

32 organic aerosol (OA) has the ability to absorb sunlight. The OA with strong light absorption is
33 called brown carbon (BrC) (Andreae et al., 2006).

34 The absorption of BC depends on its mixing state (Liu et al., 2015, 2017). Usually, BC is
35 coated with scattering material causing its light absorption to increase due to the lensing effect
36 (Fuller et al., 1999; Jacobson, 2001; Bond et al., 2006; Lack and Cappa, 2010). The absorption
37 enhancement (E_{abs}) is defined as the ratio of the aerosol absorption coefficient (b_{abs}) over the b_{abs}
38 of the pure BC particles. This enhancement can also be calculated by the ratio of the equivalent
39 mass absorption cross-sections (MAC). The MAC is defined as the ratio of b_{abs} over the BC mass.
40 The E_{abs} can be measured by using a thermodenuder (TD) for the removal of the non-refractory
41 coating material from the BC containing particle, or it can be estimated using a theoretical model
42 (for example Mie or Rayleigh-Debye-Gans theory) if the particle morphology is known.
43 Incomplete removal of the non-refractory material in the TD can lead to underestimation of the
44 E_{abs} (Healy et al., 2015; McMeeking et al., 2014).

45 Previous studies have demonstrated that lensing has a strong effect on the light absorption
46 of BC. Liu et al. (2015) found a campaign average E_{abs} of 1.3 at wavelength (λ) equal to 405 nm
47 and 1.4 at 781 nm in a rural area near London during the winter. They also suggested that the lower
48 volatility BrC has stronger absorption than the semi-volatile BrC. Knox et al. (2009) performed
49 measurements in downtown Toronto, during the wintertime using a TD at 340 °C. They reported
50 an E_{abs} of 1.43 for fresh particles, based on thermal OC/EC and photoacoustic measurements. Liu
51 et al. (2017) combined laboratory experiments with diesel exhaust emissions and ambient
52 measurements to show that particles with a ratio of non-refractory PM to BC mass (R_{BC}) less than
53 1.5 (typical for traffic emissions) had a negligible lensing effect. When the R_{BC} was above 3,
54 lensing caused significant enhancement of the absorption of BC. Zhang et al. (2018a) presented
55 three years of measurements in a suburban cite outside Paris, France, influenced by both fresh and
56 aged air masses. On average they found an $E_{abs}=2.07$ at 370 nm, and an $E_{abs}=1.53$ at 880 nm. They
57 calculated the E_{abs} by measuring the absorption coefficient (b_{abs}) with an aethalometer, while the
58 elemental carbon (EC) was measured with thermal methods using daily filters. Zhang et al. (2018b)
59 presented measurements in Beijing, China during wintertime. Using aethalometer measurements,
60 refractory and non-refractory particle size distributions and Mie theory, they calculated that the
61 lensing effect led to an E_{abs} ranging from 1.5 to 2 on average at 880 nm. Zanatta et al. (2018) found
62 an $E_{abs}=1.54$ at 550 nm for measurements at the Zeppelin Arctic Station. Lack et al. (2012)

63 analyzed measurements of biomass burning plumes near Boulder, CO during summertime. Using
64 a TD at 200 °C, they found E_{abs} values as large as 2.5 at 404 nm and 1.7 at 532 nm. Using the
65 absorption Angström exponent (AAE) and Mie theory calculations they showed the presence of
66 BrC.

