

Response to the comments about the submitted paper: Modelling mixed-phase clouds with large-eddy model UCLALES-SALSA, Ref. ACP-2019-1182.

Dear Editor, dear Reviewers, we would like to thank the Editorial Board for considering our paper for publication in ACP and the reviewers for their constructive comments. We have addressed all of them and modified the paper accordingly. Our detailed answers follow. Text from the 1st revised manuscript that has been removed in the 2nd revised manuscript is marked in red. New text in the 2nd revised manuscript is marked in blue.

Answers to Reviewer 2

Major comment R2.1 Thank you to the authors for responding to my questions/concerns. I'm still concerned that the results presented are very limited. The model is designed to study the relative importance of aerosols with different chemical compositions but only the most basic studies were done (only dust can form ice). It is not a new result that allowing ice to precipitate will reduce the IWC and allow LWC to persist longer or that smaller aerosols that are not activated at cloud top can fall through the cloud layer and be transported into the cloud layer at cloud base. At the very least, a complete analysis of the freezing of smaller aerosols in supersaturated updrafts would provide support for this statement (lines 285-287).

Answer to R2.1 We thank the referee for these comments and agree that the mentioned results are not new. However, in our study these results are gained with a detailed model where e.g. the chemical composition of the ice nucleating particles is also a prognostic variable. Aerosols in our study consist of ammonium bisulphate and dust where sulphate is needed for cloud activation and dust acts as INP. We have elaborated in our earlier answer to question R1.3 why we used only dust as INP in this study. As requested, we have now included a analysis of freezing of smaller hydrometeors in updrafts and downdrafts within the cloud layer. We added a figure to support this analysis. We also refined our references in the same chapter.

Changes in the manuscript concerning R2.1

Last chapter of Sect. 3.3 rewritten:

Figure 7c further illustrates an interesting behaviour of ice particle formation. In the beginning of the simulation ice particles are formed throughout the cloud, but later the most intensive formation takes place at the top of cloud where fresh INPs are entrained into the cloud layer. However, the maximum supersaturation in these entraining downdrafts is so low, that only the largest particles are able to form cloud droplets and consequently freeze. The smaller ones penetrate through the cloud layer as interstitial aerosol particles (i.e. unactivated particle), and are able to form cloud droplets (i.e. activate) and ice particles at the cloud base when they are recirculated back to the cloud with higher supersaturation. This can be ~~well seen at the~~ seen in Fig. 8. Figure 8a shows how in size bin 2 cloud droplets and ice particles are more frequent in updrafts compared to Fig. 8b which illustrates how aerosols are more favourable in downdrafts. Additionally, ice particles dominate in bigger sizes as aerosols freeze both in down- and updrafts (size bin 3 shown Figs. 8c and 8d). Simulated freezing in different vertical velocity conditions in other size bins does not differ from results shown already in Fig. 6. Lower peak at end of simulation ~~as there is two peaks~~ in vertical profile of freezing rate. ~~Such phenomena can be only in~~ Fig. 7c also shows how recirculated aerosols are frozen in the cloud layer. Such phenomenon has been modelled before e.g. in Solomon et al. (2015), however here the cloud is simulated with explicit calculation of in-cloud supersaturation and representation of aerosol size distribution and chemical composition ~~like is done in UCLALES-SALSA~~. If activation is not modelled with this level of details, activation and freezing might happen too early or late and in a wrong part of the cloud. Overall, Figs. 6 ~~and 7e, 7c, and 8~~ nicely demonstrate how the relative proportions of particles in different hydrometeors are size dependent and how sectional description for aerosols is required to be able to simulate such processes in LES models.

Major comment R2.2 This model is glaciating much earlier than all 11 models included in the ISDAC intercomparison for fixed ice number concentration. It would be useful to understand why in order to put the prognostic ice simulations into context. The authors say this is because the model is tracking the dry aerosol size. Why would this produce this result? Do the authors believe that this model is producing more realistic sensitivity that is not in the other models?

Answer to R2.2 We chose to track aerosol, cloud and ice particle dry size to have information about the origin of the seed aerosol and the freezing cloud droplet. However, tracking dry size means reduced resolution for their hydrated size, especially as we do not assume any pre-defined shape for ice particle size distribution within bins. This is not an issue for aerosol or cloud droplets, but ice particles can be so large that their dry size is not anymore a good tracer for particle properties – this is one reason why rain drops are always described with their wet sizes. Low ice particle size resolution has an impact on ice depositional growth and especially sedimentation. Also, tracking dry size during particle sedimentation means that ice particles that have different hydrated sizes can be mixed. The same issue is related to the other mixing processes including advection and diffusion. So question is why we wanted to use the presented microphysical model setup. In case wet size is followed, we lose the information of original aerosol size distribution within ice particles. For example, Karlsson et al. show how residuals of ice crystals contain really small aerosol nuclei (Karlsson et al.: The role of nanoparticles in Arctic cloud formation, *Atmos. Chem. Phys. Discuss.*, <https://doi.org/10.5194/acp-2020-417>, in review, 2020.). They are probably there due to secondary ice formation. The setup used in our simulations, i.e. tracking dry size, is currently the only possible way to describe how these small nuclei preserve in cloud processes. If microphysics follows the wet size, all this information about small nuclei is lost when bins following wet size are averaged by design. Tracking both wet and dry sizes correctly would be computationally really heavy with spectral microphysics.

The other explanation is related to model dependent technical details that are rarely changed or described in publications, but can have an effect on simulation results. One of these is advection flux limiter. By default UCLALES-SALSA uses minmod, but changing this to monotonized central (built-in options in UCLALES) will have a significant impact on results. However, it should be noted that this is not the only model setting that have an effect on results.

To show the impacts of these two, we show here results from ICE4 simulations (Fig. figure R2.2-1) where ice bins are described with particle size (identical with the rain drop size bins) and/or the default advection flux limiter minmod is changed to monotonized central (an example of a model dependent technical detail). Clearly, tracking ice particle size helps to maintain cloud liquid, and the combined effects of the size-tracking and flux limiter methods is even more effective in maintaining cloud liquid. More detailed analysis of the sedimentation flux shows that using dry size means reduced ice particle flux especially in the lowest 200 m leaving more particles there to evaporate. Evaporative cooling leads to a surface inversion which prevents the uplifting of moist near-surface air. This can be seen from profiles shown in Fig. figure R2.2-2. As such, the higher sensitivity to ice number concentration is partly related to the initial conditions.

Although these specific changes made UCLALES-SALSA less sensitive on ice number concentration, we cannot exclude other technical reasons. Because this explanation is highly technical and both case and model specific, we would like to keep this part of the manuscript text as brief as possible. We added relevant details to the manuscript and leave the rest here.

Tracking aerosol dry size instead of ice particle size seem to produce a higher sensitivity than is in the other ISDAC models. It is unlikely that this sensitivity or those from the other models are realistic, because they assume a constant ice number concentration. As already stated in the manuscript, prognostic ice simulations (with dry or wet size tracking) should be used for this.

