Abstract. Stratospheric ozone and water vapor are key components of the Earth system, and past and future changes to both have important impacts on global and regional climate. Here we evaluate long-term changes in these species from the pre-industrial (1850) to the end of the 21st century in CMIP6 models under a range of future emissions scenarios. There is good

40 agreement between the CMIP multi-model mean and observations, although there is substantial variation between the
individual CMIP6 models. For the CMIP6 multi-model mean, global total column ozone (TCO) has increased from ~300 DU
in 1850 to ~305 DU in 1960, before rapidly declining in the 1970s and 1980s following the use and emission of halogenated
ozone depleting substances (ODSs). TCO is projected to return to 1960's values by the middle of the 21st century under the
SSP2-4.5, SSP3-7.0, SSP4-3.4, SSP4-6.0 and SSP5-8.5 scenarios, and under the SSP3-7.0 and SSP5-8.5 scenarios TCO values
45 are projected to be ~10 DU higher than the 1960's values by 2100. However, under the SSP1-1.9 and SSP1-1.6 scenarios,
TCO is not projected to return to the 1960's values despite reductions in halogenated ODSs due to decreases in tropospheric
ozone mixing ratios. This global pattern is similar to regional patterns, except in the tropics where TCO under most scenarios
is not projected to return to 1960's values, either through reductions in tropospheric ozone under SSP1-1.9 and SSP1-2.6, or
through reductions in lower stratospheric ozone resulting from an acceleration of the Brewer-Dobson Circulation under other
50 SSPs. CMIP6 multi-model mean stratospheric water vapor mixing ratios in the tropical lower stratosphere have increased by
~0.5 ppm from the pre-industrial to the present day and are projected to increase further by the end of the 21st century. The
largest increases (~2 ppm) are simulated under the future scenarios with the highest assumed forcing pathway (e.g. SSP5-8.5).
Both TCO and tropical lower stratospheric water vapor show large variability following explosive volcanic eruptions.

1 Introduction

55 Stratospheric ozone and water vapor are key components of the Earth system, and past changes in both have had important
impacts on global and regional climate (e.g. Solomon et al., 2010; Dessler et al., 2013; Eyring et al., 2013; WMO 2018).
Depletion of the ozone layer over the last few decades of the 20th century, driven by emissions of ozone depleting substances
(ODSs), provides an excellent illustration of a forcing that has caused large dynamical and regional surface impacts, despite
an overall small global radiative forcing ($-0.05 \pm 0.10 \text{ Wm}^{-2}$ from 1750 to 2011; Myhre et al. 2013). The Antarctic ozone hole
60 has cooled the springtime Antarctic lower stratosphere and has driven a poleward expansion of the tropospheric circulation
and dry zones of the SH during the summer season (e.g. Thompson and Solomon, 2002; Gillett and Thompson, 2003;
McLandress et al., 2010; Son et al., 2010; Polvani et al., 2011; Braesicke et al., 2013; Keeble et al., 2014, Morgenstern et al.,
2018). Measurements of stratospheric water vapor (SWV) are uncertain and a long-term trend has not been established (Scherer
et al., 2008; Hurst et al., 2011; Hegglin et al., 2014). Nonetheless, large decadal variations in SWV have been suggested to
65 affect surface temperatures (e.g. Solomon et al., 2010). Given these climate impacts, it is important to understand the drivers
of stratospheric ozone and water vapor and to distinguish long-term trends from interannual and decadal variability.

The Intergovernmental Panel on Climate Change (IPCC) Fifth Assessment Report (AR5) highlights tropospheric ozone as the
third most important anthropogenic greenhouse gas (GHG) with a global mean radiative forcing of $0.35 \pm 0.2 \text{ Wm}^{-2}$, while
stratospheric water vapor changes resulting from CH₄ oxidation exert a global mean radiative forcing of $0.07 \pm 0.05 \text{ Wm}^{-2}$

70 (Hansen et al 2005, Myhre et al, 2007; Myhre et al., 2013). The primary contributor to the radiative forcing estimate for ozone is increases in tropospheric ozone ($0.4\pm 0.2 \text{ Wm}^{-2}$), while recent depletion of stratospheric ozone due to the use and emission of halogenated ODSs, compounded with impacts on ozone of increasing CO_2 , CH_4 , and N_2O , has resulted in a weakly negative radiative forcing ($-0.05\pm 0.1 \text{ Wm}^{-2}$). Recently, Checa-Garcia et al., (2018) estimated ozone radiative forcing using the ozone forcing dataset that was developed for the Coupled Model Intercomparison Project Phase 6 (CMIP6, Eyring et al., 2016), and
75 calculated values of 0.28 Wm^{-2} , which, while consistent with the IPCC-AR5 estimate, represents an increase of ~80% compared to the CMIP5 ozone forcing dataset (Cionni et al 2011, Stevenson et al, 2013). The relative uncertainties in radiative forcing estimates for both stratospheric ozone and water vapor are large due to the challenges in constraining the concentrations of both during the pre-satellite era. As a result, the current radiative forcing estimates rely on ozone and water vapor fields derived from simulations performed by global climate models and Earth system models.

80 Stratospheric ozone concentrations are determined by a balance between production and destruction of ozone through gas phase chemical reactions and transport (e.g. Brewer and Wilson, 1968). Gas phase ozone chemistry consists of sets of oxygen only photo-chemical reactions first described by Chapman (1930), alongside ozone destroying catalytic cycles involving chlorine, nitrogen, hydrogen and bromine radical species (e.g. Bates and Nicolet, 1950; Crutzen, 1970; Johnston, 1971; Molina and Rowland, 1974; Stolarski and Cicerone, 1974). Heterogeneous processes play a major role in determining ozone
85 abundances in the polar lower stratosphere (e.g. Solomon, 1999) and following large volcanic eruptions (e.g. Solomon et al., 1996; Telford et al., 2009).

Changes in anthropogenic emissions of halogenated ODSs, N_2O , CH_4 , CO_2 and other GHGs during the 21st century are expected to perturb these chemical cycles either directly through their role as source gases or by changing stratospheric temperatures and dynamics (Eyring et al., 2010; Keeble et al., 2017). Following the implementation of the Montreal Protocol
90 and its subsequent Amendments, stratospheric concentrations of inorganic chlorine and bromine levelled off in the mid-1990s and are now in decline (Mäder et al., 2010; WMO, 2018), which has led to early signs of recovery of stratospheric ozone (Keeble et al., 2018; Weber et al., 2018; WMO 2018) and the detection of statistically robust positive trends in September Antarctic ozone (Solomon et al., 2016). Total column ozone in the mid- and high latitudes is projected to return to pre-1980 values during the coming decades (Eyring et al., 2013; Dhomse et al., 2018; WMO, 2018). Future emissions of CH_4 and N_2O ,
95 which are not regulated in the same way as halogenated ODSs, are associated with greater uncertainty and future concentrations of HO_x (H, OH, HO_2) and NO_x (NO, NO_2) radicals are highly sensitive to assumptions made about their future emissions. Additionally, increases in GHG concentrations are expected to lead to an acceleration of the Brewer–Dobson circulation (BDC; Butchart et al., 2006, 2010; Shepherd and McLandress, 2011; Hardiman et al., 2014; Palmeiro et al., 2014), which may affect ozone concentrations directly through transport (e.g. Plumb, 1996; Avallone and Prather, 1996) and by controlling the
100 oxidation of Cl_y , NO_y and HO_x , reservoir species (e.g. Revell et al., 2012; Meul et al., 2014). However, recent research (Polvani et al., 2018, 2019) has shown that stratospheric ozone depletion caused by increasing ODSs has accounted for around half of

the acceleration of the BDC in recent decades. As concentrations of ODSs decline, stratospheric ozone recovery may offset, at least in part, future changes to the speed of the BDC resulting from GHG changes.

105 Stratospheric water vapor concentrations are determined predominantly through a combination of the dehydration air masses experience as they pass through the cold point tropical tropopause (Brewer, 1949; Fueglistaler et al., 2005) and *in-situ* production from CH₄ oxidation (Brasseur and Solomon, 1984; Jones et al., 1986; LeTexier et al., 1988). Direct injection by convective overshooting (Dessler et al., 2016) or following volcanic eruptions (Murcray et al., 1981; Sioris et al. 2016) are also sources of SWV.

110 Observations of stratospheric water vapor show a net increase during the late 20th century (e.g. Rosenlof et al., 2001; Scherer et al., 2008; Hurst et al., 2011), followed by a sudden decrease of ~10% after 2000 (e.g. Solomon et al., 2010). Virtually all models project increases in SWV concentrations under increased CO₂ (e.g. Gettelman et al., 2010; Banerjee et al., 2019). Projected increases over the course of the 21st century occur due to the predominant effect of increases in upper tropospheric temperatures, offset in part by the effects of a strengthening BDC (Dessler et al., 2013; Smalley et al., 2017), with additional impacts from future CH₄ emissions (Eyring et al., 2010; Gettelman et al., 2010). Eyring et al. (2010) calculate a mean increase
115 of 0.5-1 ppm per century in SWV concentrations for models contributing to the Chemistry-Climate Model Validation (CCMVal) inter-comparison project, although agreement between models on the absolute increase is poor.

To advance our understanding of long-term changes to a number of components of the Earth system, including stratospheric ozone and water vapor, the CMIP Panel, operating under the auspices of the Working Group on Coupled Modelling (WGCM) of the World Climate Research Programme (WCRP), has defined a suite of climate model experiments, which together form
120 CMIP6 (Eyring et al., 2016). Between the previous phase (CMIP5; Taylor et al., 2012) and CMIP6 there has been further development of existing models; new models have joined and a new set of future scenarios, the shared socioeconomic pathways (SSPs; Riahi et al., 2017) that are used in climate projections by CMIP6 models as part of the Scenario Model Intercomparison Project (ScenarioMIP; O'Neill et al., 2015), have been established. Earth system models have been further developed with improved physical parametrizations and some have added additional Earth system components (e.g., atmospheric chemistry,
125 nitrogen cycle, ice sheets). As a result of this advancement in model complexity, the CMIP6 multi-model ensemble provides an opportunity to re-assess past and projected future stratospheric ozone and water vapor changes. In this study, we evaluate these changes against observations over the last three decades and examine long-term changes in these quantities from 1850 to 2100 under the SSP scenarios. Section 2 describes the simulations and models used in this study, with a focus on the treatment of stratospheric ozone and water vapor. Long-term changes in ozone and water vapor are evaluated in Sections 3 and 4, respectively, and implications are discussed in Section 5. Our results inform future studies that use CMIP6 simulations
130 to investigate stratospheric composition changes and associated impacts.

2 Models and Simulations

This study evaluates long-term ozone and water vapor changes in 14 models which have performed the CMIP historical simulations and a subset of which have performed ScenarioMIP simulations. The treatment of stratospheric chemistry varies significantly across the 14 models evaluated in this study. We evaluate all models which have produced ozone and water vapor output, regardless of the complexity of the stratospheric chemistry used, as these models may be used in other studies to diagnose the impacts of stratospheric composition changes on radiative forcing and/or regional climate change. In this section, the models and simulations used in the subsequent analysis sections are described, along with the observational datasets used for evaluation. Several of the figures were created with the Earth System Model Evaluation Tool (ESMValTool) version 2.0 (Eyring et al., 2019; Righi et al., 2019), a diagnostic and performance metric tool for enhanced and more comprehensive Earth system model evaluation in CMIP.

2.1 Models

At the time of the preparation of this manuscript, 14 models (BCC-CSM2-MR, BCC-ESM1, CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-ESM2-1, E3SM-1-0, FGOALS-g3, GFDL-CM4, GFDL-ESM4, IPSL-CM6A-LR, MRI-ESM2-0, SAM0-UNICON, and UKESM1-0-LL) have provided ozone mixing ratios and 10 models (BCC-CSM2-MR, BCC-ESM1, CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-ESM2-1, GFDL-CM4, IPSL-CM6A-LR, MRI-ESM2-0, and UKESM1-0-LL) have provided water vapor as diagnostics. Of the 14 models analysed in this study, five (CESM2-WACCM, CNRM-ESM2-1, GFDL-ESM4, MRI-ESM2-0, and UKESM1-0-LL) use fully coupled, online stratospheric chemistry, while two (CNRM-CM6-1 and E3SM-1-0) use a simple chemistry scheme. The remaining seven (BCC-CSM2-MR, BCC-ESM1, CESM2, FGOALS-g3, GFDL-CM4, IPSL-CM6A-LR and SAM0-UNICON) do not include an interactive chemistry scheme, and instead prescribe stratospheric ozone according to the CMIP6 ozone database (except in the case of CESM2, which prescribes ozone values from the CESM2-WACCM model). Relevant details of each model are provided in the appendix, and a summary is provided in Table 1.

The CMIP6 ozone dataset is designed to be used by those models without interactive chemistry, and was created using a different approach from the previous CMIP5 ozone database (Cionni et al., 2011). The Cionni et al. (2011) dataset was based on stratospheric ozone values from a combination of model and observational datasets between the 1970s and 2011, and extended into the past and future based on assumptions of changes to EESC and the 11-year solar cycle. Tropospheric ozone values were based on a mean field of two models with interactive chemistry. The CMIP6 ozone dataset was created using simulations from the CMAM and CESM-WACCM models which both performed the REF-C2 simulation as part of the Chemistry-Climate Model Initiative (Eyring, et al., 2013; Morgenstern et al., 2017). As a result, the CMIP6 dataset provides a full three-dimensional field of ozone mixing ratios created using a single, consistent approach for both the stratosphere and

troposphere, extending from preindustrial times to present day, and until the end of the 21st century following the different SSP scenarios (O'Neill et al., 2015).

165 **BCC-CSM2-MR:** The BCC-CSM2-MR model, developed by the Beijing Climate Center, is a coupled ocean–atmosphere model. Ozone in the stratosphere and troposphere is prescribed using monthly mean time-varying gridded data from the CMIP6 dataset. Other GHG concentrations including CO₂, N₂O, CH₄, CFC11, CFC12 are monthly zonal-mean values using the CMIP6 datasets (Meinshausen et al., 2017, 2019). Stratospheric water vapor concentrations are prognostic values calculated in a similar way to those in the troposphere. A full description and evaluation of the BCC-CSM2-MR model is provided by Wu et al. (2019a).

170 **BCC-ESM1:** The BCC-ESM1 model, developed by the Beijing Climate Center, is a fully coupled global climate-chemistry-aerosol model. Tropospheric ozone is modelled interactively using the MOZRT2 chemistry scheme, while stratospheric ozone is prescribed to the zonally averaged, monthly mean values from 1850 to 2014 derived from the CMIP6 data package in the top two model layers, and relaxed towards the CMIP6 dataset between these layers and the tropopause. GHG concentrations including CH₄, N₂O, CO₂, CFC-11, and CFC-12 are prescribed using CMIP6 historical forcing data as suggested in the
175 AerChemMIP protocol (Collins et al., 2017). Stratospheric water vapor is a prognostic variable without any special treatment of CH₄ oxidation. A full description and evaluation of the BCC-ESM1 model is provided by Wu et al. (2019b).

CESM2: The Community Earth System Model version 2 (CESM2) is the latest generation of the coupled climate/Earth system models developed as a collaborative effort between scientists, software engineers, and students from the National Center for Atmospheric Research (NCAR), universities, and other research institutions. CESM2(CAM6) uses the Community
180 Atmosphere Model version 6 as its atmosphere component, which has 32 vertical levels from the surface to 3.6 hPa (about 40 km) and a horizontal resolution of 1.25° longitude by 0.95° latitude, and limited interactive chemistry for tropospheric aerosols. GHG concentrations including CH₄, N₂O, CO₂, CFC11eq, and CFC12 are prescribed using CMIP6 historical forcing data. CESM2 uses datasets derived from previous runs of CESM2-WACCM6, which includes complete interactive chemistry, for tropospheric oxidants (O₃, OH, NO₃, and HO₂; 3D monthly means), stratospheric water vapor production from CH₄ oxidation
185 (3D monthly means), stratospheric aerosol (zonal 5-day means), and O₃ for use in radiative transfer calculations (zonal 5-day means). A full description and evaluation of the CESM2 model is provided by Danabasoglu et al. (2019).

CESM2-WACCM: The CESM2-WACCM model uses the Whole Atmosphere Community Climate Model version 6 (WACCM6) as its atmosphere component. WACCM6 has 70 vertical levels from the surface to 6x10⁻⁶ hPa (about 140 km), a horizontal resolution of 1.25° longitude by 0.95° latitude. WACCM6 features a comprehensive chemistry mechanism with a
190 description of the troposphere, stratosphere, mesosphere, and lower thermosphere (TSMLT), including 231 species, 150 photolysis reactions, 403 gas-phase reactions, 13 tropospheric heterogeneous reactions, and 17 stratospheric heterogeneous reactions. The photolytic calculations are based on both inline chemical modules and a lookup table approach. The chemical

species within the TSMLT mechanism include the extended O_x, NO_x, HO_x, ClO_x, and BrO_x chemical families, CH₄ and its degradation products, N₂O (major source of NO_x), H₂O (major source of HO_x), plus various natural and anthropogenic precursors of the ClO_x and BrO_x families. The TSMLT mechanism also includes primary nonmethane hydrocarbons and related oxygenated organic compounds, and two very short-lived halogens (CHBr₃ and CH₂Br₂) which add an additional ~5 ppt of inorganic bromine to the stratosphere. WACCM6 features a new prognostic representation of stratospheric aerosols based on sulfur emissions from volcanoes and other sources, and a new detailed representation of secondary organic aerosols (SOAs) based on the volatility basis set approach from major anthropogenic and biogenic volatile organic compound precursors. A full description of WACCM6 is provided by Gettelman et al. (2019).

