). These non-volatile cations (NVCs) tend to reside in the coarse mode of ambient aerosol (sea salt, dust), with much lower concentration in smaller particles (Seinfeld and Pandis, 2006). Chemical transport models tend to overpredict aerosol inorganic nitrate levels in both US and Europe (Yu et al., 2005; Pye et al., 2009; Fountoukis et al., 2011; Tuccella et al., 2012; Heald et al., 2012; Walker et al., 2012; Im et al., 2015; Ciarelli et al., 2016; Bian et al., 2017; Zakoura and Pandis, 2018). One of the reasons for these errors is that these models do not simulate properly the aerosol acidity introducing errors in gas-particle partitioning of semi-volatile species, often affecting predictions of inorganic nitrate (Vasilakos et al., 2018).

65 The effect of amines and organic acids on pH is usually neglected in efforts to simulate
 aerosol pH (Pye et al., 2020). In areas with high organic aerosol concentrations and relatively
 low inorganic ion levels, organics could play a non-negligible role in determining particle pH
 (Bougiatioti et al., 2016). The aerosol pH has been estimated combining field measurements and
 aerosol thermodynamic models. Katoshevski et al. (1999) predicted that the pH of the
 70 submicrometer marine aerosol is several units lower than that of the super-micrometer particles.
 pH was estimated to be 0 to 2 for the accumulation mode and 2-5 for the coarse mode particles
 using aerosol and gas phase data collected over the Southern Ocean in combination with the
 EQUISOLV II model (Fridlind and Jacobson, 2000). Keene et al. (2004) calculated mean pH,
 ranging from 2.6 to 3.9, for 0.75-25 μm particles based on measurements by an impactor for
 75 aerosols and Teflon filters for gases in New England during summer. $\text{PM}_{2.5}$ pH was calculated
 with ISORROPIA II in Beijing during all seasons in 2016-2017 with values ranging from 3.8 to
 4.5 (Ding et al., 2019). Guo et al. (2015) estimated that PM_1 particle pH varied from 0.5 to 2 in
 the summer and 1 to 3 in the winter in the Southeastern US. PM_1 pH was estimated for the
 northeastern US and its mean value was 0.77 (Guo et al., 2016). $\text{PM}_{2.5}$ pH values of 0-2 were
 80 estimated combining ISORROPIA II and data collected at a rural southeastern US site during
 summer 2013 (Weber et al., 2016). Based on impactor measurements in Atlanta, GA during the
 spring of 2015, Fang et al. (2017) calculated a mean pH value of 3.5 for the coarse mode
 particles using the ISORROPIA II model. Guo et al. (2017) calculated PM_1 and $\text{PM}_{2.5}$ pH (equal
 to 1.9 and 2.7) from measurements during the CalNex study in combination with ISORROPIA
 85 II. An average PM_1 pH equal to 2.2 was estimated in a rural southeastern US site using
 ISORROPIA II (Nah et al., 2018). Vasilakos et al. (2018) used the three-dimensional chemical
 transport model, CMAQ, along with ISORROPIA II, to predict the annual average $\text{PM}_{2.5}$ pH
 over the Eastern US for 2001 and 2011 (pH equal to 1.6 and 2.5, respectively). Bougiatioti et al.
 (2016) calculated PM_1 pH (between -0.97 and 3.75) using ISORROPIA II in the eastern
 90 Mediterranean. Squizzato et al. (2013) estimated a mean $\text{PM}_{2.5}$ pH value equal to 3.1 over Po
 Valley, Italy during 2009 based on filter measurements using the E-AIM thermodynamic model.
 A comprehensive survey of pH studies to date including observation-based aerosol pH estimates
 in sites around the world can be found in Pye et al. (2020).

Most of the previous studies focused on the average pH of a particular size range
 95 neglecting potential pH variation with particle diameter. There is evidence that pH may vary by
 as much as 6 units between particle diameters of 0.1 μm to 10 μm (Fang et al., 2017; Ding et al.,
 2019). The majority of previous work has focused on select locations in the US, Canada and

Asia and there is still little information about Europe. Also, there is only one study that links aerosol acidity with altitude (Guo et al., 2016), indicating the need for further investigation.