67 Some studies have argued that Mie theory may overestimate the E_{abs} . Cappa et al. (2012)
68 suggested that the absorption enhancement of BC in California in the summertime was low with
69 values equal to 1.13 at 405 nm and 1.06 at 532 nm for $R_{BC}>10$. For their measurements they used
70 a TD operated at 225 °C and 250 °C. Hearnly et al. (2015) also reported practically no enhancement
71 in the BC absorption at 781 nm and $E_{abs}=1.19$ at 405 nm in Toronto, Canada during summertime.
72 During a period associated with wildfires the same authors measured $R_{BC}=6.9$ and $E_{abs}=1.39$ at
73 405 nm. They argued that there was little evidence of the lensing effect, and that BrC was driving
74 the E_{abs} . Cappa et al. (2019) performed measurements in Fresno, CA during wintertime and
75 Fontana, CA during summertime. They found that in Fresno there was absorbing OA, BrC, which
76 was related to biomass burning OA and nitrate-associated OA. In Fresno, they reported average
77 E_{abs} of 1.37, 1.22 and 1.1 at wavelengths equal to 405, 532, 781 nm, respectively, for R_{BC} ranging
78 from 1 to 4. In Fontana the E_{abs} was lower with values of 1.1 at 405 nm and 1.07 at 532 nm.
79 Laboratory measurements of McMeeking et al. (2014) for biomass burning aerosol indicated
80 higher absorption in lower wavelengths compared to higher ones and thus the presence of BrC. No
81 enhancement of absorption was observed at $R_{BC}<1$. On average they found an E_{abs} equal to 1.25 at
82 781 nm with a maximum value of $E_{abs}=4$ for $R_{BC}>10$.

83 Recent studies have suggested that the absorption efficiency of OA could be related to its
84 volatility. Saleh et al. (2014) in their laboratory biomass burning experiments showed that almost
85 all absorbing OA was associated with extremely low volatility compounds (ELVOCs), with an
86 effective saturation concentration C^* of $10^{-4} \mu\text{g m}^{-3}$. In addition, Saleh et al. (2018) using controlled
87 combustion experiments showed that the absorption activity of BrC is proportional to its molecular
88 size.

89 Despite the significant progress in understanding the absorption of atmospheric fine aerosol
90 there are still remaining questions regarding both the absorption enhancement of black carbon and
91 the absorption of OA as the aerosol evolves in the atmosphere. In this study we try to address these
92 issues for aerosol that has been aged in the atmosphere for at least a few days before arriving at
93 the island of Crete in the Eastern Mediterranean.

94 2. Experimental Methods

95 A remote location in the Eastern Mediterranean was used for the study of the absorption
96 and volatility of aged carbonaceous aerosol. The area is characterized by intense photochemistry,
97 especially during the summer (Pikridas et al., 2010) and is affected by pollutants transferred from
98 continental Europe, Turkey, Greece and Africa (Mihalopoulos et al., 1997; Lelieveld et al., 2002;
99 Kalivitis et al., 2011; Bougiatioti et al., 2014). Previous measurements have shown that the OA
100 reaching the area is highly oxidized regardless of its origin (Hidlebrandt et al., 2010; 2011). Lee
101 et al. (2010) showed that these oxidized organic compounds have much lower volatility than fresh
102 SOA. Long-term measurements in the region have revealed relatively high light absorption and
103 scattering by aerosol during the summer (Kalivitis et al., 2011; Vrekoussis et al., 2005).

104 The FAME-16 field campaign took place from May 9 to June 2, 2016. Measurements were
105 conducted at the Finokalia Station ($35^{\circ} 20' N$, $25^{\circ} 40' E$, 250 m asl), a remote site on the island of
106 Crete in Greece (Mihalopoulos et al., 1997). The nearest large city is Heraklion with 150,000
107 inhabitants located 50 km west of Finokalia (Kouvarakis et al., 2000). There are no local sources
108 near the station, allowing the investigation of aged OA from different source regions. During this
109 study, two Saharan dust events occurred from May 12 till May 15 and May 21 till May 22.

110 A Scanning Mobility Particle Sizer (SMPS, TSI classifier model 3080, CPC model 3775)
111 was used to measure the number and the size distribution of the particles. The aerosol flow was
112 set at 1 L min^{-1} and the sheath flow at 5 L min^{-1} . The sampling time was 3 min.