CNRM-CM6-1: The CNRM-CM6-1 model, developed by the Centre National de Recherches Météorologiques, is a global climate model which uses a linearised scheme to model stratospheric ozone, in which ozone mixing ratios are treated as a prognostic variable with photochemical production and loss rates computed from its associated Earth System Model CNRM-ESM2-1. Details of the linearization of the net photochemical production in the ozone continuity equation are provided by Michou et al. (2019). Tropospheric ozone mixing ratios are not calculated interactively, and are instead prescribed from the CMIP6 dataset. Methane oxidation is parameterized throughout the model domain by the introduction of a simple relaxation of the upper-stratospheric moisture source due to methane oxidation Untch (2011). A sink representing photolysis in the mesosphere is also included. A full description and evaluation of the CNRM-CM6-1 model is provided by Voltaire et al. (2019).

CNRM-ESM2-1: The CNRM-ESM2-1 model, developed by the Centre National de Recherches Météorologiques, is a coupled Earth System model. The chemistry scheme of CNRM-ESM2-1 is an on-line scheme in which the chemistry routines are part of the physics of the atmospheric climate model and are called at each time-step (Michou et al., 2011). The scheme considers 168 chemical reactions, among which 39 are photolysis reactions and 9 represent the heterogeneous chemistry. The scheme does not include tropospheric ozone non-methane hydrocarbon chemistry. The 3D concentrations of several trace gases interact with the atmospheric radiative code at each call of the radiation scheme. In addition to the non-orographic gravity wave drag parameterization, a sponge layer is also used in the upper levels to reduce spurious reflections of vertically propagating waves from the model top. This parameterization consists simply of a linear relaxation of the wind towards zero. The linear relaxation is active above 3 Pa. A full description and evaluation of the CNRM-ESM2-1 model is provided by Seferian et al. (2019), while an evaluation of the ozone radiative forcing is detailed in Michou et al. (2019).

E3SM-1-0: The E3SM-1-0 model, developed by the U.S. Department of Energy, is a coupled Earth System Model. It uses a simplified, linearized ozone photochemistry scheme to predict stratospheric ozone changes (Linoz v2; Hsu & Prather, 2009). Stratospheric water vapor does not include a source from methane oxidation. A full description of the E3SM-1-0 model is provided by Golaz et al. (2019).

FGOALS-g3: The FGOALS-g3 model, developed by the Chinese Academy of Sciences, is a coupled ocean–atmosphere
225 model. FGOALS-g3 does not include an interactive chemistry module, and ozone is prescribed in the stratosphere and
troposphere following the recommendations by CMIP6. Stratospheric water vapor concentrations are prognostic values
calculated in a similar way to those in the troposphere. A full description and evaluation of the FGOALS-g3 model is provided
by Li et al. (2019).

GFDL-CM4: The GFDL-CM4 model, developed by the National Oceanic and Atmospheric Administration's Geophysical
230 Fluid Dynamics Laboratory, is a coupled ocean–atmosphere model. Ozone is prescribed using the recommended CMIP6
dataset throughout the troposphere and stratosphere, while stratospheric water vapor is interactive, but does not include a
source from methane oxidation. A full description and evaluation of the GFDL-CM4 model is provided by Held et al. (2019).

GFDL-ESM4: The GFDL-ESM4 model, developed by the National Oceanic and Atmospheric Administration's Geophysical
Fluid Dynamics Laboratory, is a fully coupled chemistry-climate model. Stratospheric ozone is calculated using an interactive
235 tropospheric and stratospheric gas-phase and aerosol chemistry scheme. The atmospheric component (AM4.1) includes 56
prognostic (transported) tracers and 36 diagnostic (non-transported) chemical tracers, with 43 photolysis reactions, 190 gas-
phase kinetic reactions, and 15 heterogeneous reactions. The tropospheric chemistry includes reactions for the NO_x-HO_x-O_x-
CO-CH₄ system and oxidation schemes for other non-methane volatile organic compounds. The stratospheric chemistry
accounts for the major ozone loss cycles (O_x, HO_x, NO_x, ClO_x, and BrO_x) and heterogeneous reactions on liquid and solid
240 stratospheric aerosols (Austin et al., 2013). Photolysis rates are calculated interactively using the FAST-JX version 7.1 code,
accounting for the radiative effects of simulated aerosols and clouds. Details on the chemical mechanism will be included in
Horowitz et al. (in prep). A full description and evaluation of the GFDL-ESM4 model is provided by Dunne et al. (2019).

IPSL-CM6A-LR: The IPSL-CM6A-LR model, developed by the Institut Pierre-Simon Laplace, is a coupled atmosphere-
land-ocean-sea ice model. Stratospheric and tropospheric ozone is prescribed using the CMIP6 dataset but implemented so
245 that profiles are stretched in a thin region (few kilometres only) around the tropopause, ensuring that the tropopause of the
ozone climatology and that of the model match. Differences in tropopause heights would lead to spurious ozone transport
between the upper troposphere and lower stratosphere, a region where the corresponding non-physical radiative impact would
be particularly high (see e.g., Hardiman et al., 2019). Stratospheric methane oxidation is not included in the version of the
model evaluated here. A full description and evaluation of the IPSL-CM6A-LR model is provided by Servonnat et al., (2020).

MRI-ESM2-0: The MRI-ESM2-0 model, developed by the Meteorological Research Institute, Japan Meteorological Agency,
250 is a fully coupled global climate model which includes interactive chemistry. MRI-ESM2-0's chemistry component is the
MRI-CCM2.1 module, which simulates the distribution and evolution of ozone and other trace gases in the troposphere and
middle atmosphere. MRI-CCM2.1 is an updated version of MRI-CCM2 (Deushi and Shibata, 2011), which calculates a total
of 90 chemical species and 259 chemical reactions. MRI-ESM2-0 simulates the stratospheric water vapor interactively with

255 consideration for production of water vapor from CH₄ oxidation. A full description and evaluation of the MRI-ESM2-0 model is provided by Yukimoto et al. (2019).

SAM0-UNICON: The SAM0-UNICON, developed by the Seoul National University, is a general circulation model based on the CESM1 model with a Unified Convection Scheme (Park 2014a, b) that replaces shallow and deep convection schemes in CESM1. Stratospheric and tropospheric ozone is prescribed as a monthly mean 3D field with a specified annual cycle.
260 Stratospheric water vapor does not include a source from methane oxidation. A full description of the SAM0-UNICON model is provided by Park et al. (2019).

UKESM1-0-LL: The UKESM1-0-LL model, developed jointly by the United Kingdom's Met Office and Natural Environment Research Council, is a fully coupled Earth System Model. UKESM1-0-LL uses a combined troposphere-stratosphere chemistry scheme (Archibald et al., 2019), which includes 84 tracers, 199 bimolecular reactions, 25 uni- and
265 termolecular reactions, 59 photolytic reactions, 5 heterogeneous reactions and 3 aqueous phase reactions for the sulfur cycle. As a result, stratospheric ozone and water vapor are fully interactive. A full description and evaluation of the UKESM1-0-LL model is provided by Sellar et al. (2019).

2.2 Simulations

To evaluate changes in stratospheric ozone and water vapor from 1850-2100, this study makes use of two types of simulations
270 performed as part of the wider CMIP6 activity (Eyring et al., 2016): the CMIP6 historical simulation and the ScenarioMIP future simulations (O'Neill et al., 2015).

The CMIP6 historical simulation runs from 1850-2014, in which the models are forced by common datasets based on observations which include historical changes in short-lived species and long-lived GHGs, global land use, solar forcing, stratospheric aerosols from volcanic eruptions and, for models without ozone chemistry, prescribed time varying ozone
275 concentrations. These simulations are initialised from the pre-industrial control (piControl) simulation, a time-slice simulation run with 1850 perpetual pre-industrial conditions performed by each model.

The ScenarioMIP future simulations run from 2015-2100 and follow the newly developed SSPs, which provide future emissions and land use changes based on scenarios directly relevant to societal concerns regarding climate change impacts, adaptation and mitigation (Riahi et al., 2017). Broadly, the shared socioeconomic pathways follow 5 categories: sustainability (SSP1), middle of the road (SSP2), regional rivalry (SSP3) inequality (SSP4) and fossil-fueled development (SSP5). Further,
280 each scenario has an associated forcing pathway (i.e. the forcing reached by 2100 relative to the pre-industrial), and each specific scenario is referred to as SSP_x-y, where x is the SSP and y is the radiative forcing pathway (the radiative forcing at the end of the century, in W/m²). For example, SSP3-7.0 follows SSP3 (regional rivalry), and has a 2100 global mean forcing of 7.0 W/m² relative to the pre-industrial.

- 285 The SSP scenarios span a broad range of future emissions and land use changes, both of which have the potential to change total column ozone through changes in both the troposphere and/or stratosphere, and stratospheric water vapor through changes in tropical tropopause layer (TTL) temperatures or CH₄. In general, low SSPs assume lower abundances of long-lived GHGs (CO₂, CH₄, N₂O; Meinshausen et al., 2019) and lower emissions of ozone precursors (Hoesly et al., 2018). All SSPs follow the same emissions scenario for ozone depleting substances, based on continued compliance with the Montreal Protocol (Velders and Daniel, 2014), but the concentrations of ODSs vary slightly between scenarios due to changes in the lifetimes of each species associated with climate change (Meinshausen et al., 2019). It should be noted that recent studies have identified unreported emissions of CFC-11 (e.g. Montzka et al., 2018), and that the trajectory of ozone recovery is sensitive to the magnitude and duration of these emissions (e.g. Dhomse et al., 2019; Keeble et al., 2019), which are not included in the emissions assumptions of Velders and Daniel (2014).
- 290
- 295 In this study, we use ozone and water vapor output for the SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, SSP4-3.4, SSP4-6.0 and SSP5-8.5 scenarios. Details of which simulations were performed by each model are provided in Table 1.

2.3 Observation datasets

The evaluation of stratospheric ozone and water vapor makes use of two datasets: the NIWA-BS combined total column ozone database and SWOOSH zonal mean ozone and water vapor datasets.

- 300 The NIWA-BS combined total column ozone (TCO) database takes daily gridded TCO fields from 17 different satellite-based instruments, bias corrects them against the global Dobson and Brewer spectrophotometer network, and merges them into a seamless homogeneous daily gridded (1.25° longitude x 1.0° latitude) TCO data record. First, overpass data from the TOMS instruments flown onboard Nimbus-7, Meteor-3, Earth Probe, and Adeos, and from the OMI instrument on Aura, are bias corrected against the ground-based TCO measurements. Those five bias-corrected datasets then provide the basis for correcting the remaining datasets i.e. those from the GOME, GOME-2 and SCIAMACHY instruments, the SBUV instrument flown on
- 305 the Nimbus-7, and the SBUV-2 instruments flown on NOAA-9, 11, 14, 16, 17, 18 and 19. The bias corrected measurements are then combined in a way that traces uncertainties from the source data through to the final merged data product.

- A filled version 3.3 dataset was created by first filling missing data that could easily be interpolated between neighbouring values and then fitting a regression model, comprising an offset and trend basis function, expanded in spherical harmonics to account for latitudinal and longitudinal structure, to available TCO measurements from fields on day N-1, N, and N+1. The expansion indices for the spherical harmonics are adapted to the data to avoid over-fitting of the regression model. Once fitted, the regression model was then used to estimate TCO values in regions where data were missing. Such regression model derived fields were spliced into the unfilled fields to ensure a smooth transition from the measurements into the regression model
- 310

315 derived values. Monthly mean fields were calculated from the filled daily fields to provide the validation datasets used for the
CMIP6 models evaluated here.

The Stratospheric Water and OzOne Satellite Homogenized (SWOOSH) dataset is a merged record of stratospheric ozone and
water vapor measurements collected by a subset of limb sounding and solar occultation satellites spanning 1984 to the present
(see Davis et al., 2016, for details). Specifically, SWOOSH comprises data from the Stratospheric Aerosol and Gas Experiment
instruments (SAGE-II and SAGE-III/Meteor-3M), the Upper Atmosphere Research Satellite HALogen Occultation Experiment
320 (UARS HALOE), the UARS Microwave Limb Sounder (MLS), and Aura MLS.

The source satellite measurements are homogenized by applying corrections that are calculated from data taken during time
periods of instrument overlap. The primary SWOOSH product is a merged multi-instrument monthly-mean zonal-mean (10°)
dataset on the pressure grid of the Aura MLS satellite (12 levels per decade). Because the merged product contains missing
data, a merged and filled product is also provided for studies requiring a continuous dataset. These merged and filled products
325 for ozone and water vapor (combinedanomfillo3q and combineanomfillh2oq respectively) from SWOOSH version 2.6 are
used in this study for comparison with CMIP6 model fields.

3 Ozone

3.1 Evaluation over recent decades

330 Before investigating long-term changes in stratospheric ozone, we evaluate each model's performance, and the performance
of the CMIP6 multi-model mean (MMM), against observations. In the following sections we evaluate the 2000-2014
climatological zonal mean distribution of ozone and the seasonal evolution of zonal mean total column ozone against
observations, in the form of the combined zonal mean ozone dataset from SWOOSH and the TCO dataset from NIWA-BS.

3.1.1 2000-2014 climatological zonal mean and total column ozone

Latitude-height cross sections of zonal mean ozone volume mixing ratios for each CMIP6 model, the CMIP6 MMM and the
335 SWOOSH dataset, averaged over the years 2000-2014, are shown in Figure 1. There is generally good agreement between the
individual CMIP6 models and the SWOOSH dataset. All models broadly capture tropospheric and stratospheric ozone
gradients, with a clear peak in ozone mixing ratios in the tropical stratosphere at around 10 hPa, the downwards bending of the
contour lines towards high latitudes in the lower stratosphere (e.g. Plumb, 2002) and flat contour lines in the tropical upper
stratosphere in the quasi-equilibrated photochemical regime (e.g. Haigh and Pyle, 1982; Meul et al., 2014; Chiodo et al., 2018;
340 Nowack et al., 2018).

Notable differences between the models occur in the uppermost stratosphere, and around the tropopause (Figure A1). The BCC-ESM1, CESM2, FGOALS-g3 and SAM0-UNICON models all simulate much higher ozone mixing ratios in the upper stratosphere. The BCC-ESM1 and SAM0-UNICON models in particular significantly overestimate ozone mixing ratios with respect to the CMIP6 MMM and observations in the upper stratosphere, and also have a different structure in the distribution of ozone at these levels, with peaks in the mid-latitudes at 1 hPa. In the tropical tropopause region, the MRI-ESM2-0 and UKESM1-0-LL models significantly overestimate ozone mixing ratios, while the SAM0-UNICON model has much lower mixing ratios in this region with respect to the CMIP6 MMM.

The tropical tropopause is a region in which chemistry-climate models have typically performed poorly, due to the fact that ozone mixing ratios in this region are controlled by a combination of chemical production, vertical transport of ozone poor air from the troposphere and mixing of ozone rich stratospheric air. Gettelman et al. (2010) documented the seasonal cycle of ozone at 100 hPa from 18 models involved in the CCMVal-2 inter-comparison project, and showed that while there is good agreement between the MMM and the observations, there is a large spread in ozone mixing ratios between individual models, and many models do not accurately capture the observed seasonal cycle. For the CMIP6 models investigated here, there is also good agreement between the tropical (15°S-15°N) MMM ozone mixing ratios at 70 hPa and the SWOOSH dataset (Figure 2). Further, many models accurately capture the seasonal cycle of ozone, with lower ozone mixing ratios simulated between February and April, and higher values in August and September. However, as for CCMVal-2 models, there is still a large spread in modelled ozone mixing ratios in the tropical tropopause region. Both MRI-ESM2-0 and UKESM1-0-LL are high biased (both use interactive chemistry), while BCC-ESM1 is low biased compared to the observations and the CMIP6 MMM.

Despite the differences between the individual CMIP6 models, there is generally good agreement between the zonal mean distribution of ozone in the CMIP6 MMM and the SWOOSH dataset throughout much of the stratosphere (Figure 4), with differences between 70 hPa and 3 hPa typically less than $\pm 10\%$. Maximum ozone mixing ratios at ~ 10 hPa are slightly underestimated by the CMIP6 MMM, while ozone mixing ratios in the lower tropical stratosphere, and at ~ 1 hPa in the mid-latitudes, are overestimated. The CMIP6 MMM also overestimates ozone mixing ratios at all latitudes in the upper troposphere between 200-100 hPa by $\sim 20-40\%$. Since upper tropospheric ozone is a particularly important climate forcing agent (Lacis et al., 1990; Stevenson et al., 2013; Young et al., 2013; Nowack et al., 2015), this has important implications for the ozone radiative forcing estimated from climate model simulations. However, it should be noted that the uncertainties in the SWOOSH dataset are likely to be relatively large in the upper troposphere.

TCO climatologies (latitude vs month) for all 14 discussed CMIP6 models are shown in Figure 3. Overall the observed climatology patterns and annual cycle amplitudes, compared here against the NIWA-BS dataset, are well represented in the CMIP6 MMM and the individual models: lower values and smallest amplitude in the tropics that increase to the poles, with the highest TCO values around 60°S between August and November, and in the NH polar regions between January and May, and the smallest TCO values in the SH polar regions during the ozone hole period. Some models slightly underestimate TCO

in the NH polar regions (CNRM-CM6-1, CNRM-ESM2-1), and some models slightly overestimate TCO globally (MRI-ESM2-0, UKESM1-0-LL). Note that the NIWA-BS dataset statistically models high latitude values during the polar night to
375 provide a global, gap-free data field (see Section 2.3), and therefore uncertainties on the observations in these regions are higher than elsewhere.

