28 **Abstract**

29 This paper quantifies the effective radiative forcing from CMIP6 models of the present-day anthropogenic
30 emissions of NO_x, CO, VOCs, SO₂, NH₃, black carbon and primary organic carbon. Effective radiative forcing
31 from pre-industrial to present-day changes in the concentrations of methane, N₂O and halocarbons are quantified
32 and attributed to their anthropogenic emissions.

33 Emissions of reactive species can cause multiple changes in the composition of radiatively active species:
34 tropospheric ozone, stratospheric ozone, secondary inorganic and organic aerosol and methane. We therefore
35 break down the ERFs from each emitted species into the contributions from the composition changes.
36 The 1850 to 2014 mean ERFs are $-1.02 \pm 0.15 \text{ Wm}^{-2}$ for SO_2 , $-0.27 \pm 0.04 \text{ Wm}^{-2}$ for organic carbon (OC), and
37 $0.14 \pm 0.08 \text{ Wm}^{-2}$ for black carbon (BC), and for the aerosols combined it is $-0.94 \pm 0.08 \text{ Wm}^{-2}$. The means for
38 the reactive gases are $0.70 \pm 0.08 \text{ Wm}^{-2}$ for methane (CH_4), $0.05 \pm 0.06 \text{ Wm}^{-2}$ for NO_x , $-0.06 \pm 0.09 \text{ Wm}^{-2}$
39 for volatile organic carbons (VOC), $0.17 \pm 0.04 \text{ Wm}^{-2}$ for ozone (O_3), $0.23 \pm 0.03 \text{ Wm}^{-2}$ for nitrous oxide
40 (N_2O) and $-0.04 \pm 0.1 \text{ Wm}^{-2}$ for hydrocarbon (HC). Differences in ERFs calculated for the different models
41 reflect differences in the complexity of their aerosol and chemistry schemes, especially in the case of methane
42 where tropospheric chemistry captures increased forcing from ozone production.

43 1. Introduction

44 The characterisation of the responses of the atmosphere, climate, and earth systems generally is essential for
45 understanding, and countering, the impacts of climate change. As part of this effort there have been several
46 projects directed at using climate models from different groups around the world to produce a systematic
47 comparison of the simulations from these models, via the Coupled Model Intercomparison Project (CMIP), which
48 is now in its 6th iteration (Eyring et al., 2016). This CMIP work has been subdivided into different areas of interest
49 for addressing specific questions about climate, such as the impact of aerosols such as sulfates, black carbon (BC),
50 organic carbon (OC), as well as other species which react in the atmosphere, e.g. methane, hydrocarbons, ozone
51 and nitrous oxide, and the AerChemMIP (Collins et al., 2017) project is designed to examine the specific effects
52 of these factors on the climate.

53 The focus of this work is to characterise the effect of the aerosols and chemically-reactive species on the radiation
54 budget of the planet, referred to as radiative forcing, as an initial step to understanding the response of the
55 atmosphere and earth system to changes in these components, whether those changes are due directly to
56 anthropogenic emissions or to natural emissions responding to climate change (e.g. sea salt and dust which may
57 change their emissions as a response to changes in wind speed, ocean temperature etc). In previous reports of the
58 Intergovernmental Panel on Climate Change (IPCC) the effect of the various forcing agents on the radiation
59 balance has been investigated in terms of the radiative forcing, (RF), which is a measure of how the radiative
60 fluxes at the top of atmosphere (TOA) change in response to changes in e.g. emissions of CO_2 or aerosols. There
61 have been several definitions of radiative forcing, (Forster et al., 2016; Sherwood et al., 2015), which generally
62 considered the instantaneous radiative forcing (IRF), or a combination of the IRF including the adjustment of the
63 stratospheric temperature to the driver, generally termed the stratospherically-adjusted radiative forcing. More
64 recently (Boucher, 2013; Chung and Soden, 2015) there has been a move towards using the effective radiative
65 forcing (ERF) as the preferred metric, as this includes the rapid adjustments of the atmosphere to the perturbation,
66 e.g. changes in cloud cover or type, water vapour, tropospheric temperature, which may affect the overall radiative
67 balance of the atmosphere. In this work, this ERF is calculated using two atmospheric model simulations both
68 with prescribed ocean conditions, but one having the perturbation we are interested in investigating, e.g. a change
69 in emissions of aerosols. The difference in the net TOA flux between these two simulations is then defined as the
70 ERF for that perturbation.

71 Previous efforts to understand the radiative forcing due to aerosols and chemistry have resulted in a wide spread
72 of values from the different climate models, in part due to a lack of suitable model simulations for extracting the
73 ERF from e.g. a specific change to an aerosol species. The experiments in the AerChemMIP project have been
74 designed to address this in part, by defining consistent model set-ups to be used to calculate the ERFs, although
75 the individual models will still have their own aerosol and chemistry modules, with varying levels of complexity
76 and different approaches.
77 There are complexities in assessing how a particular forcing agent affects the climate system due to the interactions
78 between some of the reactive gases; for example methane and ozone are linked in complex ways, and this increases
79 the problem of understanding the specific contribution of each to the overall ERF when one of them is perturbed.
80 An attempt to understand some of these interactions is discussed in Section 3.3 below.
81 The experimental set-up and models used are described in Section 2, the results for the aerosol and chemistry
82 experiments are described in Section 3, and the results are discussed in section 4. Final conclusions are drawn in
83 Section 5.