113 The mass concentration and the chemical composition of the particles were monitored
114 using a High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-ToF-AMS, Aerodyne
115 Research, Inc.). SQUIRREL 1.56D and PIKA v1.15D were used for the data analysis, while for
116 the elemental ratio calculations the improved ambient calculation approach of Canagaratna et al.
117 (2015) was used. The HR-ToF-AMS was operated in V-mode with a sample time of 3 min. The
118 collection efficiency of the HR-ToF-AMS was calculated using the algorithm of Kostenidou et al.
119 (2007). The average CE was 0.64 ± 0.2 . Positive matrix factorization (PMF) analysis (Lanz et al.,
120 2007; Paatero and Tapper, 1994; Ulbrich et al., 2009) was performed using as input the high
121 resolution OA mass spectra and the mass-to-charge ratios (m/z) from 12 to 200.

122 A Single Particle Soot Photometer (SP2, Droplet Measurement Technologies) was used to
123 measure the BC. The instrument was calibrated using fullerene soot (Alfa Aesar, stock 40971, lot
124 L20W054) (Gysel et al., 2011). The calibration of the SP2 was verified in separate experiments

125 using a centrifugal particle mass analyzer (CPMA, Cambustion) (Saliba et al., 2016). The data
126 were analyzed using the Probe Analysis Package for Igor. In our measurements, the number
127 concentration of BC was low ($<10,000$ particles cm^{-3}), and thus it was assumed that there were no
128 coincidence artifacts in our measurements. The scattering measurement was calibrated using
129 monodisperse polystyrene latex (PSL) spheres.

130 A photoacoustic extinctions (PAX, Droplet Measurement Techniques) with a blue (405
131 nm) laser was used to measure the absorption (b_{abs}) and the scattering (b_{scat}) coefficients. Fullerene
132 soot and PSL spheres were used to calibrate the absorption and scattering signals, respectively. An
133 activated carbon denuder was placed in front of the PAX to remove NO_2 . Furthermore, a seven
134 wavelength aethalometer (AE31, Magee Scientific) was used to measure the b_{abs} at 370, 470, 520,
135 590, 660, 880 and 950 nm and to calculate the absorption Angstrom exponent (AAE), which
136 describes the wavelength dependence of the b_{abs} . The aethalometer measurements were corrected
137 for scattering and multiple scattering artifacts following Saleh et al. (2014) and Tasoglou et al.
138 (2017) using the corrections suggested by Weingartner et al. (2003) and Kirchstetter and Novakov
139 (2007).

140 The thermodenuder (TD) used in this study, was placed upstream of the HR-ToF-AMS and
141 the SMPS. The TD design was similar to that developed by An et al. (2007) and is described by
142 Louvaris et al. (2017). The TD was operated at temperatures ranging from 25 °C to 400 °C using
143 several temperature steps. One complete cycle from 25 to 400 °C and back to 25 °C lasted
144 approximately 10 h. Sampling was alternated between the ambient line and the TD line every 3
145 minutes using computer-controlled valves. Changes in particle mass concentration, composition,
146 and size due to evaporation in the TD were measured by the HR-ToF-AMS and the SMPS resulting
147 in thermograms of OA mass fraction remaining (MFR) as a function of TD temperature. The OA
148 MFR was calculated as the ratio of organic mass concentration of a sample passing through the
149 TD at time t_i over the average mass concentration of the ambient samples that passed through the
150 bypass line at times t_{i-1} and t_{i+1} . The sample residence time in the centerline of the TD was 14 s at
151 25 °C, corresponding to an average residence time in the TD of 28 s. The MFR values were
152 corrected for particle losses in the TD due to diffusion and thermophoresis. To account for these
153 losses, sample flow rate as well as size- and temperature-dependent loss corrections were applied
154 following Louvaris et al. (2017) corresponding to the operating conditions during the campaign.
155 The final step of the data analysis was to average the corrected for CE and TD losses MFR data