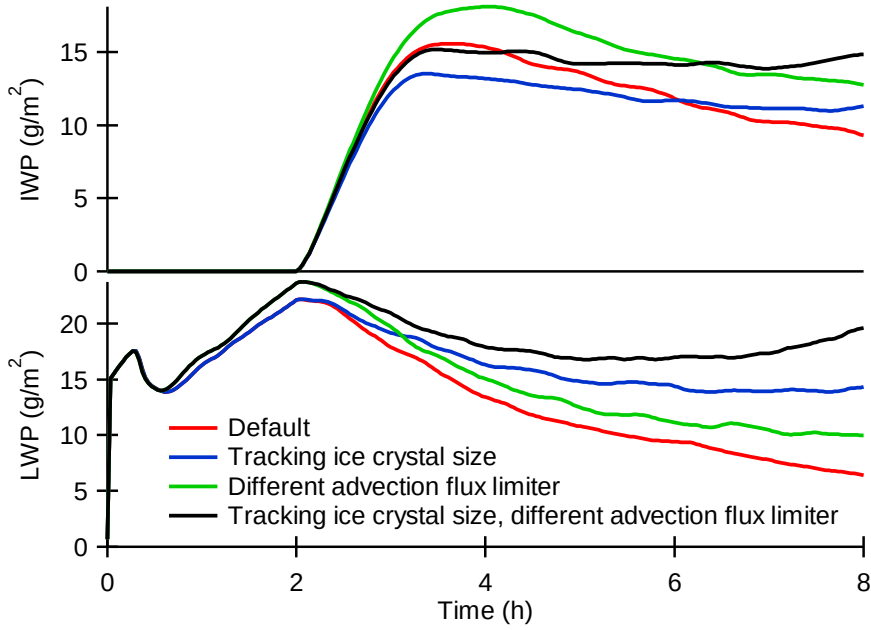

Figure R2.2-1: Time series of ice (IWP) and liquid (LWP) water paths based on the default and modified model versions.

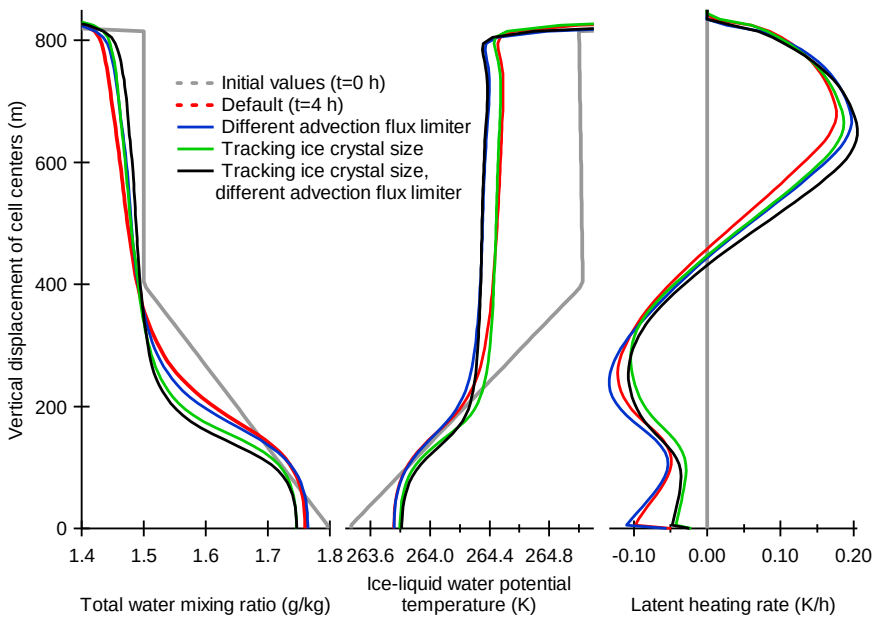

Figure R2.2-2: Profiles of total water mixing ratio, ice-liquid water potential temperature and latent heating rate due to evaporation of ice particles.

Changes in the manuscript concerning R2.2

Second to last chapter of Sect. 3.1:

Compared to the model results in Ovchinnikov et al. (2014), IWP in UCLALES-SALSA declines faster after the peak IWP has been reached in ICE4. One reason for this is that dry particle size is tracked in UCLALES-SALSA and this seem to have an important effect on ice crystal sedimentation. Namely, sedimentation velocities and particle mixing (flux divergency) are here calculated for the dry size bins rather than bins tracking ice particle size. This reduces particle flux especially in the lowest 200 m leaving more particles there to evaporate. Evaporative cooling leads to a surface inversion which prevents the mixing of moist surface air. As such, the higher sensitivity to INP concentration is partly related to the initial conditions of the ISDAC case study. The other reason is related to the model dependent technical details. Our test simulations (not shown) indicate that changing model options, such as flux limiter method, impact IWP and LWP so that the gap between UCLALES-SALSA and the other models decreases. In Ovchinnikov et al. (2014) it was also stated that when the ice number concentration gets higher the differences between models are more caused by discrepancies in microphysics than cloud dynamics. This underlines the sensitivity and significance of microphysics.

Major comment R2.3 Are the aerosols tracked after they form ice? After the ice sublimates, are the aerosols added back into the population? It looks like this is not taken into account in Figure 1. Including this process will greatly impact aerosol concentrations below the cloud layer and entrainment of aerosols at cloud base.

Answer to R2.3 Aerosols are tracked after they form ice. Also after ice sublimation the aerosol are added back into the population. We have now elaborated description of sublimation in the manuscript.

Changes in the manuscript concerning R2.3

1) Sublimation arrow from ice to aerosols added to Fig. 1.

2) In Sect. Model description:

The aerosol, cloud and ice crystal size distributions are discretised into the bins according to the dry aerosol diameter, whereas the rain droplet size distribution is defined by the wet diameter of the droplet. Identical 2a and 2b size bins are used for aerosol, cloud droplets and ice. Such parallel bins are useful for tracking aerosol development through cloud activation ~~and freezing~~, freezing and sublimation. Prognostic variables for each bin include aerosol number and masses of all compounds (water, sulphate, dust, organic carbon, sea salt, nitrate, and ammonium).

Deposition of water, i.e. diffusion limited condensation or evaporation of water vapour, is defined for aerosol when relative humidity (RH) is over 98% and always for other hydrometeors. This is based on the analytical predictor of condensation (APC) scheme by Jacobson (2005) and implemented following Tonttila et al. (2017) (Eqs. 7 and 8). According to this definition, the particles compete for the available water vapour. For solids, the condensation equation does not require Kelvin or Raoult terms. If ice sublimates, the immersed aerosol nuclei are added back to the aerosol population.

Minor comment R2.4 Figure 2 legend: “bulk” and “bin” should be switched.

Answer to R2.4 Labels switched accordingly.

Modelling mixed-phase clouds with large-eddy model UCLALES-SALSA

Abstract. The large-eddy model UCLALES-SALSA, with exceptionally detailed aerosol description for both aerosol number and chemical composition, has been extended for ice and mixed-phase clouds. Comparison to a previous mixed-phase cloud model intercomparison study confirmed the accuracy of newly implemented ice microphysics. Further simulation with a heterogeneous ice nucleation scheme, where also ice nucleating particles (INP) are a prognostic variable, captured the typical
5 layered structure of Arctic mid-altitude mixed-phase cloud: a liquid layer near cloud top and ice within and below the liquid layer. In addition, the simulation showed realistic freezing rate of droplets within the vertical cloud structure. The represented detailed sectional ice microphysics with prognostic aerosols is crucially important in reproducing mixed-phase clouds.

1 Introduction

Clouds are known to have a prominent influence on the hydrological cycle and the atmospheric radiation balance. While
10 significant advances have been made in characterisation of liquid-phase clouds, the microphysical processes, especially heterogeneous ice nucleation, dynamics and radiative effects of mixed-phase and ice clouds remain more poorly constrained. This is mainly because of challenges in obtaining representative observations and a lack of a detailed enough representation of microphysics in climate and numerical weather prediction models. Specific challenges are known to be associated with aerosol-cloud interactions (Cox, 1971; Knight and Heymsfield, 1983; Curry, 1995; Solomon et al., 2007; Stevens and Feingold, 2009;
15 Morrison et al., 2011a; Morrison, 2012; Li et al., 2013).