The aim of our work is to investigate the size-dependent aerosol pH over Europe. For this purpose, the Particulate Matter Comprehensive Air quality Model with extensions, PMCAMx, including the thermodynamic model ISORROPIA II, was used. Europe is particularly interesting, owing to the large concentration of NH_3 , nitrate, sulfate and dust across all sizes. The role of dust, Ca^{2+} and the variation of aerosol pH with altitude are analyzed in detail.

2. Model description

PMCAMx (Tsimpidi et al., 2010; Karydis et al., 2010) is based on the CAMx air quality model (Environ, 2003) to simulate the processes of horizontal and vertical advection, horizontal and vertical diffusion, wet and dry deposition, gas and aqueous-phase chemistry. A sectional approach is used to dynamically track the evolution of the aerosol mass and composition distribution across 10 size sections covering a diameter range from 40 nm to 40 μm . The first 5 size bins represent the PM_1 fraction, while 3 size bins are used to describe the coarse PM_{1-10} fraction ($\text{PM}_{1-2.5}$, $\text{PM}_{2.5-5}$, PM_{5-10}). The model assumes that each size section is internally mixed, therefore all particles in that size range have the same composition. The aerosol components modeled include sulfate, nitrate, ammonium, sodium, chloride, calcium, potassium, magnesium, other inert crustal material, elemental carbon, water, primary and secondary organic species. The thermodynamics of inorganic aerosol species is simulated using the ISORROPIA-II model (Fountoukis and Nenes, 2007), assuming that the aerosol exists only in liquid form and is therefore in a metastable equilibrium state at low relative humidity. The gas-phase chemical mechanism used in this application is based on the SAPRC mechanism (Carter, 2000; Environ, 2003). The version of SAPRC mechanism used here includes 237 reactions of 91 gases, 18 radicals and 37 aerosol species. Additional details regarding PMCAMx are provided in Fountoukis et al. (2011).

We use a hybrid approach to model inorganic aerosol mass transfer, where for particles with dry diameters less than 1 μm , bulk equilibrium is assumed. For larger particles, the mass transfer to each size section is simulated using the Multicomponent Aerosol Dynamics Model (Pilinis et al., 2000) as extended by Gaydos et al. (2003) for metastable aerosol. Two additional modifications have been made in this work in the Gaydos et al. (2003) algorithm. The first is that Ca^{2+} , K^+ and Mg^{2+} have been added to the various ionic balances in the algorithm and the corresponding mass transfer constraints. The second is that the mass transfer model now includes

an explicit constraint that nitric and hydrochloric acid do not condense when ammonia is condensing until the system equilibrates using the acidity as a drive force as described by Gaydos et al. (2003).

pH is calculated in this work for particles smaller than 1 μm , 1-2.5 μm , 2.5-5 μm and 5-10 μm , using a molal definition consistent with the pH_F definition of Pye et al. (2020):

$$\text{pH} = -\log_{10}\left(\frac{1000[H^+]}{[W]}\right), \quad (1)$$

where $[H^+]$ and $[W]$ are the concentrations of particle hydronium ion and inorganic particle water in $\mu\text{g m}^{-3}$. The water associated with organics is neglected in our study, as it has been shown that it has minor influence on the estimated pH (Guo et al., 2015; Battaglia et al., 2019).

3. Model application

PMCAMx was applied over Europe, during the EUCAARI summer intensive campaign in May 2008 for which the model has been evaluated in previous work (Fountoukis et al., 2011). The domain covers a $5400 \times 5832 \text{ km}^2$ region with $36 \times 36 \text{ km}$ grid resolution and 14 vertical layers extending up to 6 km. Inputs to the model include horizontal wind components, vertical diffusivity, temperature, pressure, water vapor, clouds and rainfall, all generated using the Weather Research and Forecast (WRF) meteorological model (Skamarock et al., 2005). Anthropogenic gas-phase emissions include land emissions from the GEMS dataset (Visschedijk et al., 2007) as well as international shipping emissions. Anthropogenic particulate emissions of organic and elemental carbon were obtained from the EUCAARI Pan-European Carbonaceous Aerosol Inventory (Kulmala et al., 2009). Industrial, domestic, agricultural and traffic emission sources are included in the two inventories. Biogenic emissions were based on MEGAN (Guenther et al., 2006), and sea-salt emission inventories were developed using the approach of O'Dowd et al. (2008). Urban dust emissions were based on the work of Kakavas et al. (2020), assuming that calcium, potassium, magnesium and sodium represented 2.4%, 1.5%, 0.9%, and 1.2% of the emitted mineral dust, respectively (Sposito, 1989). A reliable Saharan dust emissions inventory was not available; therefore the African region is excluded from the simulation analysis. Additionally, we focused on a period during which the impact of Saharan dust in Europe was minimal. The concentrations of dust and its components at the boundaries of the domain are considered constant and invariant with height and along each boundary (Table S1). More information about the inputs of PMCAMx during the simulated period can be found in Fountoukis et al. (2011) and Kakavas et al. (2020).