84 **2. Experimental Setup**

85 2.1 Models

86 This analysis is based on models participating in the Coupled Model Intercomparison Project (CMIP6) (Eyring et
87 al., 2016), which oversees climate modelling efforts from a number of centres with a view to facilitating
88 comparisons of the model results in a systematic framework. The overall CMIP6 project has a number of sub-
89 projects, where those with interests in specific aspects of the climate can design and request specific experiments
90 to be undertaken by the modelling groups. To understand the effects of aerosols and reactive chemistry on the
91 climate a set of experiments was devised under the auspices of AerChemMIP (Collins et al., 2017), described in
92 Section 2.2.
93 The emissions of the anthropogenic and reactive species for use in the models are given in (Hoesly et al., 2018)
94 and van Marle et al. (2017) although models use their own (Eyring et al., 2016) natural emissions, while the well-
95 mixed greenhouse gases (WGMHG) are specified as concentrations either at the surface or in the troposphere.
96 Not all of the models include interactive aerosols, tropospheric chemistry and stratospheric chemistry, which is
97 the ideal for the AerChemMIP experiments, but those models which do not include all these processes provide
98 results for a subset of the experiments described in Section 2.2
99 The models included in this analysis are summarised in Table 1, with an overview of the model set-up, aerosol
100 scheme and type of chemistry models used included. A more detailed table is available in the supplementary
101 materials, Table S1.
102 The CNRM-ESM2-1 model (Séférian et al 2019, Michou et al. 2019) includes an interactive tropospheric aerosol
103 scheme, and an interactive gaseous chemistry scheme down to a level of 560 hPa. The sulfate precursors evolve
104 to SO₄ using a simple dependence on latitude. The cloud droplet number concentration (CDNC) is depending on
105 SO₄, organic matter and sea-salt concentrations, so the cloud-albedo effect is represented, although other aerosol-
106 cloud interactions are not.
107 The UKESM1 model (Sellar et al., 2020) includes an interactive stratosphere-troposphere gas-phase chemistry
108 scheme (Archibald et al., 2019) using the UK Chemistry and Aerosol (UKCA; (Morgenstern et al., 2009; O'Connor

109 et al., 2014) model. The UKCA aerosol scheme, called GLOMAP-mode, is a two-moment scheme for the
110 simulation of tropospheric black carbon (BC), organic carbon (OC), SO₄, and sea salt. Dust is modelled
111 independently using the bin scheme of (Woodward, 2001). The UKCA chemistry and aerosol schemes are coupled
112 such that the secondary aerosol (SO₄, OA) formation rates depend on oxidants from the stratosphere-troposphere
113 chemistry scheme (Archibald et al., 2019; Sellar et al., 2020), Mulcahy et al 2019, in prep). Aerosol particles are
114 activated into cloud droplets using the activation scheme of (Abdul-Razzak and Ghan, 2000) which is dependent
115 on aerosol size distribution, aerosol composition, and meteorological conditions. Changes in CDNC affect cloud
116 droplet effective radius ((Jones et al., 2001) and the autoconversion of cloud liquid water in to rain water
117 (Khairoutdinov and Kogan, 2000), which both influence cloud albedo ((Mulcahy et al., 2018); Mulcahy et al.,
118 2019 in prep). Stratospheric aerosols (aerosol optical depth and surface area density) are prescribed in the model
119 (Sellar et al., 2019b). A full description and evaluation of the chemistry and aerosol schemes in UKESM1 can be
120 found in (Archibald et al., 2019) and Mulcahy et al. (2019), respectively.

121 The MIROC6 model includes the Spectral Radiation-Transport Model for Aerosol Species (SPRINTARS) aerosol
122 model which predicts mass mixing ratios of the main tropospheric aerosols and models aerosol-cloud interactions
123 in which aerosols alter cloud microphysical properties and affect the radiation budget by acting as cloud
124 condensation and ice nuclei. The sulfate and carbonaceous aerosols are treated as externally mixed in this model.
125 The CDNC and ice crystal number are used to calculate the aerosol indirect effect and cloud nucleation process
126 (Takemura et al., 2005), (Watanabe et al., 2010), Takemura et al 2018). It also includes gas phase chemistry.

127 The MRI-ESM2 model (Yukimoto et al., 2019) has the MASINGAR mk-2 aerosol scheme, and a chemistry
128 model, MRI-CCM2 ((Deushi and Shibata, 2011) which models chemistry processes for O₃ and other trace gases
129 from the surface to the stratosphere. The aerosol scheme includes aerosol-chemistry interactions, and aerosol-
130 cloud interactions (Kawai et al., 2019)

131 The BCC-ESM1 model (Wu et al., 2019b), (Wu et al., 2019a) models major aerosol species including gas-phase
132 chemical reactions, secondary aerosol formation, and aerosol-cloud interactions including indirect effects are
133 represented. It uses the BCC-AGCM3-Chem atmospheric chemistry model based on MOZART2 (Horowitz et al.,
134 2003) which does not include stratospheric chemistry, so concentrations of ozone, CH₄, and N₂O at the top two
135 model levels are the zonally and monthly values derived from the CMIP6 data package.

136 The NorESM2 model contains interactive aerosols. The OsloAero6 aerosol module (Olivie et al., in prep.) which
137 contains some slight updates since (Kirkevåg et al., 2018) describes the formation and evolution of BC, OM,
138 sulfate, dust, sea-salt and SOA. There is a limited gas-phase chemistry describing the oxidation of the aerosol
139 precursors DMS, SO₂, isoprene, and monoterpenes. Oxidant fields of OH, HO₂, NO₃ and O₃ are prescribed
140 climatological fields. As there is no ozone chemistry in the model, prescribed monthly-varying ozone fields are
141 used for the radiation.

142 The GFDL-ESM4 model consists of the GFDL AM4.1 atmosphere component (Horowitz et al in prep 2019,
143 Dunne et al in prep 2019) which includes an interactive tropospheric and stratospheric gas-phase and aerosol
144 chemistry scheme. The model includes 56 prognostic (transported) tracers and 36 diagnostic (non-transported)
145 chemical tracers, with 43 photolysis reactions, 190 gas-phase kinetic reactions, and 15 heterogeneous reactions.
146 The tropospheric chemistry includes reactions for the NO_x-HO_x-O_x-CO-CH₄ system and oxidation schemes for
147 other non-methane volatile organic compounds. The stratospheric chemistry accounts for the major ozone loss
148 cycles (O_x, HO_x, NO_x, ClO_x, and BrO_x) and heterogeneous reactions on liquid and solid stratospheric aerosols as

149 in Austin et al. (2013). The bulk aerosol scheme, including 18 transported aerosol tracers, is similar to that in
150 AM4.0 (Zhao et al., 2018), with the following updates: (1) ammonium and nitrate aerosols are treated explicitly,
151 with ISORROPIA (Fountoukis and Nenes, 2007) used to simulate the sulfate–nitrate–ammonia thermodynamic
152 equilibrium; (2) oxidation of sulfur dioxide and dimethyl sulfide to produce sulfate aerosol is driven by the gas-
153 phase oxidant concentrations (OH, H₂O₂, and O₃) and cloud pH simulated by the online chemistry scheme, and
154 (3) the rate of aging of black and organic carbon aerosols from hydrophobic to hydrophilic forms varies with
155 calculated concentrations of hydroxyl radical (OH).