What we know about mixed-phase clouds is that by definition supercooled liquid droplets coexist with ice crystals. Such clouds are frequent at temperatures between $-10^{\circ}C$ and $-25^{\circ}C$ (Filioglou et al., 2019), but can be present from $-35^{\circ}C$ to $0^{\circ}C$ and require specific microphysical and dynamical conditions (Andronache, 2017). Ice crystals can form either by homogeneous or heterogeneous freezing (term *nucleation* used also). In temperatures lower than $-38^{\circ}C$, liquid droplets can
20 freeze homogeneously without the need of ice nucleating particles (INP). In heterogeneous ice nucleation, freezing initiates from the surface of seed particle and can occur at higher temperatures than homogeneous ice nucleation. Droplet freezing processes are not yet fully understood and quantified despite of decades of research (Phillips et al., 2008; Atkinson et al., 2013; DeMott et al., 2011). Kiselev et al. (2017) stated that ice formation on aerosol particles (heterogeneous ice nucleation) is a

process of crucial importance to Earth's climate, but it is not understood at the molecular level. However, in Morrison et al. (2011a) it is noted that although many details of droplet freezing are poorly understood, enough knowledge exists to draw first-order (ice water path) conclusions. Furthermore, droplet freezing models and even the representation of cloud structure often require a resolution that is too detailed for large scale models. For instance, the structure of Arctic and mid-altitude clouds is complex with a layered structure with liquid near cloud top and ice within and below the liquid layer (Curry et al., 1997; Hobbs and Rangno, 1998; Pinto, 1998; Rangno and Hobbs, 2001; Zuidema et al., 2005; Shupe et al., 2006; Verlinde et al., 2007; de Boer et al., 2009; McFarquhar et al., 2011; Morrison et al., 2011a). The lack of a proper calculation of ice processes in climate models is seen in the comparisons to observations of mid- and high-latitude mixed-phase clouds. These models tend to underestimate the lifetime of such clouds (Andronache, 2017). Better quantification of droplet freezing processes is expected to narrow the gap between observations and model results.

The importance of including detailed aerosol description is vital in cloud resolving models. Scarcity of INP is an important factor in mixed-phase clouds lifetime and structure, since roughly one in a million particles acts as an ice nucleus and even these particles might have highly different ice-forming activity at different temperatures (Lebo et al., 2008; Morrison et al., 2011a). Therefore, the loss of INP along with precipitating ice crystals limits cloud glaciation and dissipation (Rauber and Tokay, 1991; Harrington et al., 1999; Avramov and Harrington, 2010). Describing this process is not possible without detailed description of aerosols, as is demonstrated in a 1-D cloud model study by Morrison et al. (2005). The significance of aerosols is shown in Filioglou et al. (2019) where high aerosol load was linked with a higher occurrence of mixed-phase clouds. Also, the Norgren et al. (2018) study shows how there is less ice in polluted clouds. Andronache (2017) and Morrison et al. (2011a) are comprehensive review resources to give further details about mixed-phase clouds.

There is a growing number of studies focusing on examining the properties of mixed-phase or ice clouds by combining observations and models, including large eddy simulation (LES) modelling and other cloud-resolving models (CRM) (Jiang et al., 2000; Klein et al., 2009; Morrison et al., 2011b; Ovchinnikov et al., 2014; Andronache, 2017). Large-eddy simulations are particularly attractive for modelling boundary layer clouds since they offer a good compromise between computational cost and accuracy in terms of model resolution (Tonttila et al., 2017; Andronache, 2017). LES models solve the largest eddies in turbulent flows explicitly and use parametrisations for the smallest length scales. In atmospheric applications they are usually coupled with cloud microphysical packages. Recent developments in computational performance of supercomputers have made explicit and detailed description of aerosol-cloud-ice microphysical interactions possible also in LES modelling, allowing the investigation of non-linear cloud phenomena, such as secondary ice production and heterogeneous ice nucleation.

There are several LES models that solve cloud related interactions (Fridlind et al., 2012; Khain et al., 2004; Savre and Ekman, 2015; Fu and Xue, 2017). In comparison to those models, we present a LES model UCLALES-SALSA that brings additional value with a more detailed aerosol description. UCLALES-SALSA explicitly resolves interactions between aerosols, ice crystals and cloud droplets with sectional microphysics for all hydrometeors while keeping track of the aerosol dry size distribution. Sectional description, especially for aerosols, is a clear asset of UCLALES-SALSA and we have now extended this description also for ice crystals. This sectional aerosol description allowed the implementation of a detailed heterogeneous

freezing processes. First, the model results are compared with previously published modelling results. Finally, we demonstrate the benefits of this approach to handle heterogeneous freezing over more simplified aerosol-ice-cloud treatments.

60 2 Model description

The UCLALES-SALSA (Tonttila et al., 2017) model consists of two components: first, the widely used large eddy simulator UCLALES (Stevens et al., 1999, 2005), and second the aerosol bin microphysics model SALSA (Sectional Aerosol module for Large-Scale Applications) (Kokkola et al., 2008; Tonttila et al., 2017; Kokkola et al., 2018). UCLALES handles e.g. surface fluxes, transportation of microphysical prognostic variables and atmospheric dynamics including turbulence. The previous
65 version of UCLALES-SALSA incorporated interactions between aerosols, clouds and drizzle (Tonttila et al., 2017). Now we have extended the model with a description for ice crystals. In this study, we focus on how ice crystals and ice nucleating particles (INP) interact with clouds while tracking sectional aerosol size distribution.

Figure 1 illustrates the microphysical treatment of different hydrometeor classes and their size distributions in UCLALES-SALSA. All four classes (aerosol, cloud and rain droplets and ice crystals) are tracked with a bin scheme. Bin scheme offers
70 the benefit of greater accuracy in simulating interactions between different sized hydrometeors. Better accuracy is gained by dividing the size distribution into bins. This also enables better flexibility as the shape of the distribution is allowed to evolve. Bulk schemes provide a simpler method and track one or several moments of the size distribution, where the shape of distribution is prescribed. The disadvantage of bin scheme is higher computational cost compared to bulk scheme.

Three of the hydrometeor classes, i.e. aerosol, cloud droplets and ice, are further divided into parallel bins labelled a and b
75 as shown in Fig. 1. This division into a and b bins is done to enable the tracking of externally mixed distributions and to see how different particles affect clouds. For aerosol particles, subrange 1a is an additional feature to describe nucleation mode. Otherwise, Aitken and accumulation mode size ranges are sufficient to characterise cloud phenomena.

The aerosol, cloud and ice crystal size distributions are discretised into the bins according to the dry aerosol diameter, whereas the rain droplet size distribution is defined by the wet diameter of the droplet. Identical 2a and 2b size bins are used
80 for aerosol, cloud droplets and ice. Such parallel bins are useful for tracking aerosol development through cloud activation ~~and freezing~~, freezing and sublimation. Prognostic variables for each bin include aerosol number and masses of all compounds (water, sulphate, dust, organic carbon, sea salt, nitrate, and ammonium).

In UCLALES-SALSA, recently implemented processes involving ice crystals are droplet freezing, deposition of water vapour, sublimation, melting when $T > 0^\circ\text{C}$, coagulation between different sized hydrometeors, sedimentation, and inter-
85 actions with radiation (see also Fig. 1). Most of these processes are included in a similar way as in the previously published version of UCLALES-SALSA (Tonttila et al., 2017).

Regarding the scope of this study, we describe droplet freezing in higher detail. There are five mechanisms for droplet freezing and they are all currently implemented in UCLALES-SALSA.

– Immersion freezing is possible for aqueous droplets that have an insoluble core, which in UCLALES-SALSA is either
90 dust (DU) or black carbon (BC). The rate of heterogeneous germ formation in a supercooled droplet of water or solution

is calculated mostly following Khvorostyanov and Curry (2000) and additional parameters are from Jeffery and Austin (1997), Khvorostyanov and K. Sassen (1998), Khvorostyanov and Curry (2004) and Li et al. (2013). See also App. A.