Three simulations were performed. The first was the “base case” simulation and included all emissions described above. Two other simulations were carried out and compared with the “base case” to understand how non-volatile cations (NVCs) in dust affect water uptake and aerosol pH: one where dust lacks any non-volatile soluble cations (“inert dust” simulation) and one where we neglect calcium (“no calcium” simulation) from the “base case” simulation. Calcium is the major NVC in dust and compared to the other NVCs it can react with sulfate ions and form insoluble CaSO_4 , which precipitates out of the aerosol aqueous phase and remains insoluble under subsaturated conditions - even for metastable aerosol (Fountoukis and Nenes, 2007). Particles in each size section can contain both insoluble and soluble material. Therefore, the insoluble CaSO_4 is treated as such by ISORROPIA-II. This unique interaction implies that calcium, if present in sufficient amounts, can reduce aerosol sulfate and reduce acidity, but at the same time reduce hygroscopicity that promotes acidity- in a way that is not obvious by just comparing the base case simulation with the “inert dust” simulation. In all simulations, the total dust mass emissions were the same and only its assumed composition varied.

4. Results and discussion

4.1 Size dependence of aerosol pH

The average ground level pH predictions for different size ranges are presented in Fig. 1. The domain average ground-level pH is 2.05 for PM_{10} , 2.65 for $\text{PM}_{1-2.5}$, 3.2 for $\text{PM}_{2.5-5}$ and 3.35 for PM_{5-10} . Higher pH values for all particle sizes are predicted over the Atlantic due to the presence of sea salt and the systematically higher RH and liquid water content – all of which act to reduce aerosol acidity. The acidity is higher over the Mediterranean, especially its eastern part, due to the higher sulfate and nitrate levels in that region. However, the fine particles over the Atlantic are also predicted to be quite acidic especially in the south. High pH is also predicted for parts of central and northern Europe due to the corresponding ammonia but also the effect of the alkaline dust particles. The pH of marine aerosol increases with particle size, with the highest value equal to 4.5 for the 2.5-5 μm and 5-10 μm ranges, as sea salt is emitted mainly at the super-micron range and is the main aerosol component in these areas. Over the continental region, average PM_{10} pH ranges between 1 to 3.5 with the highest values in the northern coastal parts of Europe and northern Italy; in these regions, acidity is reduced by the high levels of NH_3 present from agriculture and livestock emissions combined with high NO_x and RH levels (Guo et al., 2018; Masiol et al., 2019). $\text{PM}_{1-2.5}$ is less acidic with pH values from 1.5 to 4 over the continental region with the higher values in the northern coastal areas of Europe extending from France to

Denmark. The average pH increases further in the 2.5-5 μm range being equal to 2-3.5 over the continental regions and reaching values up to 4-5 in the coastal areas of the Netherlands, Belgium, France and Denmark. Average PM_{5-10} pH increases over the continental region compared to $\text{PM}_{2.5-5}$, especially in northern Europe, and the highest pH values (4.5-5) are predicted for the same regions. The largest pH changes across size occur for regions where fine-mode aerosol acidity is dominated by the $\text{NH}_3\text{-SO}_4$ system (i.e., relatively lower NH_3 levels – so that aerosol nitrate is low; Guo et al., 2018), and the largest sizes contain large amounts of NVCs from sea salt and dust.

Squizzato et al. (2013) calculated $\text{PM}_{2.5}$ pH equal to 2.3 and Masiol et al. (2019) equal to 2.2 in the Po Valley, Italy during the summer of 2009 and 2012, respectively. The predicted pH by PMCAMx is a little higher and equal to approximately 3.3. Guo et al. (2018) estimated that the $\text{PM}_{2.5}$ pH was equal to 3.3 in Cabauw, Netherlands during the summer of 2013, based on measurements and thermodynamic modeling. PMCAMx predicts a $\text{PM}_{2.5}$ pH by equal to 3.8 in this area during the summer. These discrepancies could be partially due to the different periods compared as the aerosol pH can be sensitive to small changes in composition but also to meteorology (e.g., relative humidity). Nonetheless, these comparisons, even if they involve different years, suggest that the model predictions are reasonable. Bougiatioti et al. (2016) determined through thermodynamic analysis of observations with ISORROPIA-II that the PM_1 pH in Finokalia, Crete is equal to 1.3 which agrees with our predictions.