156 The CESM2-WACCM model includes interactive chemistry and aerosols for the troposphere,
157 stratosphere and lower thermosphere (Emmons et al., 2010); (Gettelman et al., 2019)). It simulates 228
158 compounds, including the MAM4 4-mode Modal Aerosol Model. This version of MAM4 is modified to allow
159 for the simulation of stratospheric aerosols from volcanic eruptions (from their SO₂ emissions) and oxidation of
160 OCS (Mills et al., 2016). The representation of secondary organic aerosols follows
161 the Volatility Basis Set approached (Tilmes et al., 2019).

162 The IPSLCM6A-LR model used for this analysis has prescribed aerosols which were pre-calculated from an
163 atmosphere-only configuration and then prescribed as monthly climatologies. The O₃ is prescribed from the
164 CMIP6 official dataset. The IPSL model results presented here are only for the piClim-aer experiment, and don't
165 include results for this model for the additional AerChemMIP experiments.

166

167 **Table 1 Components used in the Earth system models (detailed Table is in Supplemental material, Table S1)**

	Aerosols	Tropospheric chemistry	Stratospheric chemistry
IPSL-CM6A-LR	Prescribed	No	No
NorESM2-LM	Interactive	SOA and sulfate precursor chemistry	No
UKESM1-LL	Interactive Tropospheric. Prescribed stratospheric	Interactive	Interactive
CNRM-ESM2-1	Interactive	Chemical reactions down to 560 hPa	Interactive
MRI-ESM2	Interactive	Interactive	Interactive
MIROC6	Interactive	SOA and sulfate precursor chemistry	No
BCC-ESM1	Interactive	Interactive	No
GFDL-ESM4	Interactive	Interactive	Interactive
CESM2-WACCM	Interactive	Interactive	Interactive

168 **2.2 Experiments**

169 The AerChemMIP timeslice experiments (Table 2) are used to determine the present day (2014) ERFs for the
 170 changes in emissions or concentrations of reactive gases, and aerosols or their precursors (Collins et al., 2017).
 171 The ERFs are calculated by comparing the change in net TOA radiation fluxes between two runs with the same
 172 prescribed sea surface temperatures (SSTs) and sea ice, but with NTCFs (reactive gas and aerosol emissions, also
 173 referred to as SLCFs – short-lived climate forcers) or WMGHG (methane, nitrous oxide, halocarbon)
 174 concentrations perturbed. The control run uses set 1850 pre-industrial values for the aerosol precursors, CH₄,
 175 N₂O, ozone precursors and CFC/HCFC, either as emissions or concentrations ((Hoesly et al., 2018;van Marle et
 176 al., 2017;Meinshausen et al., 2017). Monthly varying prescribed SSTs and sea-ice are taken from an 1850 coupled
 177 pre-industrial simulation. Each experiment then perturbs the pre-industrial value by changing one (or more) of the
 178 species to the 2014 value, while keeping SSTs and sea-ice prescribed as in the pre-industrial control. The NTCFs
 179 are perturbed individually or in groups. This provides ERFs for the specific emission or concentration change, but
 180 also for all aerosol precursor or NTCFs combined (Collins et al., 2017). For models without interactive
 181 tropospheric chemistry “NTCF” and “aer” experiments are the same; in the case of NorESM2 for the NTCF
 182 experiments the model attempts to mimic the full chemistry by setting the oxidants and ozone to 2014 values. The
 183 WMGHG experiments include the effects on aerosol oxidation, tropospheric and stratospheric ozone, and
 184 stratospheric water vapour depending on the model complexity.
 185 Thirty years of simulation are used to minimise internal variability (mainly from clouds) (Forster et al, 2016.).

187 **Table 2 List of fixed SST ERF simulations. (NTCF in Collins et al 2017 is also referred to as 'SLCF' in other**
 188 **publications) and for the purposes of this study excludes methane.**

189 3. Methods

190 In the following analysis we use several methods to analyse the ERF and the relative contributions from different
 191 aerosols, chemistry and processes to the overall ERF for the models and experiments described above, where the
 192 appropriate model diagnostics were available.

193 3.1.1 Calculation of ERF using fixed SSTs

194 The ERF is calculated from the experiments described above, where the sea surface temperatures and sea-ice are
 195 fixed to climatological values. Here the ERF is defined as the difference in the net TOA flux between the perturbed
 196 experiments and the piClim-control experiment (Sherwood et al., 2015), calculated as the global mean for the 30
 197 years of the experimental run (where the models were run longer than 30 years, the last 30 years was used). This
 198 allows us to calculate the ERF for the individual species based on the changes to the emission or concentrations
 199 between the control and perturbed runs of the models. The assumption is that there is minimal contribution from
 200 the climate feedback when the ocean state is fixed, but the resultant ERF includes rapid adjustments to the forcing
 201 agent in the atmosphere (Forster et al., 2016).