The lower row of Figure 4 shows the detailed differences between the TCO CMIP6 MMM and the observations. In the tropics and the NH mid-latitudes the differences are smaller than ± 10 DU ($< 5\%$ of the climatological value in these regions). The differences get slightly larger in the NH polar regions, and are largest in the SH mid-latitudes where the MMM overestimates
380 the observed TCO by up to 40 DU, and the SH polar regions where the MMM underestimates the observed TCO in polar winter (May to July) by 20-30 DU, and then overestimates the observed TCO during September by ~ 30 DU. Compared to CMIP5, the differences in the NH mid-latitudes and polar regions seem reduced in the MMM (Eyring et al., 2013; Lauer et al., 2017), whereas the differences between MMM and observations are similar in the SH mid-latitudes between CMIP5 and
385 CMIP6. Especially noticeable is the shift of the strongest underestimation of the MMM from SH late spring/early summer in CMIP5 to the SH winter in CMIP6, which may result from a better representation of the polar vortex duration in CMIP6 models.

Figure 5 shows Taylor diagrams of 14 CMIP6 models performance for annual and seasonal mean TCO between 60°S – 60°N against the NIWA-BS TCO dataset for the period 2000–2014. On the annual scale, the 14 CMIP6 models can accurately reproduce the spatial pattern of NIWA-BS TCO, with all correlation coefficients being greater than 0.9 and the standard
390 deviations of all the models falling between 0.75 and 1.75. On the seasonal scale, the models perform better during DJF and MAM than during JJA and SON. Overall, the GFDL-ESM4 model scores highest, not only because it is closest to the reference line, but also because its relative bias compared with the NIWA-BS dataset is smallest. Although the UKESM1-0-LL model is also close to the reference line during JJA and SON, it has a high relative bias from the NIWA-BS dataset. The SAM0-UNICON and MRI-ESM2-0 models show a larger standard deviation than other models, indicating they have a much higher
395 interannual variability.

3.1.2 Regional Total Column Ozone changes 1960-2014

The temporal evolution of observed global TCO, observed TCO for specific regions, TCO from individual CMIP6 models, and the CMIP6 MMM is shown in Figure 6. In general, the MMM overestimates the observed TCO values by up to 6% (10-20 DU) globally (Figure 6 a), in the NH and SH mid-latitudes, and in the tropics (Figure 6 c-e), but the trend in these regions
400 is well captured. The spread within the analysed CMIP6 models is large, though, with MRI-ESM2-0 and UKESM1-0-LL overestimating TCO by up to 40 DU in, for example, the SH mid-latitudes. Both of these models used an interactive chemistry scheme to calculate ozone abundances in the troposphere and stratosphere. Although these two models overestimate ozone, the other models that calculate ozone fields interactively (CESM2-WACCM, CNRM-ESM2-1, GFDL-ESM4) slightly

underestimate the observed TCO values, indicating that there is no clear distinction of models with and without interactive
405 chemistry as there was in the CMIP5 models (Eyring et al., 2013). While most of the analysed CMIP6 models show distinct
interannual variability, it is noteworthy that there is no interannual variability detectable for two models (CESM2 and SAM0-
UNICON) that used prescribed ozone fields for their historical simulations (see Section 2.1).

The CMIP6 MMM underestimates the observed decline in TCO for March in the NH polar regions during the ozone depletion
period (1980-2000) but tracks the observations well after 2000 (Figure 6f). This is also mirrored in the trends calculated for
410 these periods for observations and the individual CMIP6 models and MMM (Table 2). While the TCO October values in the
SH polar regions are overestimated in the MMM compared to observations, the overall TCO decline from 1980 to 2000 is
stronger in the models than in the observations (see Table 2). These characteristics are very similar to the trends reported in
Eyring et al. (2013) for the CMIP5 model simulations.

Table 2 follows Eyring et al. (2013, their table 2) in showing the observed and modelled trends in TCO over the period 1980-
415 2000. Additionally, we also show trends over the period of 2000-2014. They are calculated for 14 models, of which five models
have interactive stratospheric chemistry (CESM2-WACCM, CNRM-ESM2-1, GFDL-ESM4, MRI-ESM2-0, and UKESM1-
0-LL). For these five models, over the period 1980-2000, annual mean global trends range from -0.19 (MRI-ESM2-0) to -1.04
(UKESM1-0-LL) DU/year. The average trend from these models (hereafter referred to as “INTERACTIVE”) is -0.57 DU/year
which is within the uncertainty range of observed trends (from -0.56 to -0.74 DU/year). In the tropics, all models show weak
420 negative trends, and the mean of the 5-member INTERACTIVE models in the tropics (-0.18 DU/year) compares well with the
observed trends. In the northern mid-latitudes, models considerably underestimate the observed negative trends with the
exception of CNRM-ESM2-1 (-0.95 DU/year – within the range of observed trends) and UKESM1-0-LL (-1.2 DU/year –
slightly stronger than the observed negative trends). Over southern mid-latitudes, modelled trends are generally closer to the
observed trends, with the exceptions of MRI-ESM2-0 and SAM0-UNICON which have substantially weaker negative trends.
425 Again, UKESM1-0-LL overestimates the observed negative trends. At high latitudes of the NH, most of the models
substantially underestimate the observed negative trends there, with the exception of CNRM-ESM2-0 and UKESM1-0-LL
with the latter having a higher negative bias. At SH high latitudes, all models calculate large (in absolute terms) negative
trends, indicating that Antarctic ozone depletion is having a pronounced impact on ozone in the CMIP6 models. Overall, the
INTERACTIVE models have larger trends than those models without.

430 Over the period 2000-2014, most models show non-significant (at the 95% confidence level) positive trends in TCO. The
INTERACTIVE models show stronger positive trends in all regions, compared to the all-model mean. Significant and
substantial positive ozone trends occur in MRI-ESM2-0 and UKESM1-0-LL. Significant but weaker positive trends also occur
in SAM0-UNICON and CESM2 at SH high latitudes. Here, the significance is the consequence of small variability in those
models without interactive chemistry.

435 3.2 Long-term evolution of Total Column Ozone from 1850-2014

The regional evolution of zonal mean, annual mean TCO for the CMIP6 MMM from 1850-2100 is shown in Figure 7. For the near global mean (60°S-60°N), TCO increases slowly from ~300 DU in 1850 to ~305 DU in 1960, before rapidly declining through the 1980s and 1990s due to emissions of halogenated ODSs, reaching a minimum in the late 1990s. The increases in TCO are more prominent in the NH and tropics, while the decreases at the end of the 20th century are stronger in the SH. In the NH, TCO values increase by 20-30 DU between 1850 and 1960, and this increase is large enough that despite the emission of halogenated ODSs minimum NH mid-latitude TCO values in the late 1990s are larger than pre-industrial values. In contrast, SH TCO values remain relatively constant from 1850 to 1960, before rapidly declining throughout the 1970s and 1980s. The distinctive 11-year solar cycle in TCO is superimposed on these long-term. In addition, the eruption of Mt. Krakatoa in 1883 can be clearly seen as an increase in TCO of around 3-5 DU, resulting in the highest TCO values for ~100 years between 1850 and 1950.

There is poor agreement in the ability of the individual CMIP6 models to simulation pre-industrial TCO, which vary between 275 and 340 DU (Figure A2). The UKESM1-0-LL and MRI-ESM2-0 models are particularly high, while the GFDL-CM4 values are lowest. Surprisingly, there is a ~20 DU range in pre-industrial TCO values between those models prescribing the CMIP6 ozone dataset. When TCO values from each CMIP6 model are normalised to the 1960 annual mean value (Figure A3), there is a smaller difference between the modelled pre-industrial TCO values, which cover ±5 DU around the MMM. When the models are normalised to the 1960 annual mean, it is also clear that, compared to the CMIP6 MMM, the CNRM-CM6-1, CNRM-ESM2-1 and UKESM1-0-LL models have much stronger ozone declines during the period of halogenated ODS emissions (globally for the UKESM1-0-LL model and in the NH for the CNRM-CM6-1 and CNRM-ESM2-1 models), while the MRI-ESM2-0 model has much weaker TCO declines during this time.

Zonal mean, annual mean partial ozone columns for the full stratosphere, upper stratosphere and lower stratosphere, averaged from 90°S-90°N, for a subset of the models are shown in Figure 8. These partial column values indicate that stratospheric ozone, in both the lower and upper stratosphere, did not change significantly between 1850 and 1960, suggesting that the increases in TCO seen in Figure 8 arise from changes in tropospheric ozone. It is also clear from Figure 8 that much of the high TCO bias for the UKESM1-0-LL model (Figure A2) comes from elevated stratospheric ozone mixing ratios, rather than a large tropospheric ozone bias.

Climatological differences between the present day (2000-2014 average) and the preindustrial (1850-1864) zonal mean ozone mixing ratios and TCO values are shown in Figure 9. The expected general decrease in stratospheric ozone due to ODS-induced stratospheric ozone depletion (e.g. Keeble et al., 2014; Iglesias-Suarez et al., 2016) as well as a general increase in ozone in the troposphere due to the emission of ozone precursors (e.g. Stevenson et al., 2013; Young et al., 2013, 2018) are clearly captured by the CMIP6 MMM. The historical decrease in stratospheric ozone is most pronounced in the SH polar

vortex, with the maximum TCO decrease during SH spring due to the role of heterogeneous activation of chlorine reservoir species on polar stratospheric clouds (e.g. Solomon et al., 1999). In absolute values, the decreases in stratospheric ozone mixing ratios dominate over the larger fractional tropospheric ozone changes in terms of the integrated number of ozone molecules in a vertical column, leading to historically globally reduced TCO. However, there is a pronounced seasonal cycle in these changes and a clear difference between the hemispheres, with widespread ozone decreases throughout the year in the SH but small TCO increases at high latitudes in the NH during the summer and autumn.

3.3 Long-term evolution from 2015-2100

From 2015 onwards, models follow the assumptions made in the various SSP scenarios. Most models which performed the historical simulations also provided ozone data from SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5, while a much smaller number provided data from SSP1-1.9, SSP4-3.4 and SSP4-6.0 (see Table 1 for an overview of which models performed which SSP scenarios). Due to the different numbers of models performing each scenario, the MMM for each SSP is normalised to the 2014 value to produce one smooth dataset and allow for comparison between the trajectories of TCO under each SSP scenario.

Zonal mean, annual mean CMIP6 MMM TCO, averaged over 60°S-60°N, is projected in the simulations evaluated here to follow three main trajectories from 2015 to 2100 (Figure 7). Under SSP2-4.5, SSP4-3.4 and SSP4-6.0 TCO values are projected to return to their 1960's values by the middle of the 21st century, while under the SSP3-7.0 and SSP5-8.5 scenarios TCO values are projected to significantly exceed the 1960's values throughout the latter half of the 21st century. Despite the assumption that halogenated ODSs will continue to decline due to the Montreal Protocol, TCO values are not projected to return to the 1960's values under the SSP1-1.9 and SSP1-2.6 scenarios.

As for 60°S-60°N, SSP pathways which assume higher radiative forcing result in higher TCO at the end of the century for most latitude ranges (Figure 7), although the timing of the return of TCO to 1960's values varies. Annual mean TCO values at high southern latitudes are only projected to return to the 1960's values in the SSP3-7.0 and SSP5-8.5 scenarios. Conversely, TCO is projected to return to, and in most cases exceed, the 1960 annual mean value in all SSPs in the high northern latitudes. In the mid-latitudes, projected TCO values follow a pattern similar to those seen in the near global mean, although in the NH TCO is projected to return to the 1960s value in the SSP1-2.6 scenario and exceed the 1960 value under most other scenarios. Interestingly, in the NH mid- and high-latitudes the 1980 annual mean TCO is larger than that of the 1960 annual mean, and as a result NH TCO values are projected to return to the 1980 values after returning to 1960 values. However, TCO projections in the tropics are quite different to those at other latitudes, with return to 1960's values only projected to occur in SSP3-7.0 and SSP5-8.5, and under the SSP5-8.5 scenario TCO values are projected to decline again in the latter half of century (consistent with an acceleration of the BDC, e.g. Meul et al., 2016; Keeble et al., 2017).

500 Climatological differences between the end of the century (2086-2100 average) and the present day (2000-2014 average) zonal mean ozone mixing ratios and TCO values are shown in Figure 10 for SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5. Under each of these SSP scenarios, ozone mixing ratios in the upper stratosphere and SH polar lower stratosphere are projected to increase consistent with the decline in halogenated ODSs assumed in all scenarios. The magnitude of the upper stratospheric increases in ozone is larger for scenarios which project large increases in GHG loading of the atmosphere due to the resulting CO₂-induced cooling of the stratosphere. However, significant differences between the scenarios are seen in the troposphere and tropical lower stratosphere. Under the SSP1-2.6 and SSP2-4.5 scenarios, tropospheric ozone mixing ratios are projected to decrease, consistent with the large reduction in the emission of ozone precursors assumed in these scenarios (Gidden et al., 2019). Under SSP1-2.6 the decreases in tropospheric ozone are particularly strong in the NH, while the increases in stratospheric ozone outside of the Antarctic polar lower stratosphere are smaller than in other scenarios (consistent with less CO₂ induced cooling), and together these factors explain why TCO does not return to 1960 values in SSP1 scenarios. Strong emissions mitigation scenarios which decrease tropospheric ozone mixing ratios and thereby help to mitigate climate change and air quality impacts, slow or prevent ozone recovery, as measured by the return of TCO return to historic values. This calls into question whether using TCO return dates as a metric for ozone recovery and the success of the Montreal Protocol is entirely appropriate to evaluate the success of the Montreal Protocol, and if other metrics might not better reflect the recovery of stratospheric ozone driven by changes in stratospheric chlorine loading (as discussed by Eyring et al., 2013; WMO 2018).

515 In contrast, ozone mixing ratios are projected to increase throughout much of the troposphere and upper stratosphere in the SSP3-7.0 and SSP5-8.5 scenarios, explaining the projected super-recovery of TCO values in the mid- and high-latitudes under these scenarios by the end of the century. However, ozone mixing ratios are projected to be lower in the tropical lower stratosphere by the end of the century (Figure 10) due in part to the acceleration of the BDC and reduced production of ozone at these altitudes due to the thicker overhead column (Eyring et al., 2013; Meul et al., 2016; Keeble et al., 2017). These lower stratospheric decreases offset the increases at higher altitudes, resulting in TCO values being lower at the end of the 21st century compared to the present day under most emissions scenarios, despite reductions in stratospheric halogens.

4 Stratospheric Water Vapor

520 As with ozone, before investigating long-term changes in stratospheric water vapor we evaluate each model's performance, and the performance of the CMIP6 MMM, against observations. In the following sections we evaluate the 2000-2014 climatological zonal mean distribution of water vapor against the SWOOSH combined dataset and evaluate the source of stratospheric water vapor from CH₄ oxidation.

4.1 Evaluation of recent changes

525 Ten of the models used in this study provide stratospheric water vapor output from the historical simulations, with a smaller
subset providing water vapor from the SSP scenarios (see Table 1). Zonal mean water vapor volume mixing ratios for each
CMIP6 model, the CMIP6 MMM and the SWOOSH dataset, average over the years 2000-2014, are shown in Figure 11. There
is relatively poor agreement between the individual CMIP6 models and the observations. The CESM2, CESM2-WACCM and
MRI-ESM2-0 models all capture the distribution of stratospheric water vapor mixing ratios reasonably well, with the largest
530 percentage differences in the polar regions, most likely related to the formation and sedimentation of polar stratospheric cloud
particles. Several models (BCC-CSM2-MR, BCC-ESM1, GFDL-CM4 and IPSL-CM6-LR) do not accurately capture the
increase in water vapor with altitude throughout the stratosphere, as these models do not include a representation of water
vapor produced from CH₄ oxidation. In contrast, CNRM-CM6-1 and CNRM-ESM2-1 simulate very large changes in
stratospheric water vapor between the tropical lower stratosphere and upper stratosphere, consistent with an overestimate in
535 the water vapor production from CH₄ oxidation in the CNRM-ESM2-1 model (discussed below). Water vapor mixing ratios
in the UKESM1-0-LL model are biased high throughout the stratosphere compared to the SWOOSH dataset. Differences
between the individual models and the CMIP6 MMM are shown in Figure A4.

As for ozone mixing ratios, models have typically performed poorly in simulating water vapor mixing ratios in the tropical
tropopause region. Gettelman et al. (2010), show the seasonal cycle of water vapor at 80 hPa from 16 models involved in the
540 CCMVal-2 inter-comparison project, and while there is good agreement between the CMIP6 MMM and the observations,
there is a large spread in model mixing ratios, and many models do not accurately capture the seasonal cycle. Climatological
(2000-2014) tropical stratospheric water vapor mixing ratios (average over 15°S to 15°N) at 70hPa, which lies just above the
cold point entry into the stratosphere, are shown for the CMIP6 models in Figure 13. There is reasonable agreement between
the seasonality of the CMIP6 MMM and that calculated for the SWOOSH combined dataset, although the CMIP6 MMM is
545 between 0.5-1.0 ppm lower than the observations throughout the annual cycle and the minima and maxima in the seasonal
cycle both occur a few months earlier in the MMM than in the observations. However, individual models display a wide range
of water vapor concentrations (between 1.5-6 ppm). As seen in Figure 11, the UKESM1-0-LL model has high stratospheric
water vapor mixing ratios compared to the SWOOSH dataset but captures the seasonal cycle well, while the IPSL-CM6A-LR,
CNRM-CM6-1 and CNRM-ESM2-1 models all have much lower stratospheric water vapor mixing ratios and muted seasonal
550 cycles.