156 based on temperature bins of 10°C. The MFR calculation assumes implicitly that the OA
157 concentration remains constant during the measurement period. To ensure that this condition is
158 satisfied, if two consecutive OA ambient mass concentrations differed by more than 25%, the
159 corresponding MFR was not included in the analysis. Also, in order to ensure that the temperature
160 was constant during the measurement, the absolute difference between the two samples had to be
161 less than 5°C. If this difference for a TD sample was higher, then the sample was not included in
162 our analysis. The same approach was used also for the factors resulting from the PMF analysis of
163 the AMS spectra. However, in this case a minimum concentration threshold of 0.1 $\mu\text{g m}^{-3}$ was used
164 for the ambient concentrations together with the criterion of the stability of the ambient
165 concentrations during the sampling period. MFR values corresponding to concentrations of the
166 PMF factors below this threshold were not included in the dataset. Approximately 75% of the OA
167 samples satisfied all these constraints and were used in the analysis. The corresponding
168 percentages were 65% and 70% for the two identified PMF factors. In the present work the
169 complete datasets will be analyzed together, averaging the corresponding measurements. More
170 details regarding the data analysis and the sensitivity tests of the TD measurements are provided
171 in the supplementary information.

172 The concentrations of gas-phase pollutants were measured using a Proton-Transfer
173 Reaction Mass Spectrometer (PTR-QMS 500, Ionicon Analytik) and gas monitors. The PTR-MS
174 was calibrated with a standard gas mixture of VOCs. The concentration of O₃ was measured using
175 a continuous O₃ analyzer (Thermo Scientific, 49i) and the concentrations of nitrogen oxides were
176 measured using a NO/NO₂/NO_x analyzer (Thermo Scientific, 42i-TL).

177

178 3. Theoretical Analysis Methods

179 The dynamic TD evaporation model of Riipinen et al. (2010) together with the uncertainty
180 estimation algorithm of Karnezi et al. (2014) were used for the determination of the OA volatility
181 distribution. Inputs for the model included the ambient OA concentration, the OA density
182 calculated by the algorithm proposed by Kostenidou et al. (2007), the initial average particle size,
183 TD temperature, the MFR values, and TD residence time. In the volatility basis set framework of
184 Donahue et al. (2006), the volatility distribution is represented with a range of logarithmically
185 spaced C^* bins along a volatility axis. In this study 6 bins with variable mass fractions were chosen.
186 For this 6-bin solution, the best 2% of the mass fraction combinations with the lowest error were

187 used to estimate the average mass fraction along with their corresponding standard deviation for
188 the uncertainty of each bin. Additionally the parameters that affect indirectly the calculated
189 volatility such as the effective vaporization enthalpy (ΔH_{vap}), and the effective accommodation
190 coefficient (a_m) were estimated following Karnezi et al. (2014). Additional information regarding
191 the data analysis of the TD measurements are in the supplemental information (sections S1 and
192 S2).

193 A Mie theory model based on the work of Bohren and Huffman (1983) was used to
194 calculate the theoretical MAC and E_{abs} . Mie theory describes the extinction of light by spherical
195 particles due to an incoming planar electromagnetic wave. The calculations were based on the
196 SMPS and SP2 size distributions. For the BC core we assumed a refractive index of the core
197 $n_{\text{rBC}}=1.85+0.71i$ (Bond and Bergstrom, 2006) and a density of 1.8 g cm^{-3} (Mullins and Williams,
198 1987; Park et al., 2004; Wu et al., 1997). A non-absorbing coating of the BC core was assumed,
199 with a refractive index of $n_{\text{OA}} = 1.55$ (Bond and Bergstrom, 2006). The total aerosol effective
200 density used was calculated based on the SMPS and HR-ToF-AMS distributions. The average
201 effective density for the campaign was $1.66 \pm 0.11 \text{ g cm}^{-3}$. The other inputs of the model were the
202 measured BC size distributions from the SP2 and the ratio of the total aerosol mass over the BC
203 mass as measured by the SMPS and the SP2, respectively.

204

205 **4. Results and discussion**

206 The average rBC concentration of the campaign was $0.14 \mu\text{g m}^{-3}$ and the average OA
207 concentration was $1.5 \mu\text{g m}^{-3}$ (Figure 1). The two major Saharan dust events affected, as expected,
208 the aerosol optical properties. In the present study we focus only on the non-dust periods. The
209 dominant PM_{10} components were sulfate and OA, accounting for 46% and 34% of the PM_{10} ,
210 respectively. The O:C ranged from 0.65 to 1, with an average value of 0.83. These values are
211 typical in Finokalia during the spring and summer periods (Hidlebrandt et al., 2010).