202 3.1.2 Kernel Analysis

203 Where the relevant data are available, we use the radiative kernel method (Smith et al., 2018; Soden et al.,
 204 2008; Chung and Soden, 2015) to break down the ERF into the instantaneous radiative forcing (IRF) and individual
 205 rapid adjustments (designated by A) which are radiative responses to changes in atmospheric state variables that
 206 are not coupled to surface warming. In this approach, ERF is defined as:

$$207 \text{ERF} = \text{IRF} + A_T + A_{ts} + A_q + A_a + A_c + e \quad (1)$$

208 where A_T = atmospheric temp., A_{ts} = surface temp., A_q = water vapour, A_a = albedo, A_c = clouds, e = radiative
 209 kernel error. Individual rapid adjustments (A_x) are computed as:

$$210 A_x = \frac{\delta R}{\delta x} dx \quad (2)$$

211 where $\frac{\delta R}{\delta x}$ is the radiative kernel, a diagnostic tool typically computed with an offline version of a GCM radiative
 212 transfer model that is initialized with climatological base state data and dx is the climate response of atmospheric
 213 state variable x , diagnosed directly from each model. Cloud rapid adjustments (A_c) are estimated by diagnosing
 214 cloud radiative forcing from model flux diagnostics and correcting for cloud masking using the kernel-derived
 215 non-cloud adjustments and IRF, following common practice (e.g. (Soden et al., 2008; Smith et al., 2018)),
 216 whereby:

$$217 A_c = (\text{ERF} - \text{ERF}^{ctr}) - (\text{IRF} - \text{IRF}^{ctr}) - \sum_{x=[T,ts,q,a]} (A_x - A_x^{ctr}) \quad (3)$$

219 Clear-sky IRF (IRF^{ctr}) is estimated as the difference between clear-sky ERF (ERF^{ctr}) and the sum of kernel-
220 derived clear-sky rapid adjustments (A_c^{ctr}). Since estimates of A_c are dependent on IRF, the same differencing
221 method cannot be used to estimate IRF under all-sky conditions without special diagnostics (in particular the isccp
222 diagnostics) not widely available in the AerChemMIP archive. Alternatively, all-sky IRF is computed by scaling
223 IRF^{ctr} by a constant to account for cloud masking (Soden, Held et al. 2008; Kramer et al. 2020).
224 Kernels are available from several sources, and for this analysis we used kernels from CESM, ((Pendergrass et
225 al., 2018), GFDL (Soden et al., 2008), HadGEM3, (Smith and Kramer 2020, submitted), and ECHAM6 ((Block
226 and Mauritsen, 2013) and took the mean from the four kernels for each model. Overall the individual kernels
227 produced very similar results for each model, as reported in (Smith et al., 2018).

228 3.1.3. Calculation of ERF using aerosol-free radiative fluxes

229 To understand the contributions of various processes to the overall ERF we can attempt to separate the ERF that
230 is due to direct radiative forcing from that due to the effects of aerosol-cloud interactions; aerosols act on clouds
231 in a variety of complex ways, by heating the clouds to cause burn-off (semi-direct effect Ackerman et al 2000),
232 and via microphysical effects (e.g. the number of condensation nuclei and the effective radii of the cloud droplets,
233 referred to as the cloud albedo effect and the cloud lifetime effect (Twomey, 1974; Albrecht, 1989; Pincus and
234 Baker, 1994). Following the method of Ghan (2013) the direct forcing due to aerosols alone can be found by
235 calculating the radiative fluxes from the model simulation ignoring the scattering and absorption by the aerosol –
236 referred to in the equations below with the subscript ‘af’. The other effects of the aerosol on the atmosphere (i.e.
237 cloud changes, stability changes, dynamics changes) will still be present, however. The direct radiative effect
238 (ERF_{af}) here is the direct radiative forcing from the aerosol based on the all-sky fluxes with the aerosol,
239 subtracted from the all-sky fluxes without the aerosol. This is a measure of the radiative effects due only to the
240 aerosol. The effects of the aerosol on cloud radiative forcing is then obtained by using the difference between the
241 aerosol-free all-sky fluxes and the aerosol-free clear-sky fluxes, which isolates the cloud effects, where cloud
242 changes due to the presence of the aerosol will be present, but the radiative effects of the aerosol itself are removed
243 (see eqns 4-5). The final term is the ERF as calculated from fluxes with neither clouds nor aerosols (ERF_{cs,af}),
244 attributed to the effect of aerosols on the surface albedo by (Ghan, 2013).

$$245 \text{ERF}_{af} = (\text{ERF} - \text{ERF}_{af}) \quad (4)$$

$$246 \text{ERF}_{af} = \text{ERF}_{af} - \text{ERF}_{cs,af} \quad (5)$$

247 4. Results

248 4.1 Aerosols

249 4.1.1 ERF vs SARF

250 The results in Fig (1) show the ERF, the tropospheric adjustments, and the stratospheric adjusted radiative forcing
251 (SARF). As described in section 3.1.1 the ERFs are diagnosed from the radiative fluxes in the fixed SST
252 experiments, and the tropospheric adjustments A_{trop} from the sum of all adjustments in section 3.2.2 apart from
253 the stratospheric temperature adjustment. The SARF is then determined from $\text{SARF} = \text{ERF} - A_{\text{trop}}$.

254 The SARF and rapid adjustments should total the overall ERF, and comparing the ERF as calculated from the
 255 model output with the sum of the SARF and A_{trop} gives a difference of less than 3%, and in general less than
 256 1%, confirming that the total ERF is accounted for by the combination of SARF and A_{trop} .
 257 For aerosols, (with little stratospheric-temperature adjustment) the SARF is approximately the direct IRF; using
 258 the kernel method described above it is important to note that the IRF calculated here accounts for the presence
 259 of the clouds but does not include cloud changes such as the Twomey effect.