The correlation between water vapor and CH₄ mixing ratios can be used to infer the stratospheric water vapor source from
CH₄ oxidation in each model. Based on observations and chemical understanding, 2 molecules of stratospheric water vapor
will be produced for every molecule of CH₄ oxidised (LeTexier et al., 1988). Given this oxidation, typical water vapor mixing
ratios of ~3.5 ppm at the tropical tropopause and mean tropospheric mixing ratios of CH₄ ~1.75 ppm, it is expected that

555 throughout the tropical stratosphere H_2O will equal $7.0\text{-}2.0 \times \text{CH}_4$ (SPARC, 2010). Observations made by ACE and MIPAS satellites support this expected gradient (e.g. Archibald et al., 2019).

Of the models evaluated here, output of both water vapor and CH_4 mixing ratios are available from six: BCC-CSM2-MR, BCC-ESM1, CESM2-WACCM, CNRM-ESM2-1, MRI-ESM2-0 and UKESM1-0-LL. Even from this small sample, it is clear that there is a wide range in the complexity and accuracy of modelling H_2O formed from the oxidation of CH_4 . Neither BCC-
560 CSM2-MR nor BCC-ESM1 includes stratospheric water vapor production from CH_4 oxidation, and so H_2O does not increase as CH_4 decreases. Other models capture the relationship, $\text{H}_2\text{O} = 7.0\text{-}2.0 \times \text{CH}_4$, to greater or lesser extents. UKESM1-0-LL and MRI-ESM2-0 slightly under produce H_2O from CH_4 , while stratospheric water vapor increases too rapidly for every molecule of CH_4 oxidised in the CNRM-ESM2-1 model. These differences in the treatment of CH_4 oxidation has important consequences for estimates of methane's impact on the climate system and for future radiative forcing calculations, particularly
565 under high CH_4 emissions scenarios (e.g. SSP3-7.0).

4.2 Long-term evolution from 1850-2014

The evolution of annual mean water vapor mixing ratios at 70 hPa, averaged from 15°S - 15°N , in the CMIP6 MMM and individual CMIP6 models is shown in Figure 15. Water vapor mixing ratios are simulated to have remained relatively constant at just below 3 ppm from 1850 to ~1950, before slowly increasing throughout the latter half of the 20th century and first decades
570 of the 21st century. However, there is broad disagreement between the individual CMIP6 models throughout the historical period, with simulated stratospheric water vapour mixing ratios varying between 1.5-5.5 ppm in the pre-industrial period.

During this time, the largest variations in water vapor mixing ratios are associated with large magnitude volcanic eruptions, which by increasing TTL temperatures result in increased annual mean water vapor mixing ratios by up to 0.5 ppm. However, the individual models show very different sensitivities to volcanic eruptions, with very large increases in water vapor mixing
575 ratios following eruptions in the MRI-ESM2-0 and BCC-CSM2-MR models, more muted responses in the BCC-ESM1, UKESM-0-LL, CESM2, CESM2-WACCM, CNRM-CM6-1 and CNRM-ESM2-1 models, and almost no response in the GFDL-CM4 and IPSL-ESM2-0 models.

To understand the long-term trends in stratospheric water vapor, it is instructive to analyse changes in temperature in the tropics at 100 hPa, which is close to the cold point and so controls the entry values of water vapor into the stratosphere. Long-
580 term changes in CMIP6 MMM 100 hPa temperatures, averaged from 15°S - 15°N , are shown in Figure 16. The rise in 70 hPa water vapor mixing ratios in the latter part of the 20th century, and following volcanic eruptions, can be attributed to the increase in temperature at the 100 hPa level. In the CMIP6 MMM, TTL temperatures have increased by ~1 K between 1850 and 2014, and can rise by 1-2 K following explosive volcanic eruptions.

585 Climatological annual mean, zonal mean H₂O mixing ratio differences between the present day (2000-2014 averaged) and pre-
industrial (1850-1864 averaged) periods are shown in Figure 17. Simulated stratospheric water vapor mixing ratios have
increased between the pre-industrial and present-day periods throughout the stratosphere. In the lower stratosphere, this
increase is ~0.2-0.4 ppm, consistent with the increase in water vapour mixing ratios seen at 70 hPa in the tropics, and reflects
the warming of the cold point between pre-industrial and present-day. However, the increase in stratospheric water vapor
mixing ratios increases with altitude and is largest in the upper stratosphere (~0.8 ppm), reflecting increased CH₄ mixing ratios
590 and resulting increases in H₂O mixing ratios formed from CH₄ oxidation.

4.3 Long-term evolution from 2015-2100

An increase in stratospheric water vapor concentrations under climate change is projected by virtually all climate models
(Gettelman et al. 2010; Smalley et al. 2017; Banerjee et al. 2019). Eyring et al. (2010) calculate a mean increase of 0.5-1 ppm
per century in stratospheric water vapor concentrations for models involved in the CCMVal-2 inter-comparison project,
595 although agreement between models on the absolute increase is poor. The increase is likely due to the prevailing effect of a
warming troposphere over other driving factors (Dessler et al. 2013; Smalley et al. 2017), and represents a climate feedback,
as the associated radiative effect of the increases are correlated with increasing surface temperatures (Banerjee et al. 2019).
Here we find consistent results, with increasing stratospheric water vapor concentrations under each SSP scenario of climate
change (Figure 15). The magnitude of the increases generally follows the radiative forcing across the scenarios (and thus the
600 degree of tropospheric warming). Low forcing scenarios (SSP1-1.9 and SSP1-2.6) project increasing stratospheric water vapor
until the middle of the century and then a stabilization to around 3.5 ppm. Middle of the road scenarios (SSP2-4.5, SSP4-6.0
and SSP4-3.4) reach around 4 ppm by 2100. High forcing scenarios (SSP3-7.0 and SSP5-8.5) show rapid increases in
stratospheric water vapor throughout the century, reaching around 5 ppm by 2100.

As for the historical changes explored in section 4.2, projected changes in water vapor mixing ratios at 70 hPa are strongly
605 correlated with simulated changes to 100 hPa temperatures (compare Figures 15 and 16). In general, the higher the assumed
GHG emissions in the SSP scenario, the larger the projected 100 hPa temperatures by the end of the century. Under SSP1-1.9
and SSP1-2.6, 100 hPa temperatures are projected to remain relatively close to present day values but are projected to increase
by ~4.5 K under the SSP5-8.5 scenario.

Climatological annual mean, zonal mean H₂O mixing ratio differences between the end of the century (2086-2100 averaged)
610 and present day (2000-2014 averaged) periods for SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 are shown in Figure 18. Under
the SSP1-2.6 scenario, stratospheric water vapor mixing ratios are projected to remain close to present day values throughout
the stratosphere. However, in all other scenarios shown in Figure 18, stratospheric water vapor is projected to increase due to
the increases in projected 100 hPa temperatures and due to increased CH₄ mixing ratios (particularly under SSP3-7.0, the

615 scenario which assumes the largest increases in CH₄ emissions, which shows larger stratospheric water vapor increases in the upper stratosphere due to increased water vapor production from CH₄ oxidation).

5 Discussion and conclusions

620 This study presents an evaluation of stratospheric ozone and water vapor changes from the pre-industrial to the end of the 21st century in simulations performed by CMIP6 models under a range of future SSP scenarios. In total, for the historical period 1850-2014 ozone data was available from 14 models, while water vapor data was available from 10, and a subset of these models had also performed simulations under several SSP scenarios.

625 For zonal mean stratospheric ozone mixing ratios there is good agreement between the CMIP6 MMM and observations from the SWOOSH combined dataset, with biases within $\pm 10\%$, while for TCO there is good agreement between the CMIP6 MMM and the NIWA-BS dataset from 40°S-90°N, with biases within ± 20 DU ($< \pm 10\%$). Largest percentage zonal mean ozone mixing ratios biases occur in the tropical upper stratosphere, while for TCO the largest biases occur between 90°S-40°S. However, despite the agreement between the CMIP6 MMM and the observations, there are significant differences between the individual CMIP6 models.

630 From 1850 to 1960, global TCO in the CMIP6 MMM increased from 300 DU to 305 DU, before rapidly declining through the 1970s and 1980s with the onset of halogenated ODS emissions. TCO increases in the early part of the historical period were driven by increases in tropospheric ozone, particularly in the NH. Superimposed on the long-term trend is the 11-year solar cycle, which causes TCO averaged from 60°S-60°N to vary by around ± 1 DU, while the 1883 eruption of Krakatoa caused TCO values to increase by around 3-5 DU and resulted in the highest TCO values for ~ 100 years between 1850 and 1950. However, there is poor agreement between the individual CMIP6 models in the pre-industrial and throughout the historical period, with model TCO values spread across a range of ~ 60 DU.

635 For the future period, from 2015-2100, the higher the forcing pathway assumed by the various SSPs evaluated here, the higher the TCO at the end of the century. Annual mean TCO at most latitudes is projected to return to the 1960s values by the middle of the 21st century, and under the SSP3-7.0 and SSP5-8.5 scenarios significant increases above the 1960s value is simulated, driven in part by the decline in ODS concentrations, large increases in ozone mixing ratios in the upper stratosphere associated with CO₂ cooling and increases in the tropospheric ozone mixing ratios. However, TCO values are not projected to return to the 1960's values at most latitude ranges in the SSP1-1.9 and SSP1-2.6 scenarios, due, in part, to smaller ozone mixing ratio
640 increases in the stratosphere, consistent with reduced CO₂ induced cooling, and strong decreases in tropospheric ozone mixing ratios throughout the troposphere, driven by reductions in the emission of ozone precursors. While decreases in tropospheric ozone prevent TCO from returning to 1960's values, the decrease is undoubtedly a positive result for air quality, and perhaps

calls into question whether TCO values are an accurate measure of stratospheric ozone recovery, or if other metrics can more accurately reflect the profile changes expected for stratospheric ozone recovery without being influenced by tropospheric changes.
645

Stratospheric water vapor mixing ratios are poorly represented in many of the CMIP6 models investigated in this study. For the climatological 2000-2014 period, the models are dry biased, particularly in the upper stratosphere. This results from several of the models studied here not including any representation of water vapor formed from the oxidation of CH₄ in the stratosphere. The seasonal cycle and water vapor mixing ratios for individual CMIP6 models at 70 hPa in the tropics shows
650 poor agreement with the SWOOSH dataset, and further highlights the difficulties climate models have had over several generations of model intercomparison projects in the tropical tropopause region. Despite this, when averaged together the CMIP6 MMM agrees reasonably well with the observed climatological seasonal cycle.

For the CMIP6 MMM, 70 hPa water vapor mixing ratios remain relatively constant from 1850 to 1950, before slowly increasing to 2014. During this period, the largest variations in water vapor mixing ratios occur at the time of major volcanic eruptions. From 2014, tropical water vapor mixing ratios at 70 hPa are projected to increase under all SSP scenarios, with the magnitude of the increases generally following the radiative forcing across the scenarios. Under SSP1-1.9 and SSP1-2.6 water vapor mixing ratios are projected to increase from 3.2 ppm to 3.5 ppm by the middle of the 21st century before stabilising,
655 while under SSP3-7.0 and SSP5-8.5 water vapor mixing ratios show rapid increases throughout the century, reaching around 5 ppm by the 2100.

The data available from the CMIP6 models evaluated here do not allow for thorough investigation into the drivers of the changes identified here. In addition, the models evaluated here span a broad range of complexity, and so it is likely that modelled stratospheric ozone and water vapor mixing ratios have different sensitivity to changes in emissions. It is hoped that new datasets generated by models performing AerChemMIP simulations will provide greater insight into the wider chemical changes occurring throughout the atmosphere, including changes to stratospheric catalytic loss cycles and water vapor
660 produced through CH₄ oxidation.

Table 1. Overview of models and data available during the preparation of this manuscript.

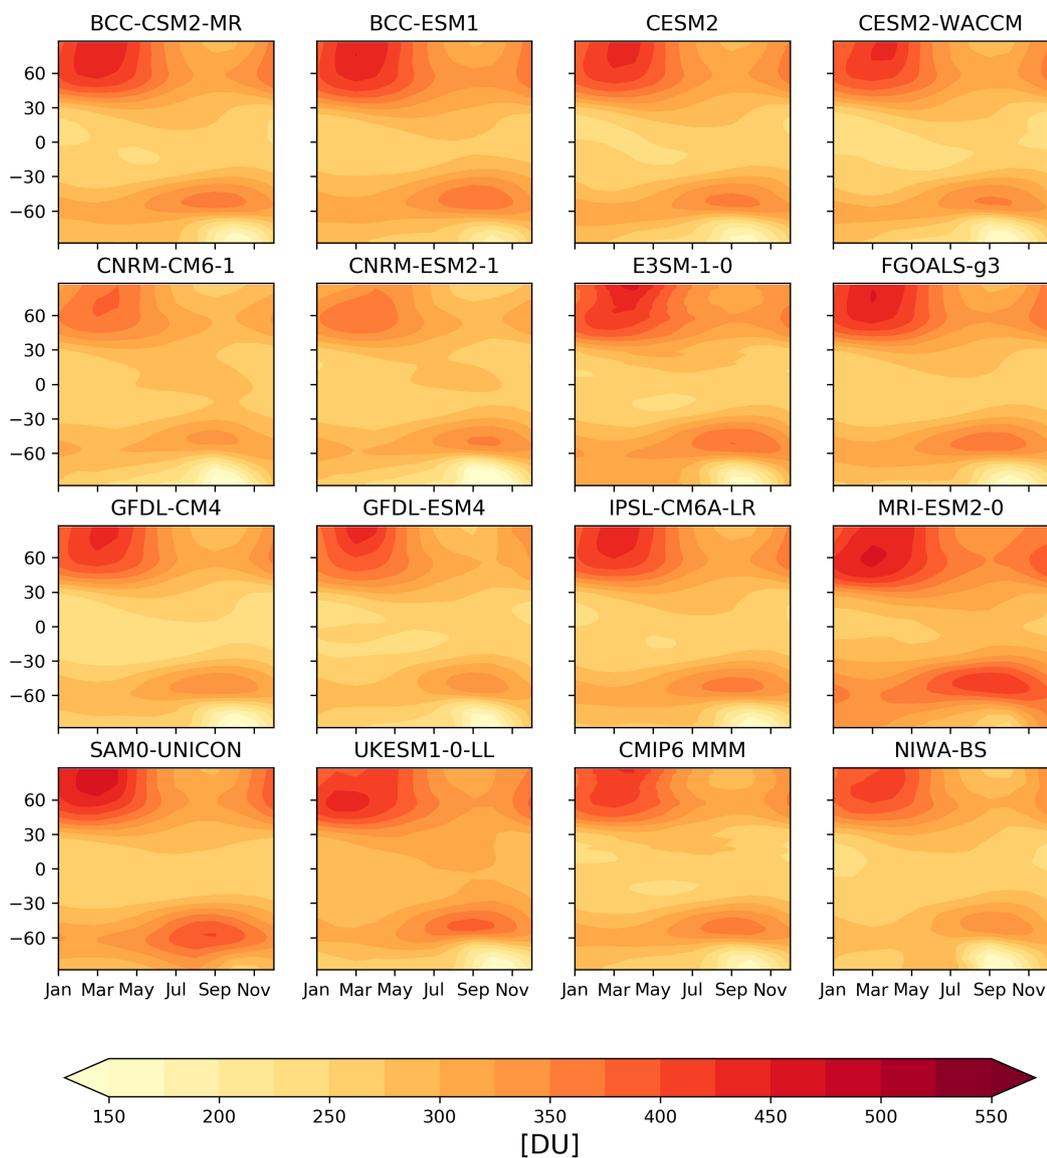

1220

Figure 1: Latitude vs altitude zonal mean ozone for CMIP6 models and observations. Climatological ozone volume mixing ratios (ppm) for 2000-2014 for each CMIP6 model, the CMIP6 multi-model mean (MMM) and SWOOSH combined dataset. GFDL-CM4 did not provide ozone output in the upper stratosphere, while the SWOOSH combined dataset only extends from ~300 hPa to 1 hPa.