- Homogeneous freezing is possible for any aqueous droplet with or without insoluble particles. This is applied to the model according to Khvorostyanov and K. Sassen (1998). See also App. B.
- 95 – Deposition freezing is possible for dry insoluble aerosol at sub-saturated conditions ($RH < 100\%$). This is implemented following Khvorostyanov and Curry (2000) and additional parameters from Hoose et al. (2010). See also App. C.
- Contact freezing is implemented in UCLALES-SALSA following Hoose et al. (2010) so that first the coagulation code is used to calculate collision rates between dry particles and liquid droplets and then immersion freezing code gives the freezing probability.
- 100 – Condensation freezing is implemented as a part of immersion freezing, because these droplets can freeze during the modelled condensational growth.

In our simulations (Sect. 3.3), only immersion freezing is active. This is due to high temperatures, when homogeneous freezing is not possible, and mixing state of the INP leading to aqueous droplets, when deposition and contact freezing are not feasible.

- 105 Deposition of water, i.e. diffusion limited condensation or evaporation of water vapour, is defined for aerosol when relative humidity (RH) is over 98% and always for other hydrometeors. This is based on the analytical predictor of condensation (APC) scheme by Jacobson (2005) and implemented following Tonttila et al. (2017) (Eqs. 7 and 8). According to this definition, the particles compete for the available water vapour. For solids, the condensation equation does not require Kelvin or Raoult terms.
[If ice sublimates, the immersed aerosol nuclei are added back to the aerosol population.](#)

- 110 Activation of aerosols to cloud droplets happens when RH is over 100% and aerosol wet diameter exceeds the critical limit corresponding to the resolved supersaturation. At this time, a certain proportion of activated aerosols (i.e. cloud condensation nuclei, CCN) are moved to cloud droplet bins.

Sedimentation is defined as before in Tonttila et al. (2017) and now extended for ice particles. For simulations in this study, a fall rate of ice particles is set as in Ovchinnikov et al. (2014).

- 115 Coagulation is implemented with the same way as before and now including also ice particles. Coagulation is affected by diffusion, especially aerosols, and by sedimentation, especially large particles. In a collision, bigger particles absorb smaller particles.

- 120 Interaction with radiation is implemented either with the same four-stream radiative transfer solver (Fu and Liou, 1993) as in Tonttila et al. (2017) with extension to include ice particles or parametrised as in Ovchinnikov et al. (2014). We used the latter method in our simulation. In the parametrised radiation, the net upward long-wave radiative flux is computed as a function of liquid water mixing ratio profile. The effect of interaction with radiation can be seen in simulations how radiative cooling weakens after liquid water path decreases below a specific value.

Furthermore, UCLALES-SALSA was upgraded with minor bug fixes and improvements. For example, hygroscopicity is now calculated with κ -Köhler (Petters et al., 2006; Petters and Kreidenweis, 2007) instead of previously used ZSR method (Stokes and Robinson, 1966).

3 Results

3.1 Model evaluation

The model performance is evaluated by simulating a well-documented mixed-phase cloud case from the Indirect and Semi-Direct Aerosol Campaign (ISDAC) Arctic study (McFarquhar et al., 2011). This observation case has been used before for comparisons to LES-models (e.g., Savre and Ekman, 2015; Fu and Xue, 2017). Ovchinnikov et al. (2014) presented an intercomparison of 11 LES models for this same case, where initial profiles were based on aircraft observations in the mixed layer (Flight F31) and idealisation of a sounding on 26th April 2008 at Barrow, AK. Nine of those models had bulk 2-moment microphysics and two of them bin microphysics.

We implemented in UCLALES-SALSA model runs the same semi-idealised simulation setup given in Ovchinnikov et al. (2014) that attempted to minimise intermodel differences by applying identical descriptions for the following processes: surface properties and fluxes (fluxes set to zero), large-scale forcings, radiation, cloud droplet freezing and ice growth processes and sedimentation, and the nudging of horizontal winds, potential temperature and water content above the altitude of 1200 m. In the simulations ice processes were excluded during the first two hours, i.e. the spinup period, to allow the mixed-layer turbulence and the warm stratus cloud to develop. After the spinup, cloud droplets are allowed to freeze until a specified target ice concentration is reached (Morrison et al., 2011b). Ice shape is described with a mass-diameter parametrisation so that ice can be considered as spherical particles with low effective density ($\rho = 84.5 \text{ kg m}^{-3}$). Ice fall speed is related to the maximum dimension while capacitance, which is used in the condensation equation, is modified from that of a sphere to $C = D/\pi$. Radiation and sedimentation were parametrised similar to Ovchinnikov et al. (2014). For the sake of simplicity, coagulation was switched off as in Ovchinnikov et al. (2014). Warm rain formation was switched off allowing more straightforward model intercomparison. Also, the warm rain mass mixing ratios would have been small due to relatively small cloud droplet size in the simulated case. Aerosol size distribution is given as a sum of lognormal accumulation and coarse modes with concentrations of 159×10^6 and $6.5 \times 10^6 \text{ kg}^{-1}$, mode mean diameters of 0.2 and 0.7 μm and geometric standard deviations of 1.5 and 2.45, respectively. Aerosol is composed of ammonium bisulphate. During the simulations this aerosol size distribution provides on average $129 \times 10^6 \text{ kg}^{-1}$ cloud droplets. These aerosol distribution parameters provide the best fit to the measured distributions below the liquid cloud layer (Earle et al., 2011; Ovchinnikov et al., 2014).

We ran UCLALES-SALSA for the three different simulation setups investigated in the Ovchinnikov et al. (2014) study: no ice (ICE0), average ice (ICE1) and high ice (ICE4) number concentration. The ice number concentration is the only variable that was changed between the evaluation simulations (either 0, 1 or 4 L^{-1}). Liquid and ice water paths (marked LWP and IWP from now on), i.e. column integrated mass values averaged over the horizontal domain, in these three cases show how water is distributed between ice and liquid phases depending on the ice crystal concentration.

Figure 2 compares the three UCLALES-SALSA simulations to the results presented in the Ovchinnikov et al. (2014) intercomparison paper. In the figure, LES model results from Ovchinnikov et al. (2014) are separated between bulk and bin microphysics to highlight the differences between microphysics schemes. First, Fig. 2a shows LWP for the baseline simulation without any ice (ICE0). It is evident that our model agrees well with the other 11 models. The simulated LWP of UCLALES-SALSA is in the middle of the model spread. Differences are most likely explained by different dynamical cores, which is stated also in Ovchinnikov et al. (2014). A more thorough testing of warm phase cloud microphysics in UCLALES-SALSA was done in the Tonttila et al. (2017), and for the remainder of this work we will concentrate on examining the properties of the ice microphysics implementation.

Second, Figs. 2b and 2c present the LWP and IWP time series, when the target ice number concentration is 1 L^{-1} , marked with ICE1. Again, LWP in UCLALES-SALSA matches well with the other models being in the lower end of the intermodel spread. As expected, the LWP growth rate is lower than in ICE0 simulation, as some of the water vapour condenses onto ice crystals. Furthermore, IWP matches well especially with other bin models in the Ovchinnikov et al. (2014) study.

Third, Fig. 2d depicts LWP time series with ice number concentration of 4 L^{-1} , which can be regarded as high ice concentration and is marked with ICE4. Now after spinup, LWP has a decreasing trend since the ice number concentration is so high that it consumes much of the water vapour. Subsequently, IWP in Fig. 2e increases rapidly after the spinup and in UCLALES-SALSA reaches its peak value of 15.7 g m^{-2} just before 4 hours of simulation. It then decreases to a value of 9.4 g m^{-2} at the end of the simulation. The reduction of IWP is caused by ice crystal precipitation at the surface and evaporation below the cloud.