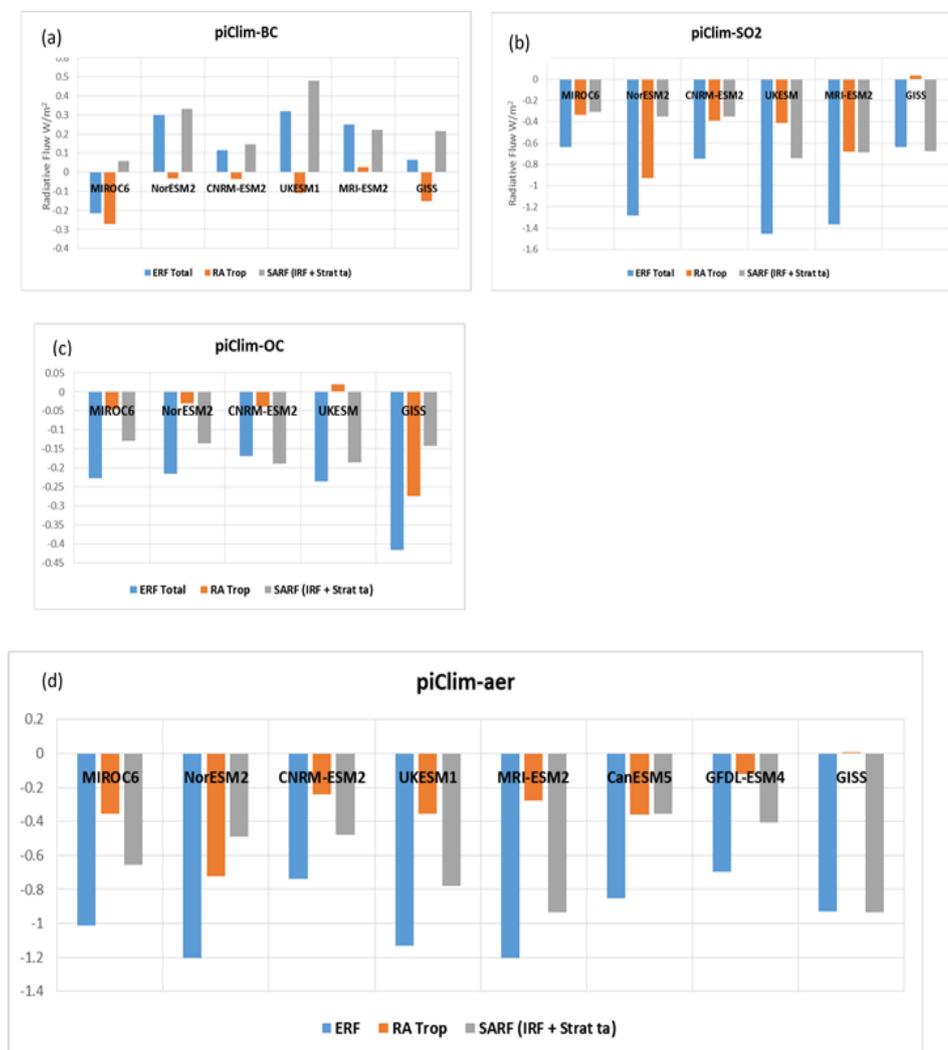

Fig. 1 Breakdown of the ERFs into the tropopause rapid adjustments and IRF (instantaneous radiative forcing) for aerosol species. (a) piClim-BC experiment, (b) piClim-SO2 experiment, (c) piClim-OC experiment, (d) piClim-aer experiment

260 The models show moderate agreement for the SARF for SO2 (range of $-0.31 Wm^{-2}$ - $0.74 Wm^{-2}$) and OC (-0.13
 261 Wm^{-2} - $0.19 Wm^{-2}$), with a much larger range for BC ($0.06 Wm^{-2}$ to $0.48 Wm^{-2}$). In MIROC6 the treatment of BC
 262 (Takemura & Suzuki 2019; Suzuki & Takemura 2019) leads to faster wet removal and hence lower SARF. Overall
 263 there is approximately a factor of 3 in the range of the SARF for total aerosols ($-0.35 Wm^{-2}$ to $-0.97 Wm^{-2}$).

264 There are significant differences between the models in the A_{trop} for SO_2 ; these vary by 0.04 Wm^{-2} to -0.93
265 Wm^{-2} , where the differences are dominated by the cloud adjustments (see Fig S3 for breakdowns of the rapid
266 adjustments for all models) which here include the Twomey effect as part of the adjustment. The adjustments to
267 BC are generally small with most models having a smaller positive adjustment to that reported by (Stjern et al.,
268 2017; Samset et al., 2016; Smith et al., 2018) and others. The MRI-ESM2 model does have a slight positive
269 adjustment, but it is small in magnitude but MIROC6 has a large negative adjustment which is large enough to
270 lead to an overall negative ERF. We explore the adjustments to BC in more detail in the figure (2).
271 Examining the breakdown of the rapid adjustments for the piClim-BC experiments (Fig 2) we see considerable
272 variability in the relative importance of the rapid adjustments; the cloud adjustment dominates in MIROC6,
273 consistent with the increase in low clouds reported for this model in (Takemura & Suzuki 2019; Suzuki &
274 Takemura 2019) causing a negative overall adjustment. The GISS model also has a large cloud rapid adjustment,
275 but the larger positive value of the SARF leads to an overall positive ERF for this model. For UKESM1, CNRM-
276 ESM2-1 and MRI-ESM2 a negative tropospheric temperature adjustment is balanced by the cloud and the water
277 vapour adjustment, although the magnitude of the adjustments for MRI-ESM2 is at least twice that for the other
278 two models.
279 The piClim-aer experiments show a broad consistency between the models, with the A_{trop} varying between 0.07
280 to -0.72 Wm^{-2} , where GISS has a slightly positive A_{trop} value. Overall the cloud rapid adjustments dominate for
281 the piClim-aer experiments, with a contribution ranging from -0.77 Wm^{-2} to -0.22 Wm^{-2} (See fig S1).
282 The breakdown of the rapid adjustments for all the models are included in supplemental fig. S1, showing the
283 contributions from each type of rapid adjustment for all the experiments for which we have the relevant
284 diagnostics.
285

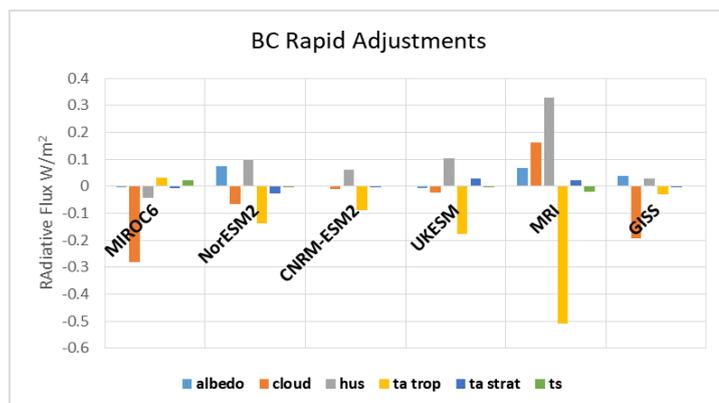

Fig. 2 Breakdown of the individual rapid adjustments for the piClim-BC experiments