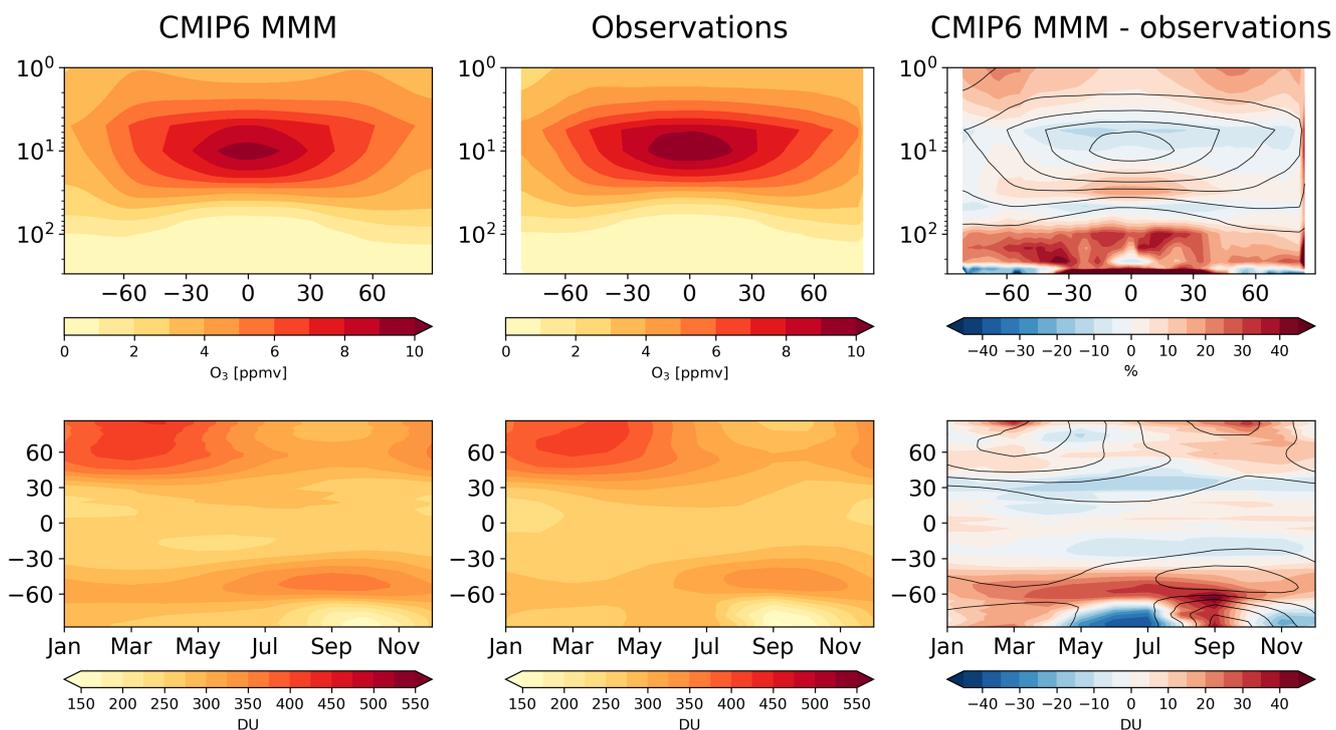

1225

Figure 2: Climatological (2000-2014) seasonal cycle of ozone (in ppm) at 70 hPa (15°S-15°N average) for CMIP6 models, CMIP6 multi-model mean (MMM; solid black line) and SWOOSH combined ozone dataset (dashed black line).

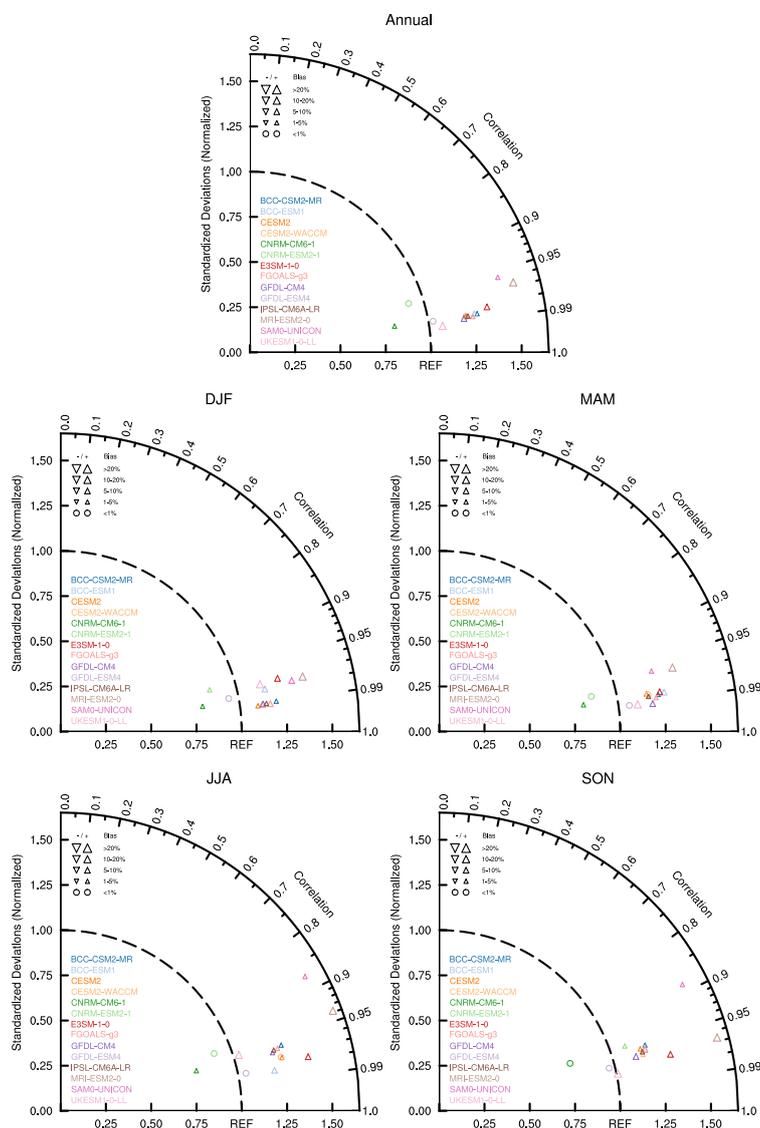

1230 **Figure 3: Month vs latitude total column ozone for CMIP6 models and observations. Climatological total column ozone (DU) for**
2000-2014 for each CMIP6 model, the CMIP6 multi-model mean (MMM) and NIWA-BS dataset. (units to be corrected, MMM to
be calculated and patched NIWA-BS dataset to be used

1235

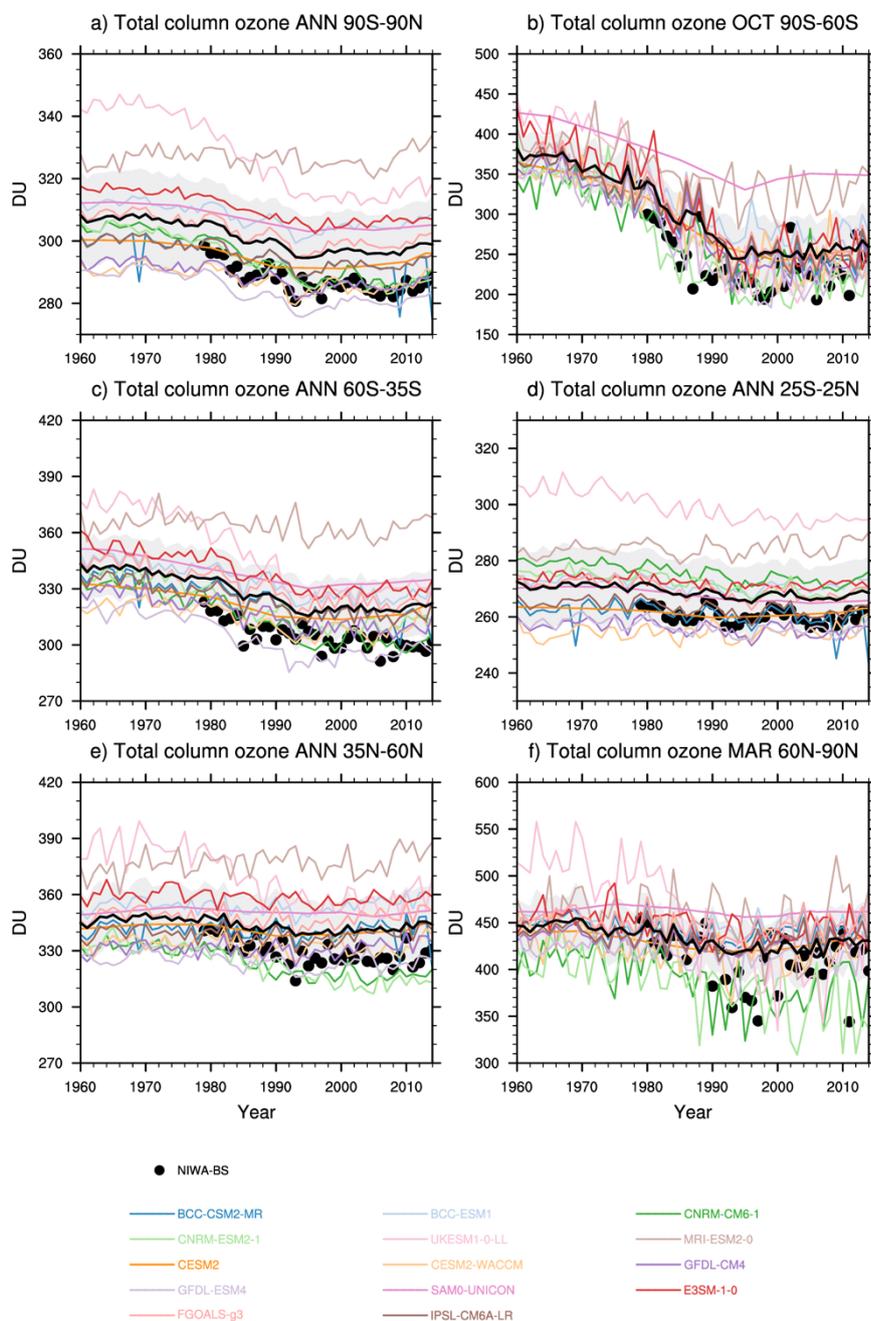

1240 **Figure 4:** Top row: 2000-2014 climatological zonal mean ozone for the CMIP6 multi-model mean (left), SWOOSH combined ozone dataset (centre) in ppm, and corresponding differences (right) in %. Bottom row: 2000-2014 climatological total column ozone for the CMIP6 multi-model mean (left), NIWA-BS dataset (centre) and corresponding differences (right) in DU.

1245

Figure 5: Taylor diagrams for annual and seasonal (DJF, MAM, JJA and SON) mean TCO between the NIWA-BS dataset and 14 CMIP6 models over 60°S–60°N for the period 2000–2014. On the Taylor diagrams, angular axes show spatial correlations between modelled and observed TCO; radial axes show spatial standard deviation (root-mean-square deviation), normalized against that of the observation; ‘REF’ represents the reference line; different symbols denote the percentage bias between observation and model. Each dot represents a model.

1250

Figure 6: Total column ozone for CMIP6 models, from 1960-2014, for a) annual mean values averaged from 90°S-90°N, b) October monthly mean values averaged from 90°S-60°S, c) annual mean values averaged from 60°S-35°S, d) annual mean values averaged from 25°S-25°N, e) annual mean values averaged from 35°N-60°N and f) March monthly mean values averaged from 60°N-90°N.

	90°S-90°N	25°N-25°S	35°N-60°N	35°S-60°S	60°N-90°N	60°S-90°S
	Annual mean	Annual mean	Annual mean	Annual mean	March mean	October mean

1255 **Table 2. Linear trends and errors in area-weighted total column ozone (TCO) (DU/year) over the periods of 1980-2000 and 2000-2014. Observed trends over 1980-2000 are taken from those in Table 2 in Eyring et al. (2013). Models highlighted in bold have interactive stratospheric ozone chemistry and their means are shown in bold. Numbers in parentheses next to the models are the number of ensembles used for that model.**