Compared to the model results in Ovchinnikov et al. (2014), IWP in UCLALES-SALSA declines faster after the peak IWP has been reached in ICE4. One reason for this is that dry particle size is tracked in UCLALES-SALSA and this seem to have an important effect on ice crystal sedimentation. Namely, sedimentation velocities and particle mixing (flux divergency) are here calculated for the dry size bins rather than bins tracking ice particle size. This reduces particle flux especially in the lowest 200 m leaving more particles there to evaporate. Evaporative cooling leads to a surface inversion which prevents the mixing of moist surface air. As such, the higher sensitivity to INP concentration is partly related to the initial conditions of the ISDAC case study. The other reason is related to the model dependent technical details. Our test simulations (not shown) indicate that changing model options, such as flux limiter method, impact IWP and LWP so that the gap between UCLALES-SALSA and the other models decreases. In Ovchinnikov et al. (2014) it was also stated that when the ice number concentration gets higher the differences between models are more caused by discrepancies in microphysics than cloud dynamics. This underlines the sensitivity and significance of microphysics.

To conclude, the spread between models, especially between bin and bulk microphysics models, gets wider as the prescribed ice number concentration gets larger and closer to the limit when the cloud glaciates completely. In UCLALES-SALSA this limit of full glaciation is lower than in other models in Ovchinnikov et al. (2014). This limit is further examined in Sect. 3.2.

3.2 Sensitivity on ice concentration

Motivated by simulated differences with the 4 L^{-1} ice concentration, we wanted to further investigate how sensitive cloud glaciation is to changes in ice number concentration. In addition to ICE1 and ICE4 simulations, we performed simulations in which the target ice number concentration was 2, 3, 5 or 6 L^{-1} (marked with ICE2, ICE3, ICE5 and ICE6 respectively). Figure 3 depicts the LWP and IWP evolution in all six UCLALES-SALSA simulations. The simulation time was extended to 24 hours in those cases where cloud still exists after 8 hours (marked with vertical line in Fig. 3). The simulation time was not extended any further, because we do not see any major changes or trends in the last simulation hours.

Figure 3 shows that when the ice number concentration is set to a higher value, LWP decreases faster and cloud glaciates sooner. In simulations ICE4, ICE5 and ICE6, the cloud dissipates totally after glaciation. The cloud glaciation happens because water vapour condenses on the ice crystals at the expense of the cloud droplets. In simulations ICE1, ICE2 and ICE3, IWP stabilises to values of approximately 6.5 , 10 and 12 g m^{-2} respectively towards the end of simulation.

From Fig. 3 we can also see that LWP still increases during the first 8 hours with ICE2 but not anymore with ICE3. With ICE1, the water paths of the cloud are very stable after 8 hours of simulation. LWP decreases about 2 g m^{-2} reaching a value of 44 g m^{-2} at the end of simulation. IWP is around 7 g m^{-2} at the end of simulation. LWP values for ICE2 and ICE3 simulations are around 22 and 18 g m^{-2} , and IWP values are 10 and 12 g m^{-2} at the end of simulation, respectively. These are close to ICE4 simulations presented in Ovchinnikov et al. (2014), and this illustrates the fine balance between co-existing liquid and ice phases.

These results show how sensitive the mixed-phase cloud is to ice number concentration either by showing how fast the cloud glaciates or when balance is reached. However, these are highly simplified due to the lack of real aerosol dependent freezing and related feedback processes. These results also show the need for more detailed feedbacks since constant ice number concentration is not a realistic assumption for real clouds.

3.3 Prognostic ice simulation

One of the unique features of our model is its ability to keep track of the chemical composition along with sectional aerosol size distribution also in cloud phase. This allows us to model freezing processes related to an ice nucleating compound like dust. Furthermore, parallel bins allow for analysing the relative contribution of e.g. dust particles (INP) on ice formation. We call this prognostic ice because here freezing probability is related to dust aerosol which mass and number concentrations are prognostic variables. We allow interactions between all hydrometeors and ice formation is modelled using the implemented ice nucleation theories, which relate ambient conditions and droplet properties to their freezing rates.

To see the difference between fixed and prognostic droplet freezing, we made a prognostic ice simulation that was targeted to have similar IWP during the first 8 hours as in the simulation with ice number concentration of 4 L^{-1} (ICE4) (see Sections 3.1 and 3.2). This ICE4 simulation was selected for comparison because it is close to the tipping point where cloud either stabilises or glaciates (see Sect. 3.2).

220 To achieve the target IWP, we adjusted accordingly the freezing properties of aerosols that can act as an INP. The total number concentration and size distribution of the aerosol remain the same as in the fixed ice number simulations (Sect. 3.1 and 3.2), thus they are the same as in Ovchinnikov et al. (2014). In the absence of more detailed aerosol observations, INP number concentration and mixing state, and contact angle were considered as adjustable parameters impacting ice nucleation ability. Here, contact angle represents the angle between the ice embryo and the ice nucleus in an aqueous medium.

225 First, in order to set the INP number concentration, we incorporated b bins (For more information about bin description, see Sect. 2 and Fig. 1). Proportion $x = 0.015$ of the total aerosol number concentration was partitioned in b bins as INPs. Proportion $(1 - x)$ of remained in a bins. Resulting number concentrations of INPs in accumulation and coarse modes were 238.5×10^3 and $9.75 \times 10^3 \text{kg}^{-1}$, respectively.

Second, the INP mixing state was adjusted so that the particles in the b bins were set to have an insoluble dust core, 50% of
230 the dry mass, and ammonium bisulphate for the other half. Here, dust acts as the INP.

Third, the freezing rate was adjusted by setting the cosine of the contact angle of dust to $m_{is} = 0.57$ (Eq. A3 in Appendix A).

It should be noted that the target IWP could have been reached using different combinations of INP mixing state, x and m_{is} but these simulations showed that the results depend mostly on the resulting ice number concentration rather than the applied
235 parametrisation. These characteristics of aerosol are uniform throughout the whole simulation domain.

The simulation time for the prognostic ice run was set to 32 hours. The water paths of the mixed-phase cloud are quite stable after that. The simulation time of ICE4, used to compare with the prognostic run, was not extended any further from 24 hours since the cloud dissipates around 12 hours of simulation.

As in the ICE4 simulation, in the prognostic ice simulation, droplet freezing was set to start after a spinup of 2 hours. Figures
240 4a and 4b illustrate that the prognostic ice and ICE4 simulations have similar IWP and LWP during the first 8 hours. Hence, the targeting is successful and the initial conditions of the simulations match each other. After that, the prognostic ice simulation diverges from the ICE4 simulation.

Figure 4a shows that in the prognostic ice simulation LWP starts to increase after 4.5 hours of simulation. This is caused by a decrease of ice number concentration (Fig. 4c) to such a low level which allows more water vapour for condensation to liquid
245 droplets. The same figure also depicts how the ice number concentration is set to a target value (simulation ICE4) and how the concentration is stable until the cloud dissipates. Figure 4d depicts how droplet number concentration lowers especially right after spinup period when ice number concentration is increasing. However, changes in droplet number concentration is not the driving force behind complete removal of liquid phase. Figure 4e illustrates how the whole cloud with prognostic droplet freezing descends and how the ICE4 is affected by entrainment both below and above the cloud, cloud gets thinner and
250 dissipates. In all simulations, droplet number concentration is specified as prognostic variable.