286 4.1.2 Radiation and Cloud interactions

287 The second method of breaking down the ERF to constituents is described in Section 3.1.3, (the Gahn method),
288 the results from which are shown in Table 3. Only four of the models under consideration have so far produced
289 the necessary diagnostics for this calculation, and the results are presented in Table 3. For the experiments on

290 aerosols (aer, BC, SO₂, OC) the ERF_{cs,af} (the contribution due to the albedo changes from the aerosol)
 291 contribution is

292

293

294 **Table 3 Results for ERF_{Fari}, ERF_{Faci} and ERF_{cs,af} for aerosol experiments from several models**

	UKESM1			CNRM-ESM2			NorESM2			MRI-ESM2		
	ERF _{Fari}	cs,af	ERF _{Faci}									
aer	-0.16	0.05	-1.02	-0.21	0.08	-0.61	0.03	-0.03	-1.21	-0.32	0.09	-0.98
BC	0.38	0.00	-0.06	0.13	0.01	-0.03	0.35	0.07	-0.12	0.26	0.08	-0.09
OC	-0.15	-0.03	-0.09	-0.07	0.04	-0.14	-0.07	0.02	-0.16	-0.07	-0.05	-0.21
SO ₂	-0.48	0.02	-0.99	-0.29	0.08	-0.53	-0.19	-0.09	-1.01	-0.48	0.05	-0.93

295

296 small, and the ERF is largely a combination of the direct radiative effect, ERF_{Fari}, and the cloud radiative effect,
 297 ERF_{Faci}. The ERF_{Fari} is the direct effect of the aerosol due to scattering and absorption, and may be considered
 298 roughly equivalent to the rapid adjustments due to clouds (see Section 3.2.1).

299 For the BC experiment for CNRM-ESM2, MRI-ESM2 and UKESM1 the contribution of the cloud radiative effect
 300 is small, suggesting that the effects of the BC on the clouds through the semi-direct and indirect effects is minimal.

301 The SO₂ experiment shows a large cloud radiative effect, in fact the ERF_{Faci} is mostly double the ERF_{Fari} in all
 302 the models, due to the large effect on clouds of SO₂ and sulfates through the indirect and semi-direct effect. For
 303 the OC experiments the ERF_{Faci} is at least double the ERF_{Fari} for all models.

304 Comparing the ERF_{Fari} with the SARF calculated via the kernel analysis (Section 3.2.1) where the relevant model
 305 results are available, for the BC experiment we have reasonable agreement for all the models: UKESM1 (ERF_{Fari}
 306 = 0.38 Wm⁻² and SARF = 0.48 Wm⁻²), CNRM-ESM2 (ERF_{Fari} = 0.13 Wm⁻² and SARF = 0.15 Wm⁻²), NorESM2
 307 (ERF_{Fari} = 0.35 Wm⁻² and SARF = 0.33 Wm⁻² and MRI-ESM2 (ERF_{Fari} = 0.26 Wm⁻² and SARF = 0.22 Wm⁻² ,
 308 although the values for NorESM are smaller than for the other 3 models. The results for the SO₂ and OC
 309 experiments are less clear. In the case of SO₂ the SARF is higher than the ERF_{Fari} for NorESM2 (ERF_{Fari} = -0.19
 310 Wm⁻², SARF = -0.35 Wm⁻²), for CNRM-ESM2 the ERF_{Fari} is similar to the SARF value (ERF_{Fari} = -0.29 Wm⁻²
 311 and SARF = -0.35 Wm⁻²), MRI-ESM2 and UKESM1 are similar with both having ERF_{Fari} = -0.48 Wm⁻² with
 312 SARFs of -0.69 Wm⁻² (MRI-ESM2) and -0.74 Wm⁻² (UKESM1). The OC results have the SARF much larger
 313 than the ERF_{Fari} for CNRM-ESM2 (ERF_{Fari} = -0.07 Wm⁻², SARF = -0.19 Wm⁻²), NorESM2 (ERF_{Fari} = -0.07 Wm⁻²
 314 ², SARF = -0.14 Wm⁻²), but UKESM1 has similar values for both (ERF_{Fari} = -0.15 Wm⁻², SARF = -0.13 Wm⁻²).

315 Comparing the ERF_{Faci} values with those for the cloud adjustments (Section 3.2.1) for the BC experiments we
 316 have a similar value for the ERF_{Faci} and the cloud adjustments, although NorESM2 has a higher ERF_{Faci} than both
 317 the other models, which is double the cloud adjustments for this model. For the SO₂ experiments the values of
 318 ERF_{Faci} and the overall cloud adjustments are in broad agreement, although the ERF_{Faci} tends to be larger and for
 319 the OC experiments the cloud adjustments tend to be about half the ERF_{Faci} values.

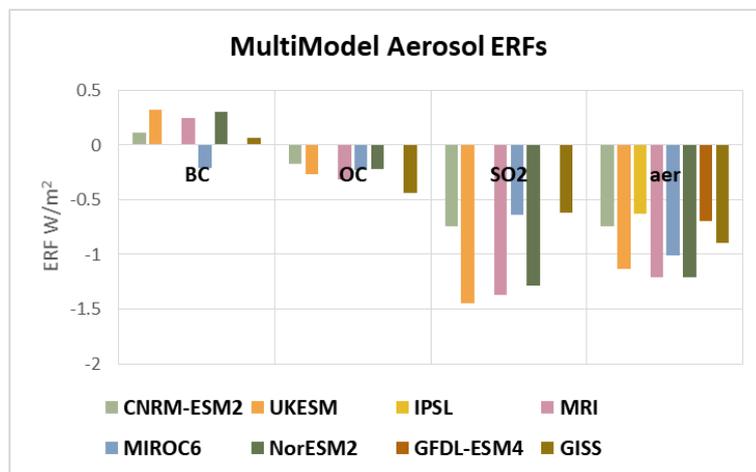

320

321 4.1.3 Intermodel Variability

322 A summary chart of the ERFs is shown in Fig 4 for those models with available results – it should be noted that
323 not all models ran all the experiments. A table of the values for each model are in Table S2 in the supplemental
324 materials.