CMIP6 MMM Total Column Ozone

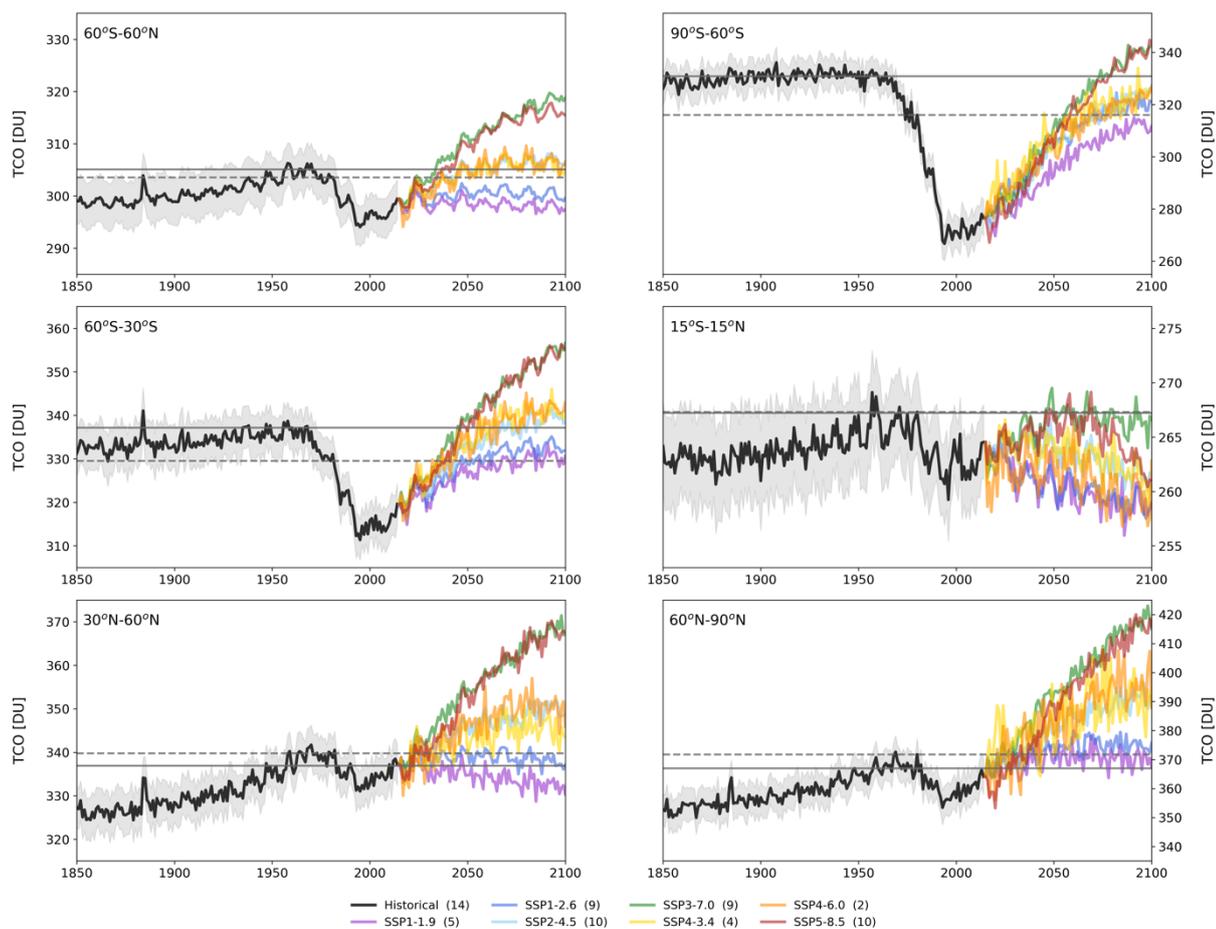

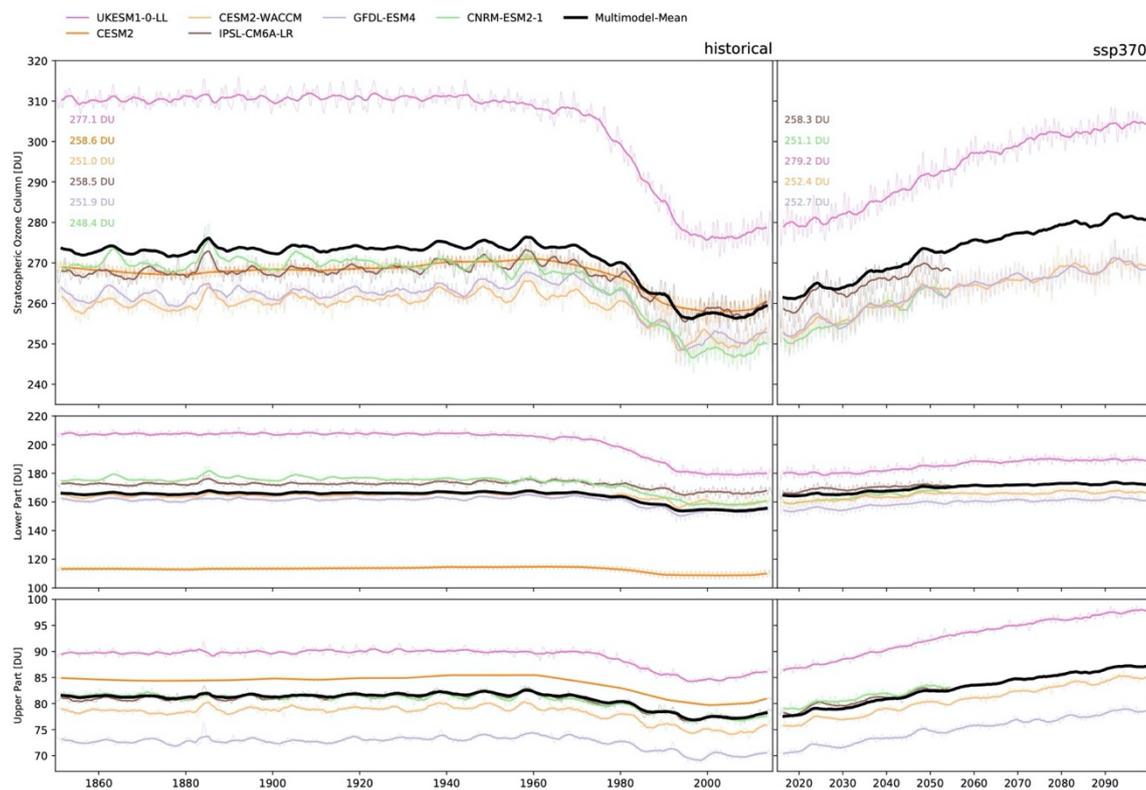

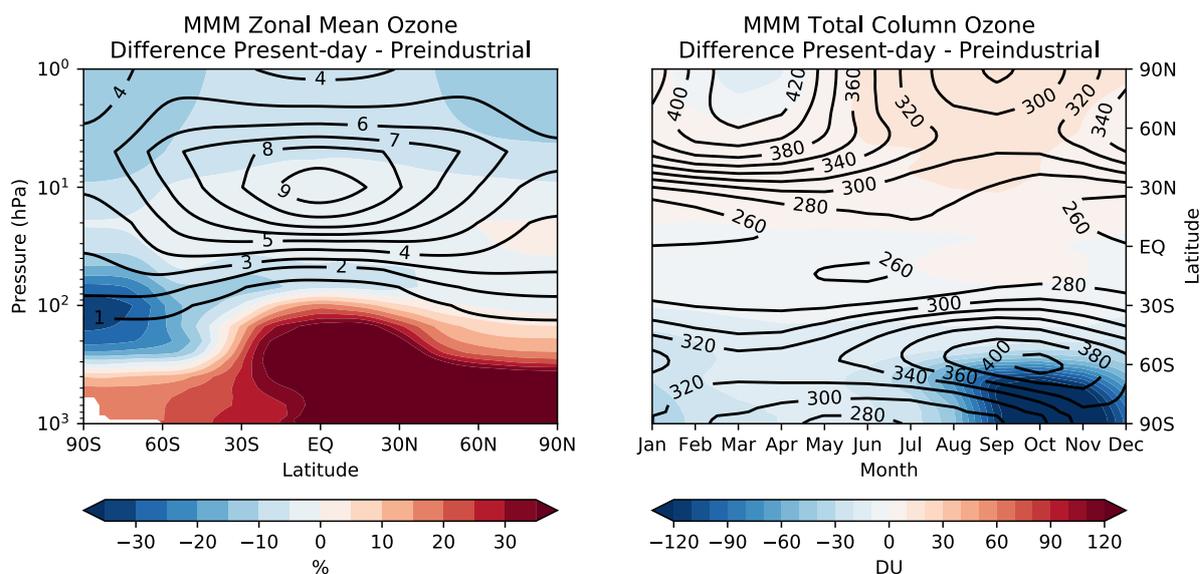

Figure 7: Regional average CMIP6 multi-model mean total column ozone for the historical simulation (black line), and SSP scenarios (coloured lines). The number of models performing each simulation is provide in parentheses in the legend. The light grey envelope indicates the model spread for the historical simulations (calculated as the standard error). Total column ozone values for the 1960 annual mean and 1980 annual mean are given by the solid and dashed horizontal grey lines respectively.

1265

1270 **Figure 8: Partial ozone columns from 1850-2014 following the historical simulation, and from 2014-2100 following the SSP3.7-0 scenario for a subset of the CMIP6 models evaluated in this study. Partial columns are calculated for the full stratosphere (tropopause to 1 hPa; upper panel), lower stratosphere (tropopause to 10 hPa; middle panel) and upper stratosphere (10 hPa to 1 hPa; lower panel).**

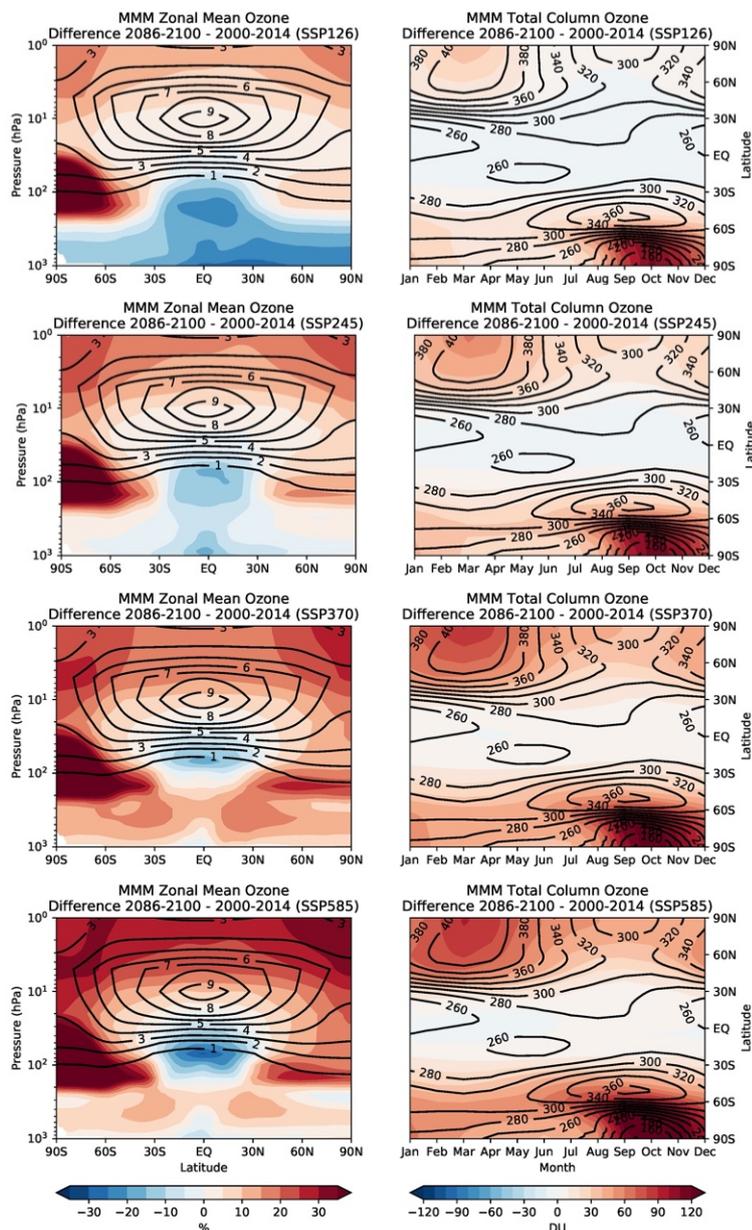

1275

1280 **Figure 9: CMIP6 MMM historical changes between the pre-industrial (1850-1864 averaged) and present day (2000-2014 averaged) modelled annual mean, zonal mean ozone mixing ratios in % (left), and seasonal TCO in DU (right), calculated for 13 of the 14 CMIP6 models evaluated in this study (GFDL-CM4 was excluded due to its low model top). The 2000-2014 averaged climatologies for both zonal mean ozone mixing ratios and TCO are shown in black contours.**

Figure 10: CMIP6 MMM projected changes under the SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5 scenarios between the present day (2000-2014 averaged) and end of century (2086-2100 averaged) modelled annual mean, zonal mean ozone mixing ratios in % (left), and seasonal TCO in DU (right), calculated using 9 of the 14 CMIP6 models evaluated in this study (BCC-CSM2-MR, CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-ESM2-1, GFDL-ESM4, IPSL-CM6A-LR, MRI-ESM2-0 and UKESM1-0-LL). The 2000-2014 averaged climatologies for both zonal mean ozone mixing ratios and TCO are shown in black contours.

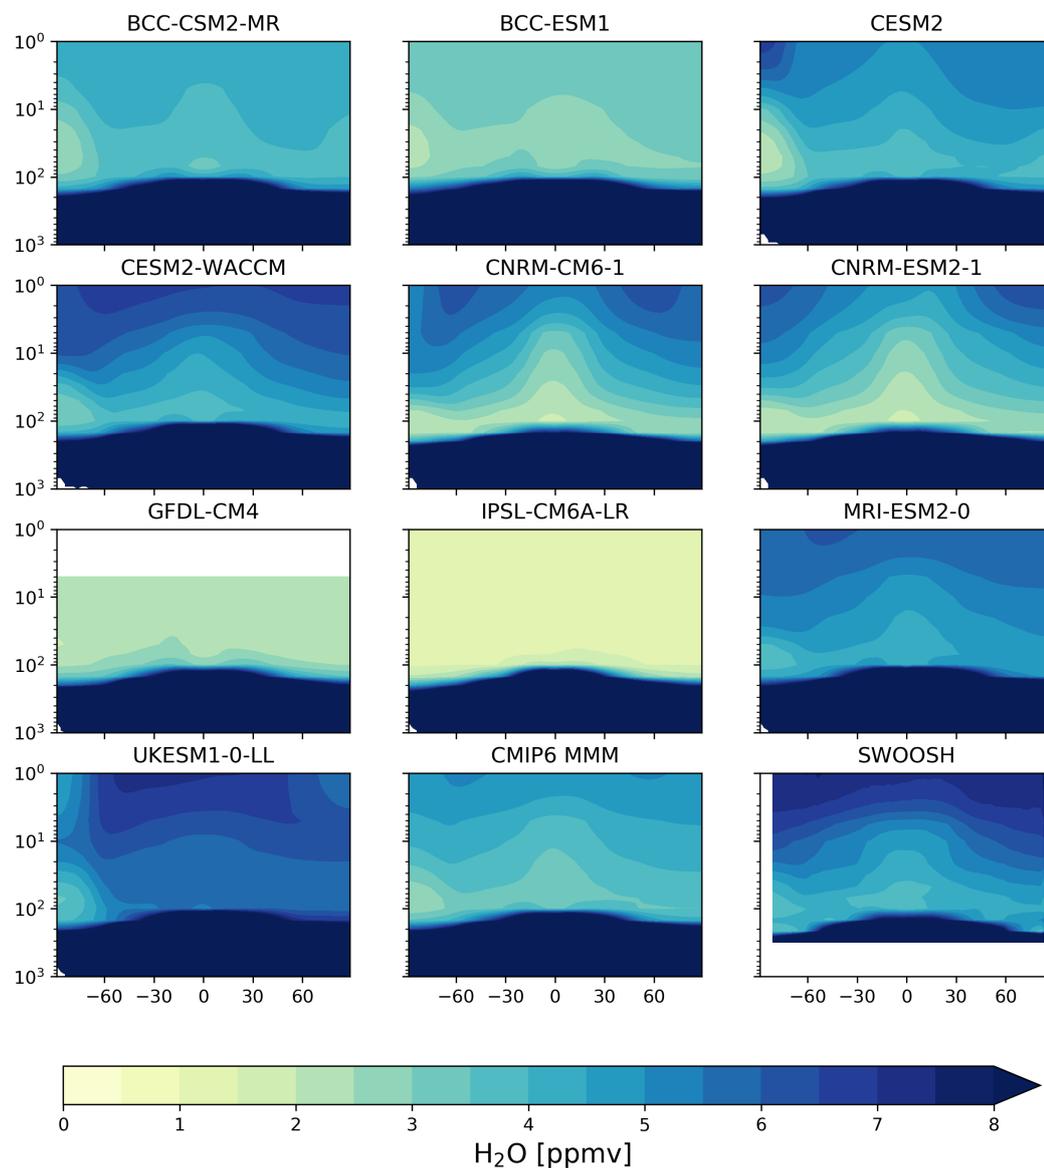

Figure 11: Latitude vs altitude zonal mean H₂O for CMIP6 models and observations. Climatological H₂O volume mixing ratios (ppm) for the years 2000-2014 for each CMIP6 model, the CMIP6 multi-model mean (MMM) and SWOOSH combined dataset. GFDL-CM4 did not provide H₂O data in the upper stratosphere, while the SWOOSH combined dataset only extends from ~300 hPa to 1 hPa.

1300

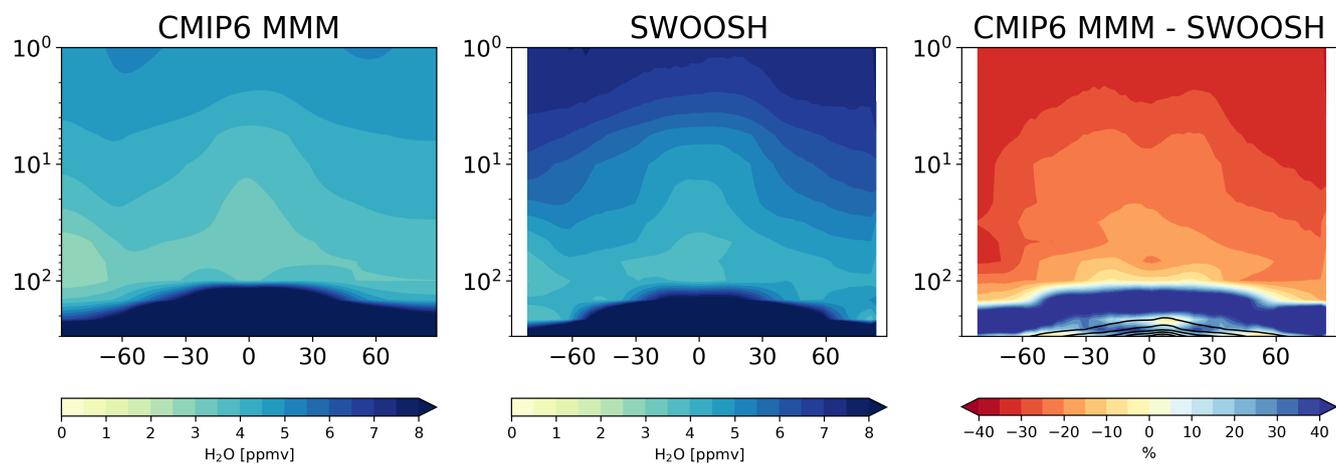

Figure 12: 2000-2014 climatological zonal mean H₂O for the CMIP6 multi-model mean (left), SWOOSH combined H₂O dataset (centre) in ppm, and corresponding differences (right) in %. Note that for the differences, red colours indicate the model is drier (i.e. less H₂O in the CMIP6 MMM compared with the observations).

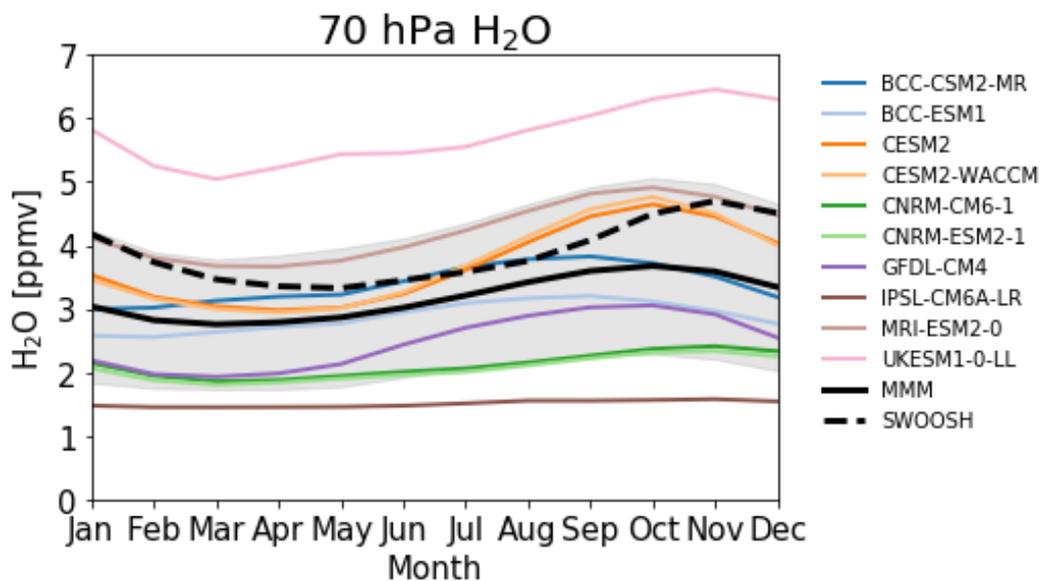

Figure 13: Climatological (2000-2014) seasonal cycle of H₂O (in ppm) at 70 hPa for CMIP6 models, CMIP6 multi-model mean (MMM; solid black line) and SWOOSH combined ozone dataset (dashed black line).