The pH of $\text{PM}_{2.5}$ has often been the focus of previous measurement studies, due to the availability of the corresponding filter samples. However, the pH in the 1-2.5 range can be quite different from that in the sub-micrometer range (Fang et al., 2017; Ding et al., 2019). This difference may have important implications for aerosol toxicity, metal solubility, nitrate partitioning and other processes. The difference of average ground level aerosol pH predictions between $\text{PM}_{1-2.5}$ and PM_1 is shown in Fig. 2. The pH of these size ranges can differ up to 1.2 units over the continental region due to the effect of NVCs from dust in the $\text{PM}_{1-2.5}$. This difference is predicted to be smaller over most marine areas (up to 1 unit).

Particle water concentrations for the different particle sizes are shown in Fig. 3. PM_1 has the most water, compared to the other size fractions over the continental region. The coarse particles in $\text{PM}_{1-2.5}$ and $\text{PM}_{2.5-5}$ have the most water in the marine areas because of the sea salt, which is found in higher levels in these particles, and exhibits the highest hygroscopicity – compared to all other inorganic salts found in aerosol. Water levels for all particle sizes are higher at areas closer to the sea, owing to the relatively high dry aerosol mass concentration

combined with the high RH typically associated with the marine environments; in just the 2.5-5 μm size range alone, water content exceeds $20 \mu\text{g m}^{-3}$.

Northern Scotland is predicted to have lower pH values compared to the rest of Great Britain for all size ranges during the simulated period. This happens because particles across all sizes have lower water content (Fig. 3) in this area. Also, the predicted dust concentrations are lower than the rest of Great Britain (Fig. S8). The lower aerosol water content and lower dust concentrations lead to more acidic particles in Northern Scotland for all size ranges according to PMCAMx.

4.2 Temporal evolution of pH

To study the temporal evolution of pH, eight sites (Fig. S1) with different characteristics were selected based on their different type, location and dust/sea salt levels (Table S2). Finokalia, has the lowest PM_{10} pH of all examined locations with a value equal to 1.3 (Fig. S2). During most of the time the PM_{10} pH in that area in the eastern Mediterranean is predicted to be within 0.1-0.2 units of its average even if there are limited periods with both very low (pH=0.3) and high (pH=7.7) hourly average pH (not shown). The predicted pH for larger particles is higher, but remains the lowest of the examined group of sites due to the high sulfate levels in the area. This site is affected by both relatively dry air masses with continental aerosol characteristics and by air masses with relatively high sea-salt and dust levels as well as biomass burning influences (Bougiatioti et al., 2016). Cabauw, on the other hand, has the highest average PM_{10} pH (3.0) with hourly average values ranging between 1.5 and 4.5. The distribution of pH values of the 1-2.5 μm diameter particles moves to higher values (less acidic particles) for all sites compared to the sub-micrometer particles. The pH values of all sites for the 2.5-5 μm range are similar to those in the 5-10 μm range and higher than the fine aerosol pH values.

The pH diurnal profiles for Cabauw, Melpitz, Paris, Finokalia are shown in Fig. 4. These sites were selected based on their different type, location and dust/sea salt levels (Table S2) – and because ambient pH data is available for most of them (Pye et al., 2020). pH follows similar trends for all particle sizes in each of the four sites. Cabauw is characterized by lower PM_{10} and $\text{PM}_{1-2.5}$ pH during the afternoon and relatively constant average diurnal $\text{P}_{2.5-5}$ and PM_{5-10} pH with slightly higher values early in the morning. The average pH in Melpitz is characterized for all particle sizes by early morning and an evening peaks and a strong afternoon minimum. The behavior in Paris is similar to that in Melpitz, but the variation in $\text{PM}_{1-2.5}$ is predicted to be stronger than in other size ranges due to the combined effects of photochemistry, relative

humidity and urban dust emissions. The average pH in the remote site of Finokalia has the lowest variability of all four sites. It has a little higher values during the night and lower during the day. These variations are caused by a variety of factors including the relative humidity (that is higher during the early morning, leading to higher liquid water content and higher pH), the temperature (which tends to evaporate nitrate) and mixing height variation (which in turn tends to affect precursor concentrations). The aerosol pH diurnal profiles in the four examined sites of our study follow the same pattern as the corresponding RH diurnal profiles, underlying the importance of RH as a driver of these average variations (Fig. S3).