In the beginning of the prognostic ice run, domain mean of dust containing aerosols is approximately 27L^{-1} . After 32 hours of simulation the same mean value is about 13L^{-1} . Here, the loss of INPs limits the ice number concentration. The mixed-phase cloud persists because the ice number concentration can change. This is so-called self-adjustment of INPs which better reproduces observed evolution of mixed-phase clouds since usually they are more resilient in observations than in models

255 (Andronache, 2017; Morrison et al., 2011a). This is also in line with previous modelling studies, where prognostic INP will reduce the number of ice crystals because of precipitation, thus allowing cloud liquid to sustain (Fridlind et al., 2012; Solomon et al., 2015, 2018). The decrease of dust (INP) mass concentration in different hydrometeor types is shown in Fig. 5. Dust is an efficient ice nuclei so it will soon end up in ice crystals which are removed from the system by sedimentation (Fig. 5c). Free troposphere is the only source for the boundary layer dust, and the relevant mechanisms are entrainment and large
260 scale subsidence. Subsidence is described with a downward vertical velocity moving mass and energy. Entrainment in this case describes any other kind of mass exchange between cloud top and free troposphere. For instance, subsidence is 0.004 m s^{-1} at the cloud top and aerosol number concentration in dust containing bins above the cloud is about 24000 m^{-3} , so the dust aerosol flux from the free troposphere is approximately $100 \text{ m}^{-2} \text{ s}^{-1}$. Because radiative cooling is strengthening the supersaturation at the cloud top, the most CCN active part of these entrained dust containing particles can be activated
265 immediately as cloud droplets. This can be seen as a higher dust mass concentration within cloud droplets in the upper layer of the cloud (Fig. 5b). If the temperature is low enough, these dust containing droplets will subsequently freeze during the following time steps and therefore takes part in preserving the mixed-phase cloud.

A more detailed examination of droplet activation and ice formation can be done by studying the time evolution of the size distribution. Figure 6 shows how different sized particles are partitioned between different hydrometeor types within the cloud
270 layer. Figures 6c and 6d show how the larger particles freeze first and their number concentration decreases quickly as these particles deposit at the surface within falling ice hydrometeors and are removed from the system. Even though the entrainment from above is providing more particles, this is not fast enough to maintain the original concentration. Removal of the smaller INPs is slower as those are less likely to activate as cloud droplets and the resulting droplets are also less likely to freeze due to the smaller dust core area. However, with time and because of continuous mixing of boundary layer eventually also the smaller
275 INPs are able to form cloud droplet within the strongest updrafts and formed droplets will freeze within the cloud. This will lead to stabilisation of aerosol size distribution. The increase in the total number of particles in bin 1 is a numerical artefact caused by the bin adjustment routine, which can move particles from one bin to another in order to keep the dry size within the predefined bin limits. When a large proportion of particles in bin 2 are activated as cloud droplets, some of the remaining are moved to the smaller bin to avoid numerical problems. However, this numerical artefact does not affect the results.

280 Figures 7a and 7b illustrate that super-cooled liquid droplets are dominant in the upper layers of the mixed-phase cloud compared to ice crystals. Here the total ice number concentration stabilises at approximately 0.44 L^{-1} , whereas it is obvious from Sect. 3.2 that a much higher concentration is needed to completely glaciate the cloud. Correspondingly, the cloud droplet number concentration stabilises at approximately 175 cm^{-3} . Remarkably, these values are in line with aircraft observations (Flight F31) of this ISDAC case. The observed ice and cloud droplet number concentration are 0.35 L^{-1} and 185 cm^{-3} ,
285 respectively (McFarquhar et al., 2011; Savre and Ekman, 2015). Ice number concentration is also approximately two orders of magnitude less than the number concentration of efficient INPs above the cloud layer. From that we can estimate that the concentration of INPs entraining from above the cloud should be in the order of 0.1 to 1.0 cm^{-3} to glaciate the cloud.

Figure 7c further illustrates an interesting behaviour of ice particle formation. In the beginning of the simulation ice particles are formed throughout the cloud, but later the most intensive formation takes place at the top of cloud where fresh INPs are

290 entrained into the cloud layer. However, the maximum supersaturation in these entraining downdrafts is so low, that only the largest particles are able to form cloud droplets and consequently freeze. The smaller ones penetrate through the cloud layer as interstitial aerosol particles (i.e. unactivated particle), and are able to form cloud droplets (i.e. activate) and ice particles at the cloud base when they are recirculated back to the cloud with higher supersaturation. This can be ~~well seen at the~~ seen in Fig. 8. Figure 8a shows how in size bin 2 cloud droplets and ice particles are more frequent in updrafts compared to Fig.
295 8b which illustrates how aerosols are more favourable in downdrafts. Additionally, ice particles dominate in bigger sizes as aerosols freeze both in down- and updrafts (size bin 3 shown Figs. 8c and 8d). Simulated freezing in different vertical velocity conditions in other size bins does not differ from results shown already in Fig. 6. Lower peak at end of simulation ~~as there is two peaks~~ in vertical profile of freezing rate .Such phenomena can be only in Fig. 7c also shows how recirculated aerosols are frozen in the cloud layer. Such phenomenon has been modelled before e.g. in Solomon et al. (2015), however here the cloud
300 is simulated with explicit calculation of in-cloud supersaturation and representation of aerosol size distribution and chemical composition ~~like is done in UCLALES-SALSA~~. If activation is not modelled with this level of details, activation and freezing might happen too early or late and in a wrong part of the cloud. Overall, Figs. ~~6 and 7e~~, 7c, and 8 nicely demonstrate how the relative proportions of particles in different hydrometeors are size dependent and how sectional description for aerosols is required to be able to simulate such processes in LES models.

305 4 Conclusions

In this study we have extended our large-eddy model UCLALES-SALSA (Tonttila et al., 2017) for ice and mixed-phase clouds. The model has an exceptionally detailed sectional aerosol description for both aerosol number and chemical composition, which makes this model suitable for examining aerosol-cloud interactions and dynamics. Specifically, this allows the description of an ice nucleation active material such as mineral dust, which can be used in calculating ice formation rates from
310 the nucleation theory.

As the first step, we compared our model predictions with those from a mixed-phase cloud model intercomparison study (Ovchinnikov et al., 2014) to confirm the accuracy of the newly implemented ice microphysics. In this simplified model intercomparison setup, where any cloud droplet will freeze until a specified ice number concentration (from zero up to four particles per liter) is reached, the focus is on cloud dynamics. In agreement with Ovchinnikov et al. (2014) and several other
315 studies (e.g., Klein et al., 2009; Morrison et al., 2011b; Stevens et al., 2018) we conclude that microphysical details such as the fact that dry particle size is tracked in UCLALES-SALSA while most other sectional models track the ice particle size have an impact on predictions. Such details become more important close to the tipping point where the further addition of ice particles leads to the rapid glaciation of the cloud.

In the second part, we constructed a case where ice formation is modelled using a heterogeneous ice nucleation scheme and
320 a prognostic ice nucleating particle population containing mineral dust. This so-called prognostic ice simulation was designed so that it matched with the previous fixed ice number concentration simulation where the cloud was close to the tipping point. When the simulation with fixed ice concentration showed a complete glaciation after about 12 hours, the prognostic ice

simulation reached an equilibrium state which lasted up to end of the 32 hour simulation. With this the prognostic simulation showed the importance of the self-adjustment of ice nucleation active particles. This is in good agreement with previous
 325 modelling studies (Fridlind et al., 2012; Solomon et al., 2015, 2018) and a observational study where resilient mixed-phase clouds are seen together with relatively high ice nuclei concentrations (Filioglou et al., 2019).

Further examination of the prognostic ice simulation revealed that the efficient INPs entrained from the free troposphere are able to maintain the mixed phase cloud with ice particle number concentration on average 0.1-0.2 % of the INP concentration above the cloud. These entrained particles do not immediately form ice particles in the cloud top. The detailed analysis of the
 330 model outputs reveals how particle size and supersaturation-dependent cloud activation eventually control the formation of ice through immersion freezing. Part of entrained INPs penetrate through the cloud as interstitial particles, get mixed within boundary layer air and contribute ice formation later when recycled back to the cloud. Thus the entrainment process is maintaining INP concentration in the whole boundary layer.