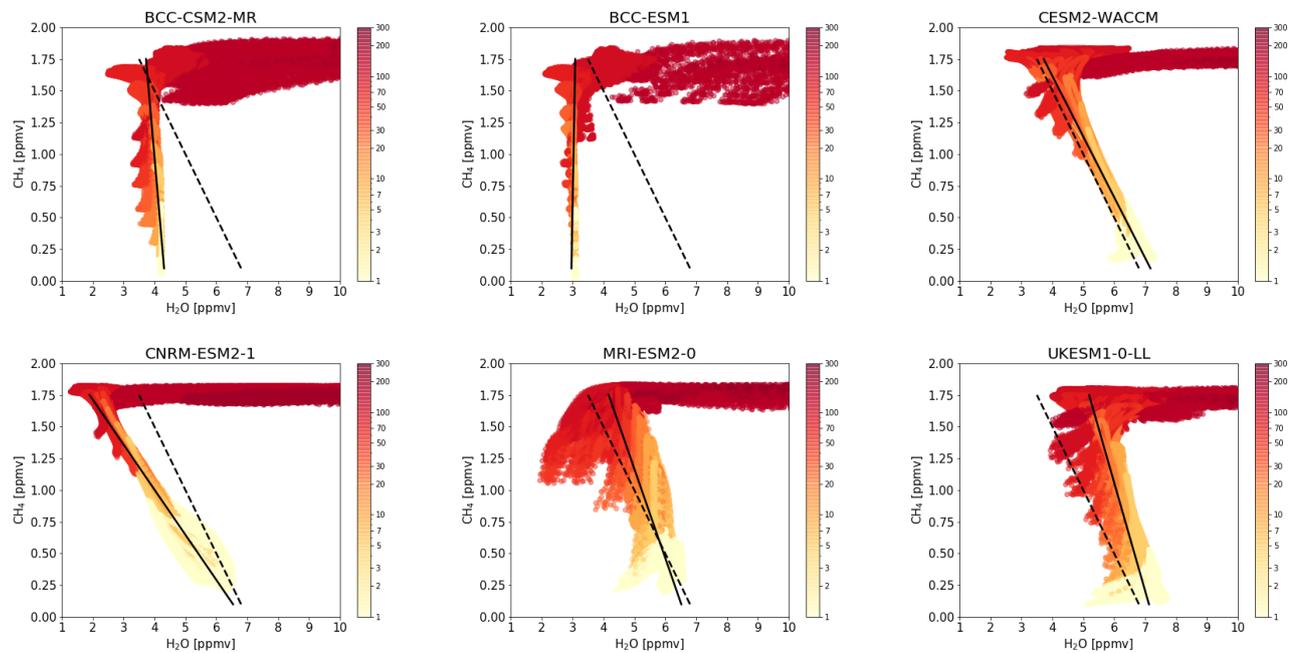

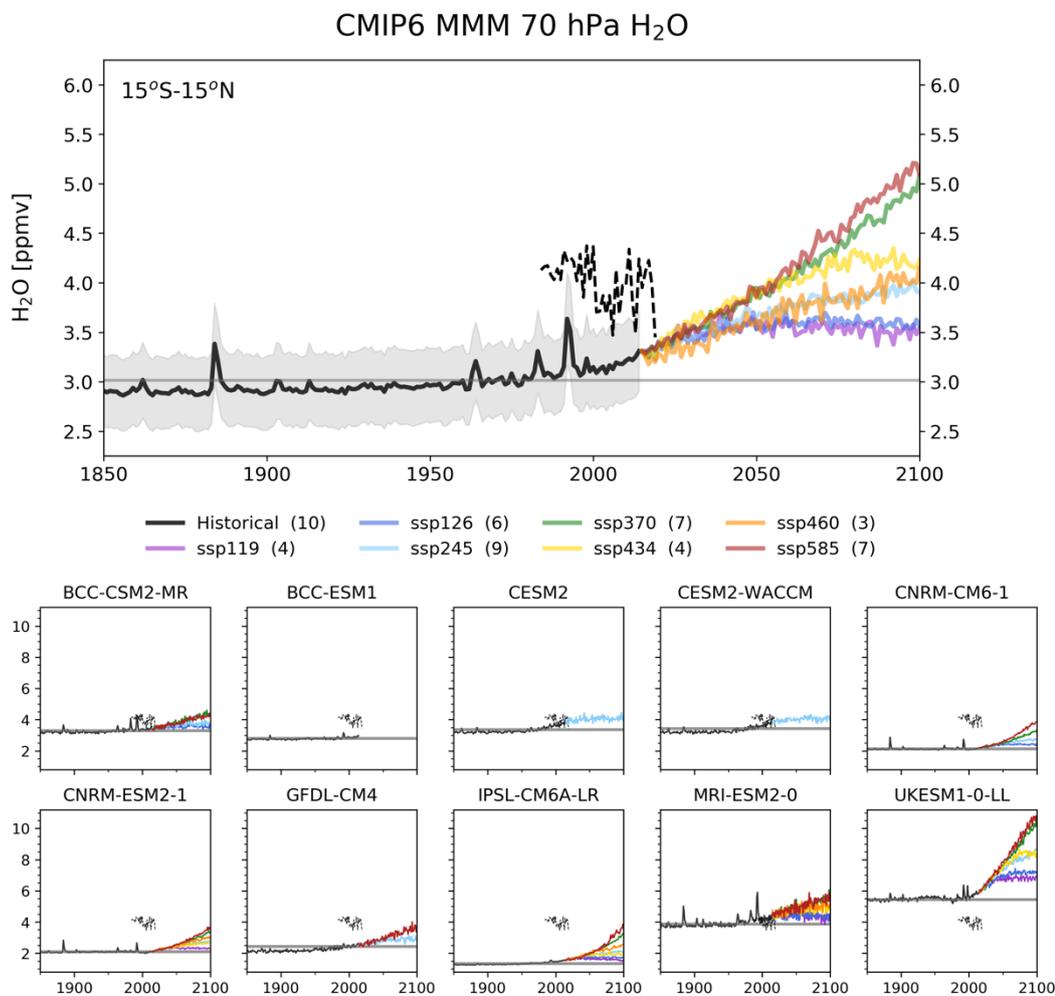

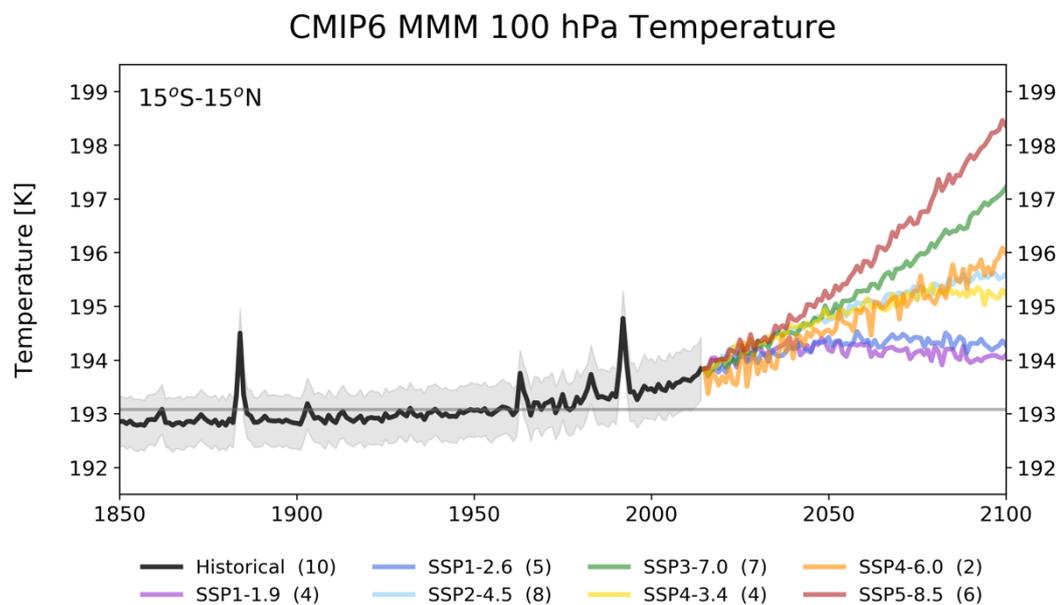

Figure 14: H₂O vs CH₄ scatter plots. Black line gives model gradient, dashed black line gives SPARC estimate ($H_2O = 7-2*CH_4$)

1320

Figure 15: Upper panel: CMIP6 multi-model mean H₂O mixing ratio (ppm), averaged from 15°S-15°N at 70 hPa for the historical simulation (black line), and SSP scenarios (coloured lines). The number of models performing each simulation is provide in parentheses in the legend. The light grey envelope indicates the model spread for the historical simulations (calculated as the standard error). H₂O mixing ratios for the 1960 annual mean is given by the horizontal grey line. Observations from the SWOOSH combined dataset are shown in the dashed black line. Lower panels: As upper panel, but for each individual CMIP6 model.

1325 **Figure 16: MIP6 multi-model mean Temperature (K), averaged from 15°S-15°N at 100 hPa for the historical simulation (black line),**
and SSP scenarios (coloured lines). The number of models performing each simulation is provide in parentheses in the legend. The
light grey envelope indicates the model spread for the historical simulations (calculated as the standard error). Temperature for the
1960 annual mean is given by the horizontal grey line.

1330

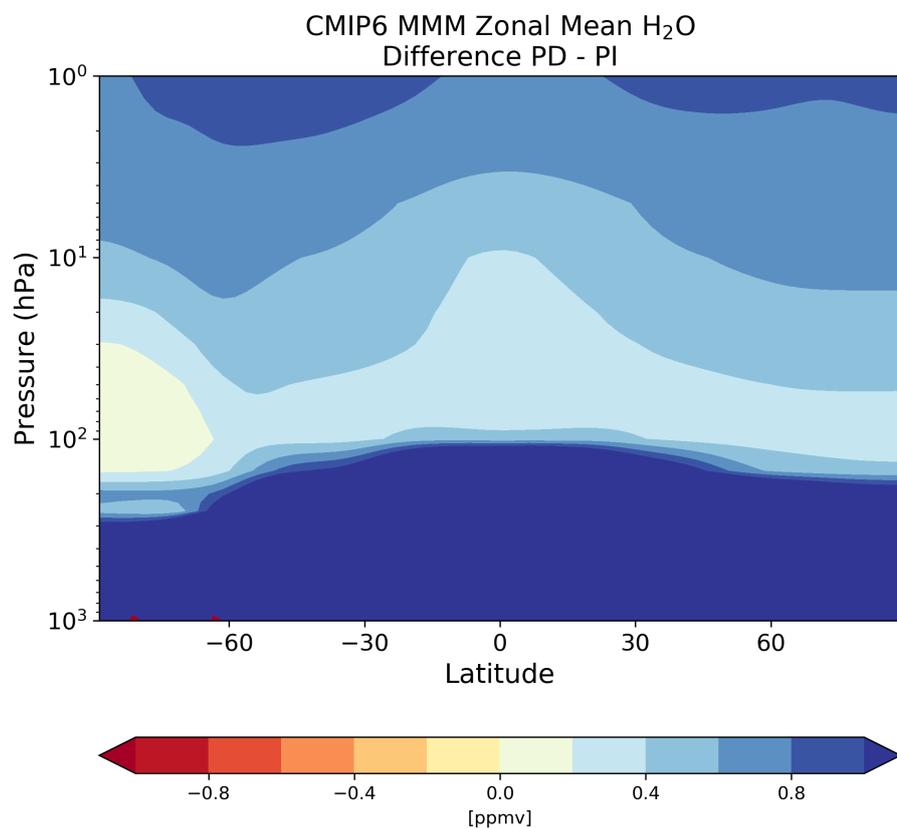

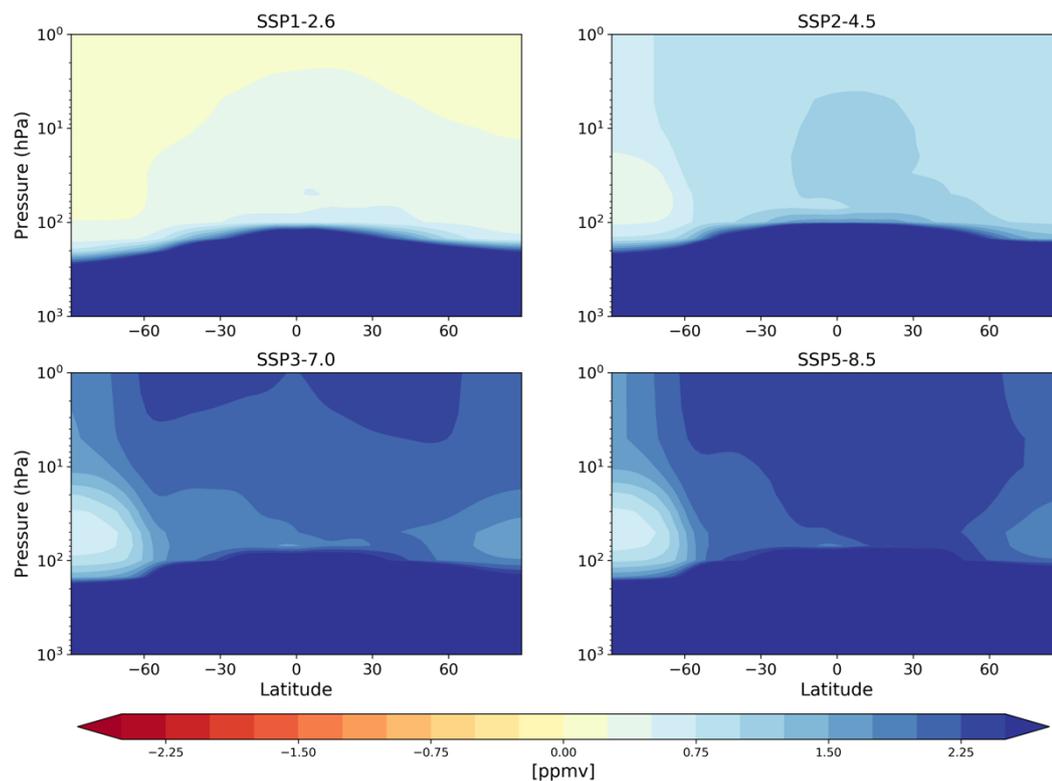

Figure 17: Historical changes between the pre-industrial (1850-1864 averaged) and present day (2000-2014 averaged) modelled annual mean, zonal mean CMIP6 MMM H₂O mixing ratios (ppm), calculated using 9 of the 10 CMIP6 models evaluated in this study (GFDL-CM4 was excluded due to its low model top).

1335

CMIP6 MMM Zonal Mean H₂O Difference
(2086-2100) - (2000-2014)

1340 **Figure 18: Projected changes between the present day (2000-2014 averaged) and end of century (2086-2100 averaged) modelled annual mean, zonal mean CMIP6 MMM H₂O volume mixing ratios (ppm), calculated using 5 of the 10 CMIP6 models evaluated in this study (BCC-CSM2-MR, CNRM-CM6-1, IPSL-CM6A-LR, MRI-ESM2-0 and UKESM1-0-LL).**

Appendix

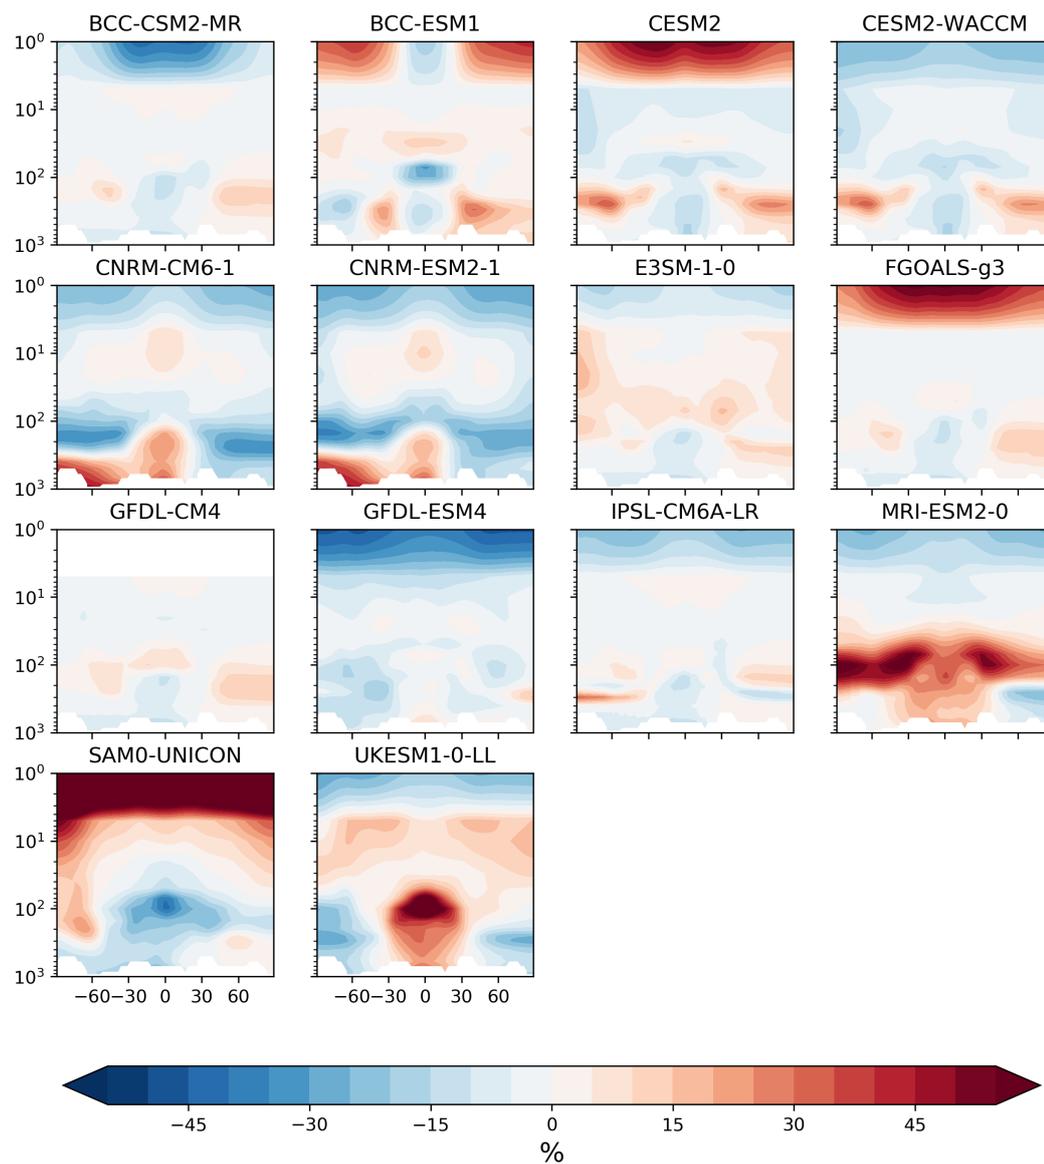

Figure A1: Latitude vs altitude ozone anomalies (in %) for individual CMIP6 models compared to the CMIP6 multi-model mean (MMM) averaged for the years 2000-2014. Differences calculated as model – CMIP6 MMM.