325

326

327 Fig. 3 Aerosol ERFs for the models with the available diagnostics for the aerosol species experiments.

328

329 For the piClim-BC results, the range of values is from -0.21 Wm^{-2} to 0.32 Wm^{-2} , where the MIROC6 model has
330 a negative ERF for BC, contrasting with the positive values from the other models, as discussed in Section 3.2.1.

331 The experiments for the OC (organic carbon) have a range from -0.17 Wm^{-2} to -0.44 Wm^{-2} , and the variability
332 between the models is much less than for the other experiments. The calculated ERFs for the SO₂ experiment
333 show a variation from -0.637 Wm^{-2} to -1.367 Wm^{-2} , with CNRM-ESM2-1, MIROC6 and GISS at the lower end
334 of the range. These models show a smaller rapid adjustment to clouds, with GISS actually showing a slight
335 positive cloud rapid adjustment (see fig S1); also note that CNRM-ESM2-1 does not include aerosol effects apart
336 from the cloud-albedo effect.

337 The piClim-aer experiment which uses the 2014 values of aerosol precursors and PI (pre-industrial) values for
338 CH₄, N₂O and ozone precursors shows a range from -0.633 Wm^{-2} to -1.2 Wm^{-2} among the models, making it
339 difficult to narrow the range of uncertainty of aerosols from global models. However, the range in the CMIP6
340 models is consistent with that reported in Bellouin et al. (2019), who suggest a probable range of -1.60 to -0.65
341 W m^{-2} for the overall aerosol ERF. The multi-model means are shown in Table 4, with the standard deviation and
342 the number of models used to calculate the means.

343 Table 4 Multimodel means for the ERFs based on the 30 year fixed SST timeslice experiments from the available model
344 output.

	MultiModel Mean ERF (Wm⁻²)	Std Dev	Num Models
BC	0.14	0.18	6
OC	-0.27	0.09	6
SO2	-1.02	0.35	6
aer	-0.94	0.22	8

345

346 **4.1.4 AOD and Burden**

347 In order to break down the contributions of the various aerosol species to the overall ERF, we use the AOD
 348 (aerosol optical depth) for each of the species to scale their contributions to the overall aerosol ERF.

349 By looking at the single species piClim-BC, piClim-OC and piClim-SO2 experiments we can find the ERF due
 350 to the change in emission of these species from the PI control run, and the change in AOD resulting from this
 351 change, to arrive at a scale for the ERF as a function of the AOD change. Table 5 shows the scaling factors for
 352 the piClim-BC, piClim-SO2 and piClim-OC experiments for each of the three models which had the relevant
 353 optical depth diagnostics available.

354 **Table 5 Values of ERF, ΔAOD and ERF/AOD change for aerosol experiments for CNRM-ESM2-, MIROC6, Nor-**
 355 **ESM2, models**

BC Exp	BC ERF	Change in BC AOD	ERF/AOD

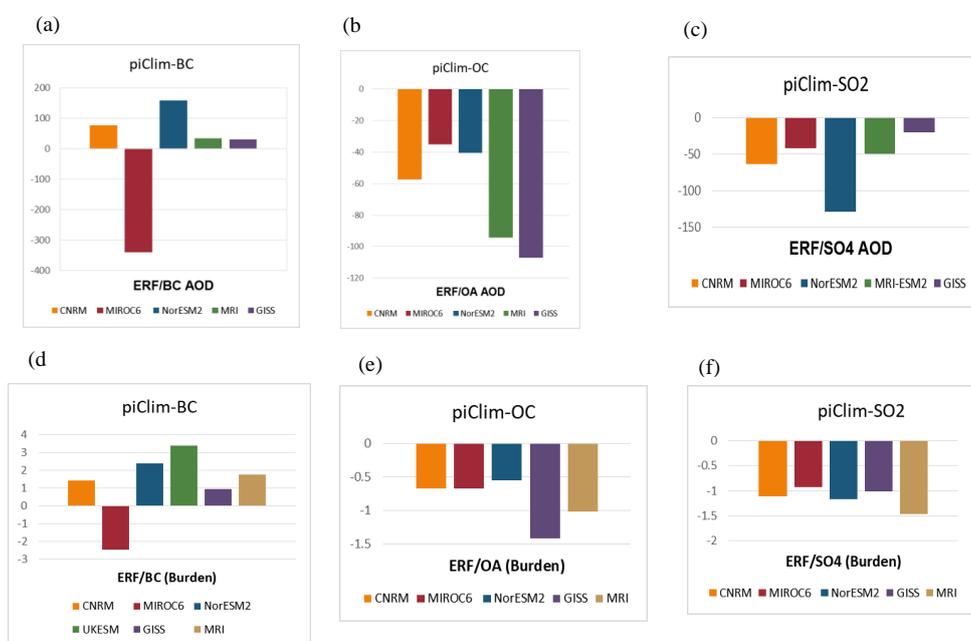

Fig. 4 ERF scaled against AOD and burdens (a) ERF/BC AOD in piClim-BC experiment, (b) ERF/OA AOD in piClim-OC experiment, (c) ERF/SO4 AOD in piClim-SO2 experiment. (d) ERF/burden for BC burden in piClim-BC experiment, (e) ERF/OA burden in piClim-OC experiment, (f) ERF/SO4 burden in piClim-SO2 experiment

356 The MIROC6 model results in a negative scaling for BC due to the negative ERF for this experiment for this
 357 model (Takemura & Suzuki 2019; Suzuki & Takemura 2019) (see Section 3.2.). The change in the BC OD is
 358 similar for CNRM-ESM2 and Nor-ESM2, and the scale factors reflect the differences in the ERF. The scaling for
 359 the SO4 in the NorESM2 experiment is twice that of the other models, suggesting a larger impact of the SO4 AOD
 360 on the ERF in this model. These values differ somewhat from those found in Myhre et al. (2013b) where they
 361 examined the radiative forcing normalised to the AOD using models in the AeroCom Phase II experiments. They
 362 found values for sulfate ranging from -8 Wm^{-2} to -21 Wm^{-2} , much lower than those in our results. However, it is
 363 important to note that in the AeroCom Phase II experiments the cloud and cloud optical properties are identical
 364 between their control and perturbed runs, so no aerosol indirect effects are included. For the BC experiment their
 365 values range from 84 Wm^{-2} to 216 Wm^{-2} , broadly similar to the results presented here (with the exception of the
 366 anomalous MIROC6 result); this may suggest that the cloud indirect effects are less important here. Their results
 367 for OA (organic aerosols) which include fossil fuel and biofuel emissions have values ranging from -10 Wm^{-2} to

368 -26 Wm^{-2} , lower than our values for the piClim-OC experiments which range from -35 Wm^{-2} to -107 Wm^{-2} but
369 include the cloud indirect effects here.