This study emphasises the benefits of the detailed aerosol-cloud-ice module within a LES model. In fact, UCLALES-SALSA
 335 is one of the few cloud scale models (Fridlind et al., 2012; Khain et al., 2004; Savre and Ekman, 2015; Fu and Xue, 2017) where details about aerosol and cloud droplet chemical composition can be utilised by using the particle level theoretical understanding about ice nucleation. The model will be a useful tool for the mixed-phase cloud research, which has started to attract more widespread interest.

Appendix A: Immersion freezing

The rate J of heterogeneous germ formation by immersion freezing is a function of T temperature in kelvins, r_N radius of
 345 insoluble substrate and S_w equilibrium saturation ratio at droplet surface based on Kohler theory and is determined as

$$J(T, r_N, S_w) = C_{het} \exp \left[- \frac{\Delta F_{act} + \Delta F_{cr}}{kT} \right] (\text{s}^{-1}), \quad (\text{A1})$$

$$C_{het} = \frac{kT}{h} c_{1s} 4\pi r_N^2,$$

where k and h Boltzmann's and Planck's constants, ΔF_{act} is the activation energy at the solution-ice interface, ΔF_{cr} is the critical energy of germ formation, C_{het} is the normalizing function, r_N the radius of an insoluble fraction of an aerosol particle (INP), and c_{1s} is the concentration of water molecules adsorbed on 1cm^{-2} of a surface (Eq. 2.1 Khvorostyanov and Curry
 350 (2004)). Used parameter values are $C = 1.7 \times 10.999850^{10} \text{ N m}^{-2}$ and $c_{1s} = 1 \times 10^{19} \text{ m}^{-2}$.

Activation energy ΔF_{act} is calculated based on Eq. 15 in Jeffery and Austin (1997)

$$\Delta F_{act} = RT \left(\frac{B}{T - T_*} - \ln \frac{D_*}{D_0} \right) / N_A, \quad (\text{A2})$$

where T is temperature in kelvin, R is the molar gas constant and N_A is the Avogadro constant and parameter values $B = 347$, $T_* = 177$, $D_* = 4.17$ and $D_0 = 349$ for $p = 1$ bar are gained from Table 2 in Khvorostyanov and Curry (2004).

355 Critical energy is based on Eq. 2.10 in Khvorostyanov and Curry (2000)

$$\Delta F_{cr} = \frac{4\pi}{3} \sigma_{is} r_{cr}^2 f(m_{is}, x) - \alpha r_N^2 (1 - m_{is}), \quad (\text{A3})$$

where

$$\sigma_{is} = 28 \times 10^{-3} + 0.25 T_c \times 10^{-3} \text{ J m}^{-2} \quad (\text{A4})$$

is surface tension between ice and solution, where T_c is temperature in Celsius degrees (Khvorostyanov and K. Sassen, 1998);

360 ice germ radius:

$$r_{cr} = \frac{\sigma_{is}}{\rho_{ice} L_m^{ef} \ln \left(\frac{T_0}{T} S_W^G \right) - C \epsilon^2}, \quad (\text{A5})$$

where $\rho_{ice} = 900$ (kg m⁻³ is the density of ice, $T_0 = 273.15$ K;

$$L_m^{ef} = (79.7 + 0.708 T_c - 2.5 \times 10^{-3} \times T_c^2) \times 4.186810^3 \text{ J/kg} \quad (\text{A6})$$

is the effective latent heat of melting (Eq. 6 Khvorostyanov and K. Sassen (1998)); dimensionless parameter

$$365 \quad G = \frac{RT}{M_w L_m^{ef}}, \quad (\text{A7})$$

where M_w is the molar mass of water (Eq. 2.7 in Khvorostyanov and Curry (2000)).

The shape factor f is defined as a function of ratio $x = r_N / r_{cr}$ and $m = m_{is}$. It is gained from Eq. 2.9 in Khvorostyanov and Curry (2000), originally from Fletcher (1962),

$$2f(m, x) = 1 + [(1 - mx)/\phi]^3 + x^3(2 - 3\psi + \psi^3) + 3mx^3(\psi - 1), \psi = (x - m)/\phi, \phi = (1 - 2mx + x^2)^{1/2} \quad (\text{A8})$$

370 Case dependent parameters ϵ , elastic strain produced in ice embryo by the insoluble substrate; α , relative area of active sites; m_{is} , cosine of the contact angle; are defined in our results 3.3 to be

$$\epsilon = 0$$

$$\alpha = 0 \quad (\text{A9})$$

$$m_{is} = 0.57.$$

The m_{is} was used as targeting parameter since the simulation tests were found to be very sensitive for this parameter. Other case dependent parameters ϵ and α were not altered and had their default values.

375 Appendix B: Homogeneous freezing

Homogeneous freezing is possible for any aqueous droplet with or without insoluble particles. This is applied to the model according to Khvorostyanov and K. Sassen (1998).

The number of crystals formed by homogeneous nucleation due to the freezing of supercooled pure water or deliquescent condensation nuclei is described by Eq. 1 in Khvorostyanov and K. Sassen (1998):

$$380 \quad J = 2N_c \left(\frac{\rho_w kT}{\rho_{ice} h} \right) \sqrt{\frac{\sigma_{is}}{kT}} \exp \left[- \frac{\Delta F_{act} + \Delta F_{cr}}{kT} \right], \quad (B1)$$

where k and h Boltzmann's and Planck's constants, ρ_w is density of water, ρ_{ice} is density of ice (same as in A) and $N_c = 5.85e16m^{-2}$ is the number of water molecules contacting unit area of ice germ (Khvorostyanov and Curry, 2000).

Case dependent activation-energy $\Delta F_{act}(T) = 0.694 \times 10^{-19} \times (1 + 0.027(T_c + 30)) \text{kg m}^2 \text{s}^{-2}$, when $T_c < -30^\circ\text{C}$ (Khvorostyanov and K. Sassen, 1998).

385 Effective latent heat of melting L_m^{ef} is same as A6. Dimensionless parameter G is same as A7. Surface tension between ice and solution σ_{is} is same as A4.

Ice germ radius is defined as

$$r_{cr} = \frac{\sigma_{is}}{\rho_{ice} L_m^{ef} \ln \left(\frac{T_0}{T} S_W^G \right)}, \quad (B2)$$

which is same as A5 with $\epsilon = 0$ (Khvorostyanov and Curry, 2000).

390 Hence we get the critical energy of germ formation (Khvorostyanov and K. Sassen, 1998, Eq. 9b)

$$\Delta F_{cr} = \frac{4}{3} \pi \sigma_{is} r_{cr}^2 \quad (B3)$$

Appendix C: Deposition freezing

Deposition freezing is possible for dry insoluble aerosol at sub-saturated conditions ($RH < 100\%$). This is implemented following Khvorostyanov and Curry (2000) and additional parameters from Hoose et al. (2010).

395 The rate of germ formation J (s^{-1}) through deposition freezing is defined as in Khvorostyanov and Curry (2000, Eq 2.13)

The pre-exponential factor (kinetic coefficient) is about

$$J = 10^{30} \times r_n^2 \exp \left[- \frac{\Delta F_{act} + \Delta F_{cr}}{kT} \right], \quad (C1)$$

where r_n is the radius of the insoluble portion of the droplet, k is Boltzmann's constant, T is temperature. The pre-exponential factor (kinetic coefficient) is $10^{26} (\text{cm}^{-2}) r_n^2$ (Fletcher, 1962). Here case-dependent activation energy ΔF_{act} is set to zero

400 (Khvorostyanov and Curry, 2000).