4.3 pH variation with height

All the results presented so far are for the ground level (lowest 50 m). The predicted aerosol water content for all size ranges decreases with altitude (Fig. S4). This is mainly due to the decrease of the relative humidity and aerosol concentrations with altitude (Mishra et al., 2015; Wang et al., 2018). As height increases, pH values for all particle sizes decrease, due to the reduction of aerosol water per unit mass of dry aerosol, with height (Fig. 5) – which is exclusively an effect of relative humidity decrease. A secondary effect is that the lower concentration of aerosol tends to drive partitioning of semi-volatile species (nitrate, ammonium) to the gas phase (Nenes et al., 2019). As a result, particles of all sizes that are acidic at ground level become more acidic when they move higher in the atmosphere.

For PM_{10} , in the less acidic areas over Europe the pH decreases from 3-3.5 near the ground to around 2-2.5 at 2.5 km altitude. For $PM_{1-2.5}$, the reduction is even larger, since the pH values decrease from 3.5-4.0 at the ground to 1.5-2.0 at 2.5 km (the larger drop in pH is a result of the evaporation of nitrate aerosol and the decrease of liquid water content). Similar decreases of 2-2.5 pH units are predicted for the coarse particles in the first 2.5 km of the atmosphere in areas over land. The predicted decrease in aerosol water content and pH for the super-micrometer particles is even more pronounced in the marine atmosphere and coastal areas due to the high levels of sea-salt near the ground. This reduction of pH with altitude is smaller for the PM_{10} size range in the marine atmosphere. A comparison of the average vertical profiles for the inorganic aerosol components is shown in Fountoukis et al. (2011). The measured reduction of PM_{10} nitrate levels over central and northern Europe from their maximum near the ground to close to zero at 3-4 km was reproduced well on average by PMCAMx.

4.4 Effect of aerosol pH on inorganic nitrate

The model predicts significant concentrations of inorganic nitrate both in central Europe and in parts of northern and southern Europe (Figure S5). PMCAMx does not simulate the concentrations of organonitrates. The high ammonia levels together with the high NO_x emissions and photochemistry over Belgium, the Netherlands and the UK according to PMCAMx result in high levels of nitrate both in the fine and coarse particles in these areas. In parts of southern Europe, the relatively high sea-salt concentrations result in modest levels of coarse nitrate in areas with very low or zero levels of fine nitrate. High average nitrate levels are predicted in several areas in which the pH exceeds 2.5 are predicted for the 1-2.5 µm size range (Fig. S5). Nitrate partitioning to the aerosol phase is favored at these higher pH (Guo et al., 2016; Vasilakos et al., 2018). At the same time, the mass transfer of the produced nitric acid to the aerosol phase is faster for the particles in the 1-2.5 µm range compared to those in the PM_{2.5-5} and PM₅₋₁₀ range also contributing to higher concentration. Finally, the removal of the larger particles from the atmosphere is faster adding one more reason for the maximum of the nitrate size distribution. Modest nitrate levels are predicted in central Europe during this period because both nitric acid and ammonia levels were modest and the temperature was relatively high.

The size-dependent average nitrate diurnal profiles for Cabauw, Melpitz, Paris, and Finokalia, are shown in Fig. 6. In Cabauw, predicted total nitrate levels start to increase early in the morning and peak around 9:00. Lower values are predicted during midday and early afternoon, with fine nitrate starting to increase in the early evening. Most of this variation is due to the formation of ammonium nitrate in the PM₁ size range. The increase in PM₁ nitrate is accompanied by an increase in the ammonium levels (Fig. S6) in this area that is characterized by high ammonia concentrations. Predicted supermicrometer nitrate levels are less variable (in absolute terms) during the day. In Cabauw, coarse particles have on average pH above 2.5 throughout the day (Figure 4a), favoring the partitioning of nitrate to the aerosol phase forming also coarse ammonium nitrate. The predicted average PM₁ nitrate diurnal variation is in very good agreement with the measurements in that site during the EUCAARI campaign (Figure S7).