212

213 **4.1 OA Volatility**

214 The estimated volatility distribution for the total OA in Finokalia during FAME-16 is
215 depicted in Figure 2. Use of OA with $C^* = 10^{-8} \mu\text{g m}^{-3}$ was needed to capture the behavior of the
216 OA at $400 \text{ }^\circ\text{C}$. Almost 40% of the OA consisted of semi-volatile organic compounds (SVOCs),

217 35% of low volatility organic compounds (LVOCs), and the rest was extremely low volatility
218 organic compounds (ELVOCs).

219 The estimated value of the effective vaporization enthalpy was $80 \pm 20 \text{ kJ mol}^{-1}$. This value
220 was in agreement with the reported value by Lee et al. (2010) of 80 kJ mol^{-1} for the FAME-08
221 campaign. The estimated accommodation coefficient was 0.27, ranging from 0.1 to 0.8. This value
222 was a little higher than the 0.05 value reported in the earlier study. However, both suggest only
223 moderate resistances to mass transfer during the evaporation in the TD.

224 The corresponding measured and predicted thermograms are depicted in Figure 3. Almost
225 30% of the OA had not evaporated even after heating at $400 \text{ }^\circ\text{C}$. The temperature at which half of
226 the OA evaporated was $T_{50}=120 \text{ }^\circ\text{C}$, a value similar to that observed by Lee et al. (2010). The
227 composition of the OA leaving the TD changed significantly as temperature increased according
228 to the model. At $125 \text{ }^\circ\text{C}$ the LVOCs and ELVOCs contributed equally to the remaining OA mass.
229 For further temperature increases the LVOC fraction was reduced until $375 \text{ }^\circ\text{C}$, at which point only
230 the ELVOCs remained.

231 PMF analysis resulted in a two-factor solution (Florou et al., in prep.). Factor 1
232 corresponded to more oxidized oxygenated OA (MO-OOA) and Factor 2 to a less oxidized
233 component (LO-OOA). The average contribution of the two factors was 47% for the MO-OOA
234 and 53% for the LO-OOA. The O:C for the MO-OOA was 0.95 ($OS_C = 0.59$) and for the LO-
235 OOA it was 0.56 ($OS_C = -0.27$). The Finokalia area is characterized by the absence of local sources
236 and as result the absence of fresh OA. The OA during FAME-08, was also found to consist entirely
237 of OOA with no primary OA present (Hildebrandt et al., 2010). POA evaporates and gets oxidized
238 rapidly in the photochemically active environment of the Eastern Mediterranean during its
239 transport from its sources to this remote site.

240 The volatility distributions of the two PMF factors were estimated following the same
241 approach as that for the total OA. The measured thermograms for the two PMF factors are shown
242 in Figure 4. Almost 50% of both the MO-OOA and the LO-OOA evaporated at $150 \text{ }^\circ\text{C}$. Almost
243 30% of the MO-OOA mass, and about 20% of the LO-OOA did not evaporate even at temperatures
244 as high as 400°C . The model reproduced the observed MFR values for both factors. Both factors
245 contained components with a wide volatility range. The MO-OOA exhibited a bimodal volatility
246 distribution with peaks at effective saturation concentrations of 10^{-8} and $10 \mu\text{g m}^{-3}$. Its effective
247 enthalpy of vaporization was approximately $90 \pm 35 \text{ kJ mol}^{-1}$ and its accommodation coefficient

248 was 0.27. The estimated volatility distribution of the LO-OOA was a little more uniform peaking
249 at an effective saturation concentration of $1 \mu\text{g m}^{-3}$. The calculated average volatility of LO-OOA
250 was $0.016 \mu\text{g m}^{-3}$, an order of magnitude higher than that of the MO-OOA. The LO-OOA enthalpy
251 of vaporization was $70 \pm 20 \text{ kJ mol}^{-1}$, 20 kJ mol^{-1} lower than that of the MO-OOA. Its
252 accommodation coefficient was approximately 0.1 indicating small mass transfer resistances. MO-
253 OOA consisted of approximately 40% SVOCs, 30% LVOCs, and 30% ELVOCs. On the contrary,
254 LO-OOA consisted of almost 45% SVOCs, 40% LVOCs and only 15% ELVOCs.