CMIP6 MMM Total Column Ozone

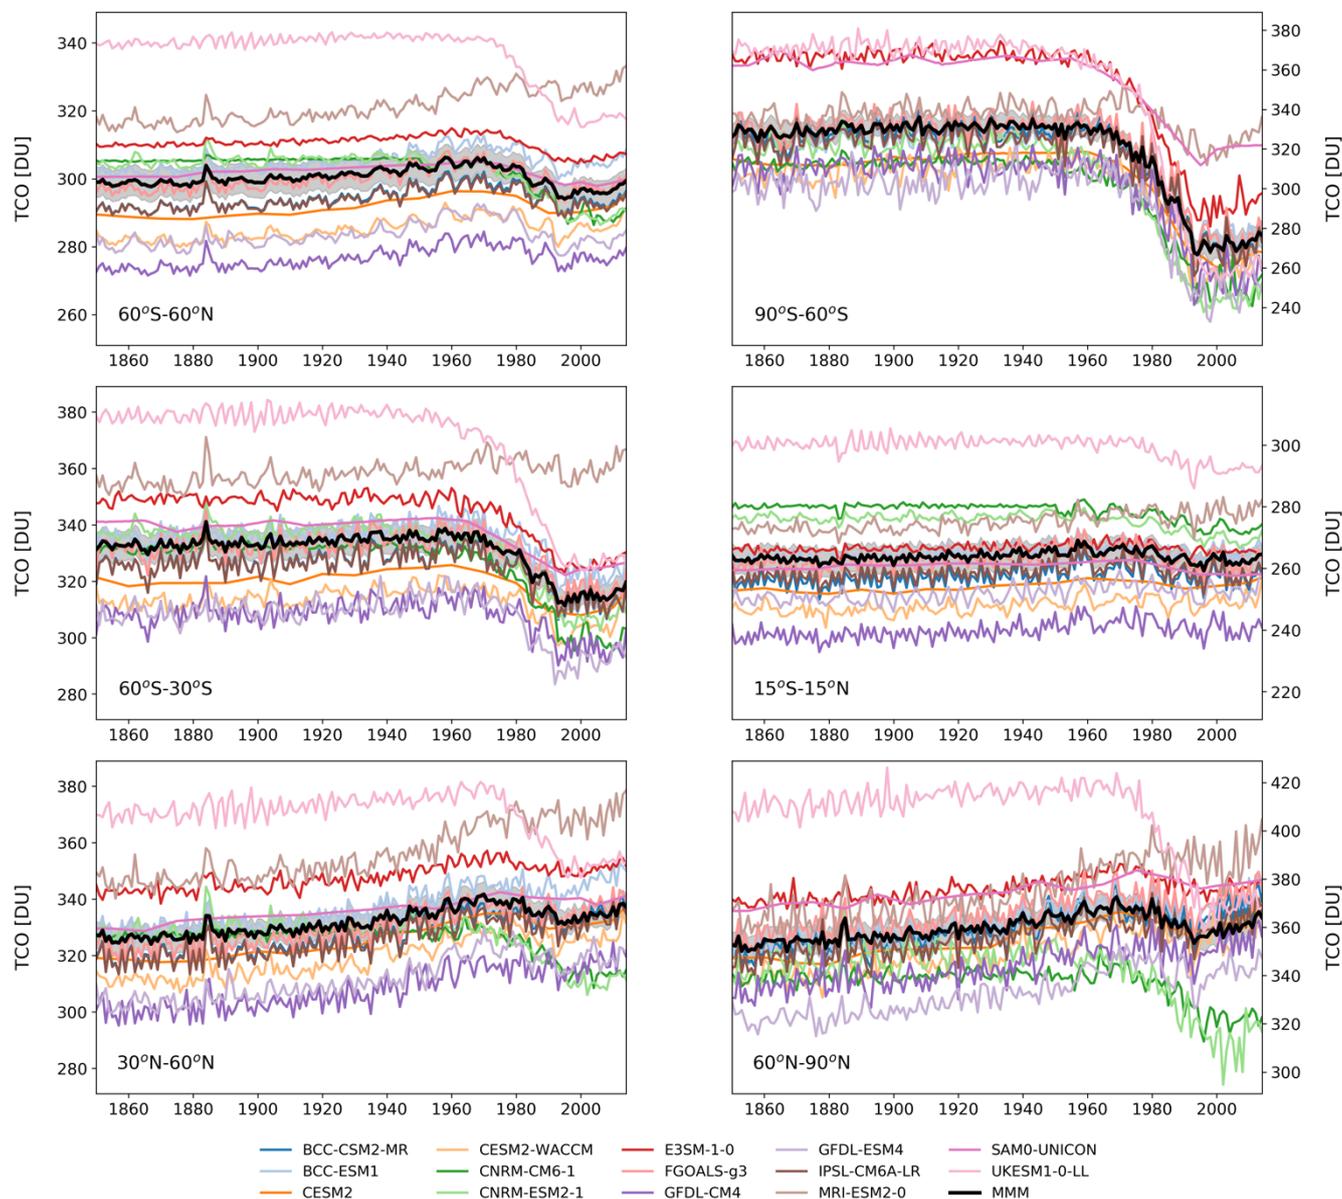

Figure A2: Regional average total column ozone from each CMIP6 model (coloured lines) for the historical simulation, the CMIP6 multi-model mean (black line), and the multi-model spread (calculated as the standard error; grey shading).

CMIP6 MMM Total Column Ozone

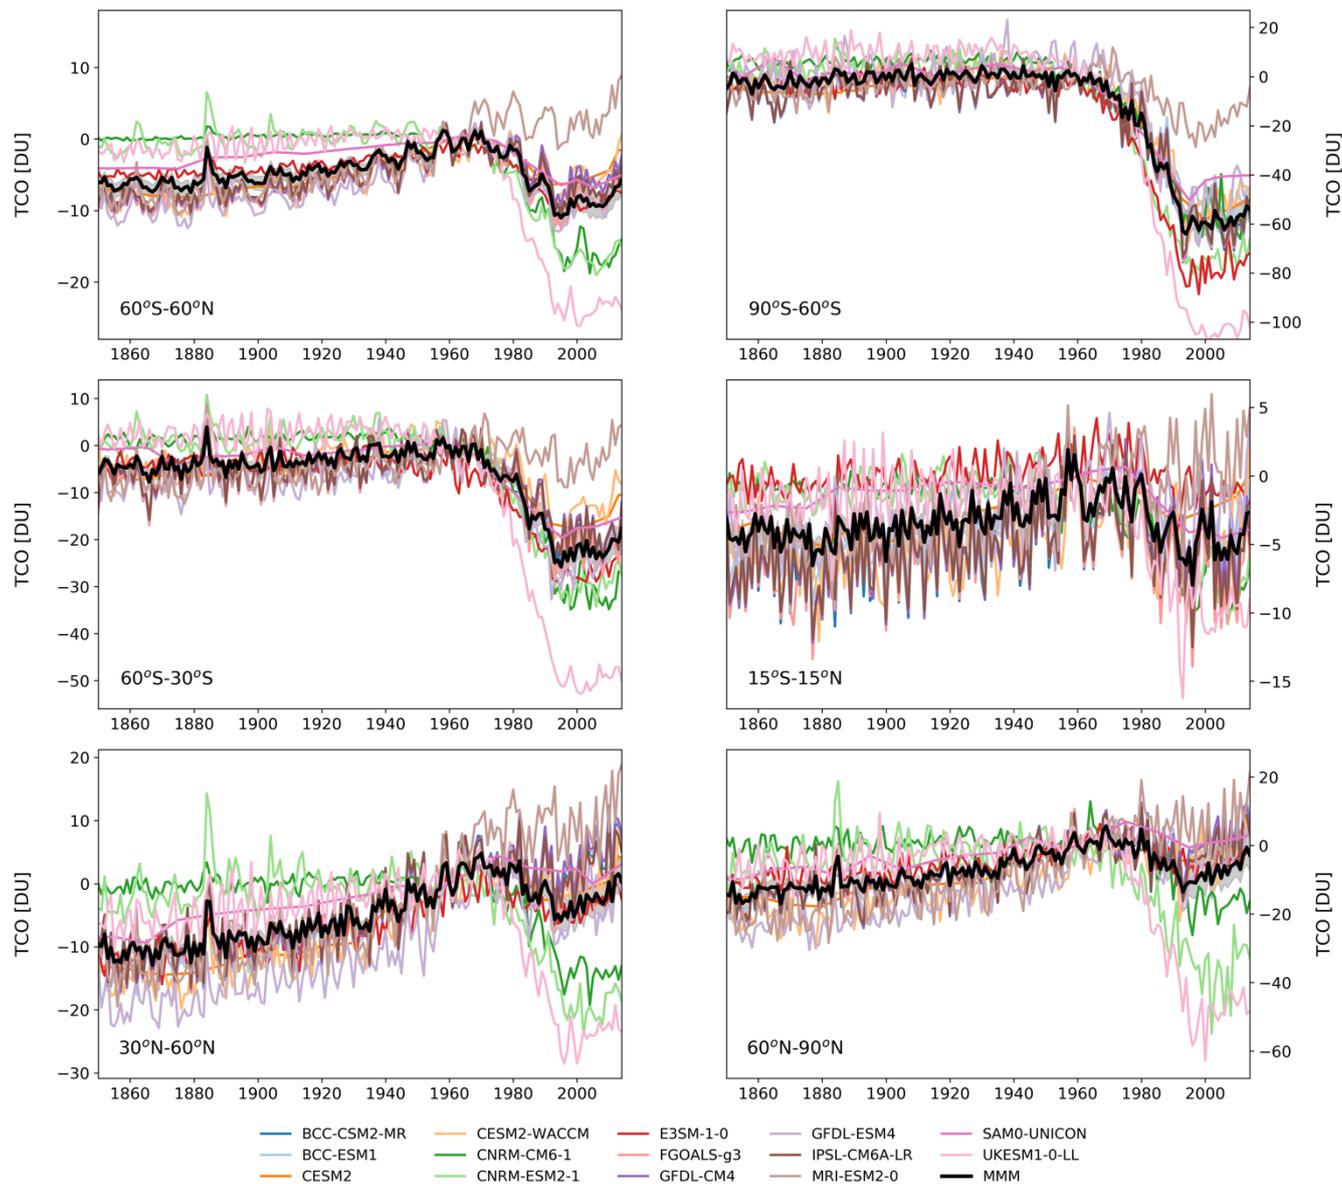

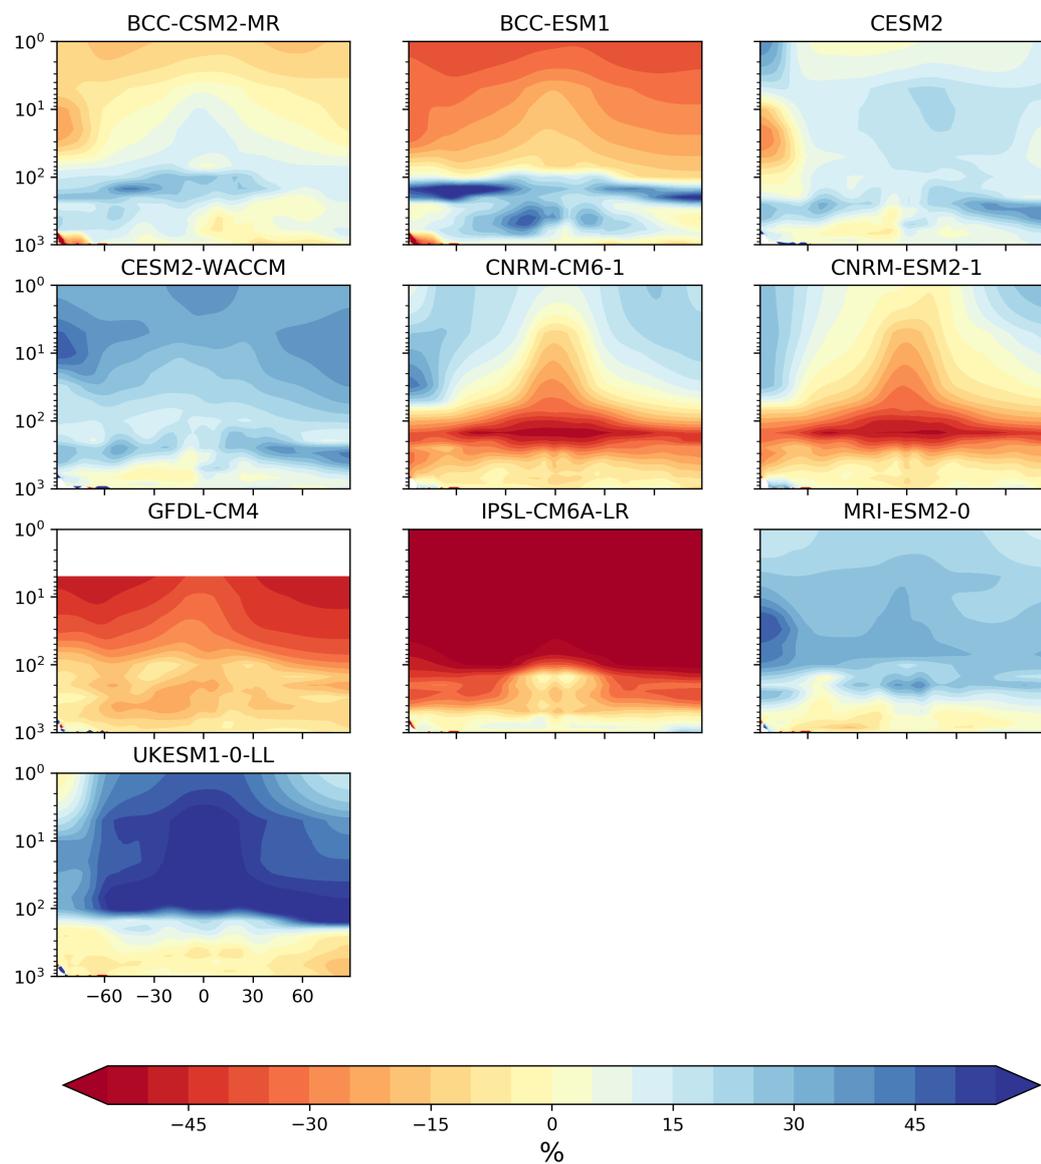

Figure A3: As for A2, but each model is normalised to its 1960 value.

1355

A4: Latitude vs altitude H₂O anomalies (in %) for individual CMIP6 models compared to the CMIP6 multi-model mean (MMM) averaged for the years 2000-2014. Differences calculated as model – CMIP6 MMM. Note that for the differences, red colours indicate the model is drier (i.e. less H₂O in the CMIP6 MMM compared with the observations).

1360

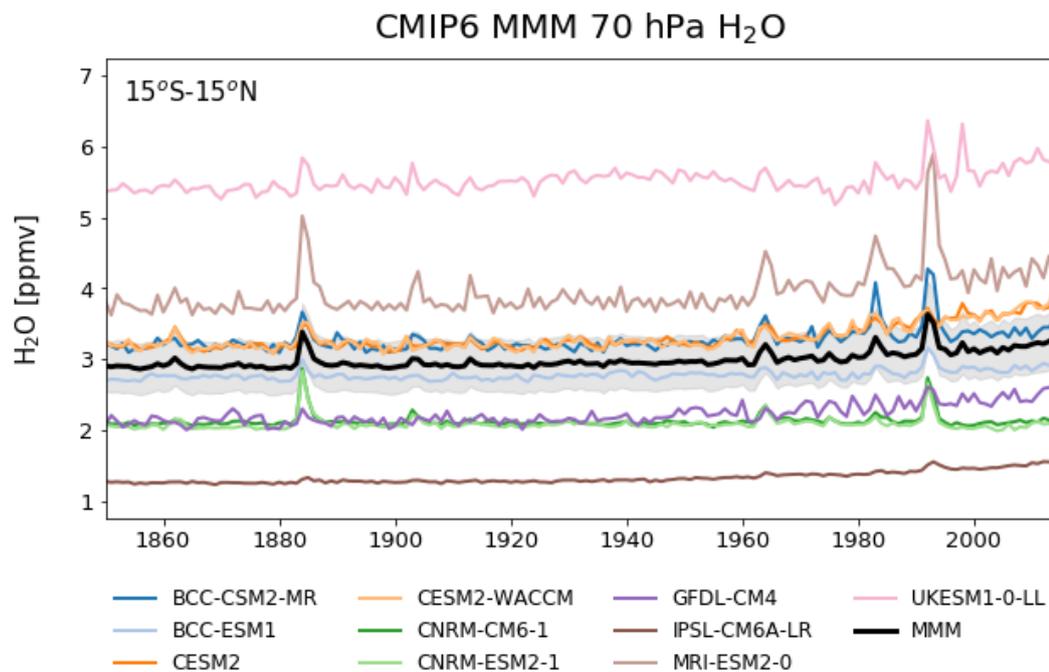

Figure A5: 70 hPa H₂O mixing ratio (ppm) from each CMIP6 model (coloured lines) for the historical simulation, the CMIP6 multi-model mean (black line), and the multi-model spread (calculated as the standard error; grey shading).