In Melpitz, the predicted behavior of nitrate is almost the same as in Cabauw, but with lower fine nitrate levels (Fig. 6). PM₁ nitrate peaks early in the morning with peaks in coarse nitrate a few hours later. The peak in fine nitrate is at the same period as the pH in this range, while for the coarse particles it is a few hours later due to the delays in mass transfer to the larger particles. Nitrate levels in all size ranges are predicted to decrease during the afternoon with nitrate reaching a minimum in the late afternoon. The predicted diurnal pattern is the same as the

observed values but the model tends to overpredict nitrate in this area by approximately $0.5 \mu\text{g m}^{-3}$. The behavior of nitrate in the fine and coarse particles in Paris is quite similar as in Melpitz reflecting the similarity in the behavior of pH. Nitrate in all size sections peaks in the early morning and has a minimum in the afternoon. The main difference in this case is that there is more nitrate in the coarse particles due to the higher predicted levels of dust in this megacity. In Finokalia, the predicted fine nitrate is quite low reaching a peak of approximately $0.2 \mu\text{g m}^{-3}$ at 11:00 UTC. These very low levels are consistent with the corresponding measurements of very low fine nitrate (approximately $0.1 \mu\text{g m}^{-3}$) in this area during this summertime period. The nitrate in the coarse particles is significantly higher and peaks a few hours later. increases gradually in all sizes during the morning, reaches its maximum values in the afternoon and then gradually decreases. These higher levels of coarse nitrate exceeding $1 \mu\text{g m}^{-3}$ are consistent with the $1\text{--}2 \mu\text{g m}^{-3}$ of coarse nitrate measured in Finokalia during this EUCAARI campaign. So PMCAMx reproduces well the size distribution of nitrate in this area, with practically all of the mass in the super-micrometer range.

4.5 Effect of dust composition on particle pH

The impact of the NVCs from dust on pH can be quantified comparing the results of the simulation in which the dust was assumed to be inert with the base case simulation. The NVCs in dust affect directly and indirectly the aerosol water content for both the fine and coarse particles (Fig. S8). The predicted dust concentrations are shown in Fig. S9 and their effects on aerosol water in the different size sections are predicted to be both positive and negative. This complex picture is due to series of effects of the dust NVCs on the particle composition. In general, the the presence of dust causes an increase in coarse nitrate and a reduction in fine nitrate. At the same time, there is increase water absorption by the coarse particles. These effects, dominate near the sources of dust, but at the same there an increase in removal rates of the nitrates leading to reductions further downwind of their sources. The result of these processes are reductions in fine nitrate in most areas of continental Europe (Fig. S10) accompanied by a reduction in fine aerosol water. However, there are some reductions of PM_{10} water due to the presence of the NVCs in marine areas. On the other hand, for the larger coarse particles the presence of the dust NVCs leads to an increase in aerosol water practically everywhere. For the particles in the intermediate size ranges ($\text{PM}_{1-2.5}$ and $\text{PM}_{2.5-5}$) the effects of dust NVCs on aerosol water are mixed, with both increases and decreases predicted due to changes in the total concentrations and

size distributions of the water-soluble aerosol components. These results highlight the complex effect of the coarse dust particles on aerosol water and its size distribution.

The predicted aerosol pH is lower in all particle sizes for the inert dust case compared to the base case simulation (Fig. 7). The soluble NVCs in dust tend to increase pH, because due to their lack of volatility they irreversibly neutralize sulfates ions. NVCs also tend to elevate aerosol water in a way that leads to pH increase, directly through their hygroscopicity and indirectly, through promoting the condensation of aerosol nitrate and its associated water content (Guo et al., 2018). PM_1 is slightly affected, because it contains small amounts of dust. The average PM_1 pH changes due to dust by less than 0.05 units. The corresponding pH increase is around 0.1 units for $PM_{1-2.5}$, 0.2-1 units for $PM_{2.5-5}$ and 0.3-1 units for PM_{5-10} .