Surface tension between ice and vapor (Hoose et al., 2010) is calculated with

$$\sigma_{iv} = \left[(76.1 - 0.155T_c) + (28.5 + 0.25T_c) \right] \times 10^{-3} \text{ J m}^{-2} \quad (\text{C2})$$

Ice germ radius r_{cr} (Khvorostyanov and Curry, 2000, Eq. 2.12) and defined as

$$r_{cr} = \frac{2\sigma_{iv}}{\left(R_v \frac{\rho_{ice}}{M_w} T \ln S_i - C\epsilon^2 \right)}, \quad (\text{C3})$$

405 where S_i is water vapor saturation ratio over ice, T is temperature, C is constant $1.7 \times 10^{10} (\text{N m}^{-2})$.

From previous values we get the critical energy of germ formation :

$$\Delta F_{cr} = \frac{4}{3} \pi \sigma_{iv} r_{cr}^2 f(m, x), \quad (\text{C4})$$

where the shape factor $f(m, x)$ is defined as in A8.

410 *Author contributions.* Ahola made the simulations with the help from Raatikainen. Ahola analysed the data with help from Raatikainen and Romakkaniemi. Ahola wrote the paper with comments from Kokkola, Korhonen, Raatikainen, Romakkaniemi and Tonttila. Ahola, Raatikainen, Tonttila, Kokkola and Romakkaniemi have contributed in developing the UCLALES-SALSA model. Korhonen supervised the project.

Competing interests. The authors declare that they have no conflict of interest.

415 *Acknowledgements.* This study has been funded by the European Research Council (Consolidator Grant 646857). Tomi Raatikainen acknowledges Academy of Finland for Research Fellow funding (grant number 322532). Dr. Mikhail Ovchinnikov is acknowledged for providing the simulation data of Ovchinnikov et al. (2014).

Zuidema, P., Baker, B., Han, Y., Intrieri, J., Key, J., Lawson, P., Matrosov, S., Shupe, M., Stone, R., and Uttal, T.: An Arctic Springtime Mixed-Phase Cloudy Boundary Layer Observed during SHEBA, *J. Atmospheric Sci.*, 62, 160–176, <https://doi.org/10.1175/JAS-3368.1>, 2005.

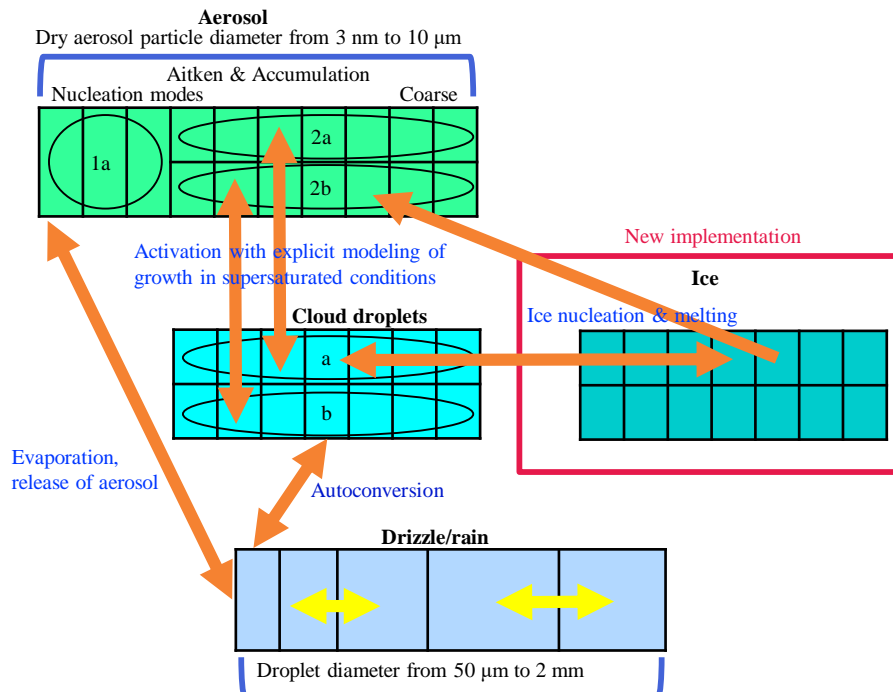

Figure 1. Bin scheme of UCLALES-SALSA with newly implemented particles, see also Fig. 1 in Tonttila et al. (2017).

Figure 2. Liquid and ice water path time series in UCLALES-SALSA simulations with fixed ice number concentration of 0, 1 and 4 L^{-1} (ICE0, ICE1, ICE4 respectively). Black and grey lines show results in the Ovchinnikov et al. (2014) study.

Figure 3. Liquid and ice water path time series in UCLALES-SALSA simulations with fixed ice number concentrations of 1, 2, 3, 4, 5 and 6 L^{-1} (ICE1, ICE2, ICE3, ICE4, ICE5 and ICE6, respectively).

Figure 4. Time series of water paths, mean ice number concentration in icy regions, in-cloud CDNC and cloud top and base of UCLALES-SALSA simulation of 32 hours with prognostic droplet freezing (Prognostic ice) compared with UCLALES-SALSA simulation of 24 hours with fixed ice number concentration of 4 L^{-1} (ICE4).

Figure 5. Logarithmic total mass mixing ratios (kg kg^{-1}) of dust in different hydrometeors given as cloud profile time series in UCLALES-SALSA simulation from the prognostic ice simulation. Cloud top is not plotted to keep the figure clearer because it is practically the same as upper RHi line.

Figure 6. Relative proportions of hydrometeors at each time step in the cloud layer. Cloud layer is defined when both cloud liquid water and ice mixing ratios are over 0.001 ($g\ kg^{-1}$). Black line represents relative change of the total number concentration in each bin.

Figure 7. Vertical profiles of liquid water and ice and freezing rate of droplets (nucleation rate) UCLALES-SALSA simulation with prognostic droplet freezing.

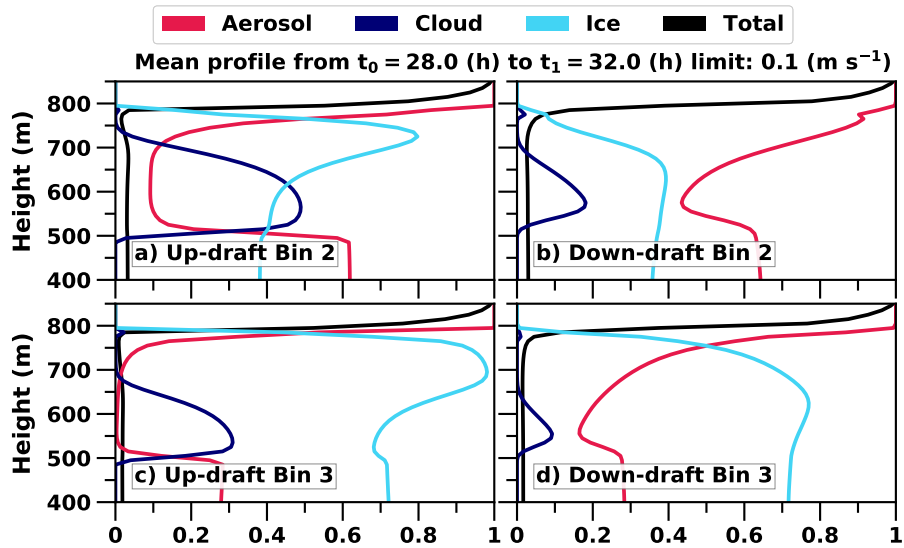

Figure 8. Mean profiles of relative proportions of hydrometeors in different vertical velocity conditions. Velocities smaller than 0.1 m s^{-1} are neglected. Averaging is done from simulation hours 28 to 32. Black line shows relative change of total number of hydrometeors. Only bins 2 and 3 are shown since they provide additional information in comparison to Fig. 6.