255 The fitting of the individual factor thermograms implicitly assumes that each factor had the
256 same size distribution as the total OA and also that the two factors were externally mixed. The
257 uncertainty introduced by these two assumptions was implicitly evaluated comparing the estimated
258 total OA of volatility distribution with the composition-weighted average of the volatility
259 distributions of the two OA factors. The two distributions agreed within a few percent for $10^{-3} < C^* <$
260 10^0 and within 10% for the lowest and highest volatility bins.

261

262 4.2 Aerosol optical properties

263 The measured b_{scat} at 405 nm ranged from 11.5 to 47 Mm^{-1} with an average campaign value
264 of 26.5 Mm^{-1} (Figure 5). Similarly, b_{abs} at 405 nm ranged from 0.64 to 5.6 Mm^{-1} with an average
265 value of 2.1 Mm^{-1} .

266 Acetonitrile is a known biomass burning marker and can help identify the potential
267 influence of the site by biomass burning events or wildfires during the campaign. The acetonitrile
268 concentration measured by the PTR-MS remained close to 0.4 ppb during the campaign, which is
269 the local background level. This together with the low BC levels indicate that the site was not
270 impacted by nearby biomass burning during the study.

271 The $b_{\text{abs},405}$ variation followed that of the rBC ($R^2=0.74$ for the hourly averages). The ratio
272 of the $b_{\text{abs},405}$ over the rBC, MAC_{405} , was equal to $16.3 \pm 4.2 \text{ m}^2 \text{ g}^{-1}$. Previous studies have shown
273 that freshly generated BC has a MAC_{532} of $7.5 \text{ m}^2 \text{ g}^{-1}$ (Clarke et al., 2004; Bond and
274 Bergstrom, 2006). Using the definition of the AAE,

$$275 \quad \text{AAE} = -\frac{\ln\left[\frac{\text{MAC}_{405}}{\text{MAC}_{532}}\right]}{\ln\left[\frac{405}{532}\right]},$$

276 we can calculate the MAC of freshly generated BC 405 nm. Assuming that the AAE is equal to
277 unity for BC particles, we find that the MAC_{405} of BC was approximately $9.9 \text{ m}^2 \text{ g}^{-1}$. The difference

278 between the measured and the theoretical value of MAC_{405} can be due to the coating of BC by
279 other PM components (lensing effect) and/or the existence of other absorbing material. This will
280 be explored below.

281 The campaign average AAE of PM for wavelengths ranging from 370 to 950 nm was
282 0.97 ± 0.22 . The AAE of coated BC cores can deviate from the typical $AAE=1$ with values greater
283 or lower than unity (Gyawali et al., 2009). In addition, Lack and Cappa (2010) suggested that an
284 $AAE > 1.6$ should confirm the presence of non-BC absorbing material, however an $AAE < 1.6$ does
285 not exclude its presence.

286 Mie theory calculations were performed in order to estimate the MAC_{405} and the E_{abs} due
287 to the lensing effect of the shell covering the BC core. Initially, a non-absorbing shell was assumed.
288 The predicted MAC_{405} had an average value of $14.1 \text{ m}^2 \text{ g}^{-1}$. The average E_{abs} due to lensing effect
289 was 2.07. The average predicted MAC_{405} was 13% lower than the measured suggesting the
290 existence of non-refractory absorbing material (Figure 6).

291 In the next step, the Mie theory calculations were repeated assuming an absorbing shell
292 with a refractive index of $n_{OA} = 1.55 + ki$, where the imaginary part, k , was allowed to vary from
293 0 to 0.4. This range of k values was selected based on previous literature (Kirchstetter et al., 2004;
294 Alexander et al., 2008; Chakrabarty et al., 2010; Chen and Bond, 2010; Saleh et al., 2014;
295 Chakrabarty et al., 2016, Li et al., 2016; Saleh et al., 2018). One third of the resulting k values
296 during the campaign were zero, suggesting a non-absorbing shell, while the other two thirds were
297 positive. More specifically, 22% of the estimated k values ranged from 0.01 to 0.1, 22% from 0.11
298 to 0.2, 19% from 0.21 to 0.3, and 4% of the k values ranged from 0.31 to 0.4.