The effects of dust on pH and aerosol water are reflected on the predicted aerosol nitrate. Nitrate in the submicron range increases and for bigger particle sizes decreases when dust is assumed to be inert (Fig. S10). The average effect of dust on submicrometer nitrate is negligible in several areas, but there are significant effects in the Netherlands and the surrounding areas. The dust is predicted to cause average increases of $PM_{1-2.5}$, $PM_{2.5-5}$ and PM_{5-10} nitrate up to $0.01 \mu g m^{-3}$, $0.1 \mu g m^{-3}$ and $0.08 \mu g m^{-3}$, respectively in parts of northern Europe with higher dust levels and also Italy. This nonlinear impact of relatively minor amounts of NVCs from dust occurs because relatively small changes in aerosol pH, when occurring in the “pH sensitivity window” of nitrate partitioning can lead to large responses in nitrate uptake (Vasilakos et al., 2018).

If only calcium is neglected in the simulation, aerosol pH decreases for all particle sizes compared to the base case simulation (Fig. 8). This decrease varies from 0.01 to 0.03 units for PM_1 , 0.05-0.1 units for $PM_{1-2.5}$, 0.1-0.7 for $PM_{2.5-5}$ and 0.4-0.7 for PM_{5-10} over continental Europe. The highest pH differences are predicted for the coarse particles, consistent with that the coarse particles are richest in calcium. Considering the possible effects calcium can have on soluble sulfate and water uptake, the simulations suggests that the primary effect of calcium is through its action as a soluble ion.

5. Conclusions

The size-dependent aerosol pH was simulated over Europe during an early summer period. We find that fine mode aerosol is persistently more acidic than coarse mode particles. The size-dependence of pH is strongest in northern and southern Europe, where the difference can be as large as 2 units between submicron and $10 \mu m$ particles. This difference is reduced over other

continental regions, but can still be as large as 1 pH unit between PM_1 and $PM_{1-2.5}$. PM_1 has the most water over continental areas, while coarse PM has the most water in marine and coastal areas.

Particles of all sizes become increasingly acidic with altitude owing to the reduction of aerosol water levels with height and volatilization of particulate ammonium and nitrate due to dilution. The highest pH decrease between the ground and 2.5 km altitude is 1-1.5 units for PM_1 , 2-2.5 units for $PM_{1-2.5}$, $PM_{2.5-5}$ and PM_{5-10} . The largest drop in pH is observed for the $PM_{1-2.5}$ fraction, because it coincides with where aerosol nitrate resides most – hence its evaporation with altitude tends to have a larger impact on pH than reductions of liquid water from the RH effect alone.

The nitrate concentration tends to peak a few hours later than the pH in most sites due to the time required for the production of nitric acid and its partitioning to the aerosol phase. If aerosol pH becomes low enough to impede fine mode nitrate formation, its preferential condensation to larger sizes tends to increase the pH difference between fine and coarse particles.

The water soluble components of dust have a rather complex effect on aerosol water causing both increases and decreases of the aerosol water levels. The average increase in water levels ranges from 0.1 to $1.5 \mu g m^{-3}$ with the highest change for PM_{5-10} in parts of northern Europe. Dust causes an increase in aerosol pH for all particle sizes with higher effects in the coarse particles. This effect can be more than 1 pH unit. This increase in pH is accompanied by increases in aerosol nitrate. This effect of dust is mainly due to its calcium content, suggesting the importance of simulating accurately not only the dust concentration, but also the calcium levels. This study focused on periods during which the impact of Saharan dust on Europe was minimal and the predicted dust was dominated by local sources. The effect of Saharan dust on the aerosol pH of Europe is expected to be even more important than our results indicate and will be the topic of future work.

This study shows that aerosol acidity and liquid water content changes considerably across size, location, time and height over Europe. These changes will impact aerosol formation and its response to emissions controls, solubility of aerosol trace metals and deposition. With this realization, aerosol pH and liquid water content emerge as powerful aerosol state variables (Nenes et al., 2019) that could help elucidate the complex impacts of aerosol on public health, ecosystems and climate.

Competing interests. The authors declare that they have no conflicts of interest.

Author contributions. SK extended the hybrid module in the revision stage of the paper, repeated all simulations, analyzed the revised results and wrote the final version of the paper. He also contributed the dust emissions and NVC scheme. DP assisted in the extension of the hybrid module and the development and implementation of the final pH calculation scheme and the analysis of the final results. MZ developed and implemented the original pH calculation scheme in PMCAMx, carried out the initial simulations and was responsible for the first draft of the paper. SN and AN conceived and led the study and helped in the writing of the paper. All authors were involved in the scientific interpretation of the simulations, provided feedback on the analysis approach and extensively commented on the manuscript.