299

300 **4.3 The role of ELVOCs**

301 The hypothesis that the presence of ELVOCs could explain the higher aerosol light
302 absorption was tested. The unexplained MAC (ΔMAC) difference of measured and predicted
303 values was compared with the total ELVOC mass concentration. The ELVOC concentration was
304 estimated based on the results on the volatility analysis of the two PMF factors:

$$305 \quad [ELVOC] = 0.15 [LO\text{-}OOA] + 0.3 [MO\text{-}OOA]$$

306 The least-squares fit between the 3-hour averaged ΔMAC and ELVOC had $R^2=0.65$ (Figure 7).
307 This result suggests that the ELVOCs were probably contributing to the total absorption and could
308 explain the difference in the MAC.

309 5. Conclusions

310 A month-long campaign was conducted at a remote site, in Finokalia, Crete during May of
311 2016. The dominant PM₁ components were sulfate and aged organics with O/C=0.81. The average
312 ambient OA concentration was 1.5 µg m⁻³ and the rBC was 0.14 µg m⁻³. Continuous monitoring of
313 biomass burning markers revealed that there was no detectable impact of wildfires on the site
314 during the campaign. PMF analysis resulted in two secondary OA factors: one more oxidized
315 (MO-OOA) and one less oxidized (LO-OOA). Total OA consisted on average of 40% SVOCs,
316 35% LVOCs and 25% ELVOCs. Both OA components with a wide range of volatilities.
317 Approximately 30% of the MO-OOA was ELVOCs, 30% LVOCs and 40% semi-volatile material.
318 The LO-OOA was more volatile on average with 40% consisting of LVOCs and 45% of SVOCs
319 and 15% of ELVOCs.

320 Aerosol optical properties were measured. The average b_{scat} at 405 nm was 26.5 Mm⁻¹ and
321 the average b_{abs} at 405 nm was 2.1 Mm⁻¹. Furthermore, the average AAE was 0.97 and the MAC₄₀₅
322 was 16.3. Mie theory calculations were able to reproduce one third of the measured MAC₄₀₅ values
323 assuming core-shell morphology and a non-absorbing shell ($k=0$). We estimated that the non-
324 absorbing shell was causing an enhancement of the absorption by a factor of 2.07. For the other
325 two thirds of the measurements the presence of an absorbing shell with an average k of 0.21 was
326 needed to explain the measurements.

327 The ELVOCs mass concentration was estimated using the volatility distributions of the two
328 factors. The ELVOC concentration was highly correlated ($R^2=0.65$) with the difference of the
329 unexplained MAC₄₀₅, defined as the difference of the measured MAC₄₀₅ the measured and the one
330 predicted by Mie theory for $k=0$.

331

332 *Data availability.* The data in the study are available from the authors upon request
333 (spyros@chemeng.upatras.gr).

334

335 *Author contributions.* AT conducted the absorption measurements, analysed the results and wrote
336 the paper. EL performed the thermodenuder measurements and analysed the results. KF performed
337 the AMS measurements and analysed the results. AL performed the PTR-MS measurements and
338 analysis. EK was responsible for the OA volatility analysis. CK coordinated the field campaign
339 and assisted with all measurements. NW assisted with all measurements SNP was responsible for

340 the design and coordination of the study and the synthesis of the results. All co-authors contributed
341 to the writing of the manuscript.

342

343 *Competing interests.* The authors declare that they have no conflict of interest.

344

345 **Acknowledgements**

346 This work was supported by U.S. Environmental Protection Agency STAR program [grant
347 number R835035]. Travel support was provided by the European Research Infrastructure
348 ACTRIS. The authors would like to thank the Finokalia station personnel for the accommodation
349 and for providing the aethalometer measurements.