370 Using this scaling factor to convert the change in AOD to a change in ERF we can ascertain the contributions of
371 the individual species to the overall ERF in the piClim-aer experiment, where the various aerosols were combined.
372 The sum of the individual AODs from BC, SO₄, OA, dust and sea salt combine to give the total aerosol AOD in
373 this experiment. In Fig. 6 the relative contributions to the ERF from black carbon (BC), organic aerosols (OA)

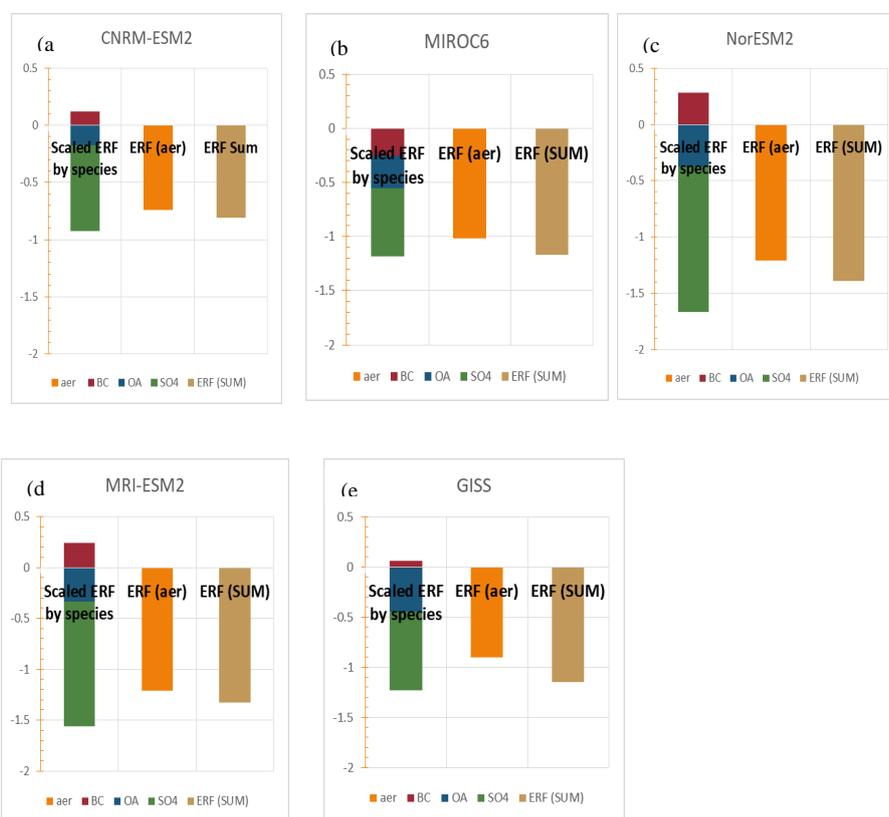

Fig. 5 The contributions to the ERF for piClim-aer from the individual species, compared with the ERF calculated directly from the piClim-aer experiment, and the sum of the scaled ERFs, for five of the models.

374 and sulfate (SO₄) are shown for three of the models. The sum of the ERFs from the individual species is also
375 compared to the ERF calculated from the piClim-aer experiment (NB the sea salt and dust contributions to the
376 ERF are less than 1%, and not shown in this figure for clarity - the ERF/AOD scaling for these is presented in
377 (Thornhill et al., 2020). There is considerable variation in the ERF for the piClim-aer experiments between models
378 (see Section 3.2.1), but from this analysis the SO₄ is the largest contributor in all cases, although in the case of
379 the MIROC6 model its relative importance is reduced. The positive ERF contribution from the BC tends to offset
380 that from the OA and SO₄, except in the MIROC6 model, where the BC has a negative contribution to the ERF.

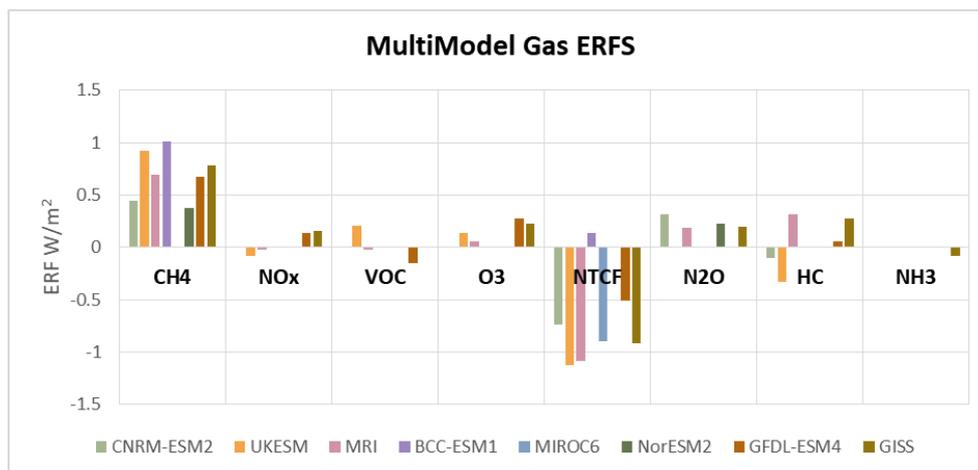

381 The difference between the calculated ERF from the sum of the scaled ERFs suggests that not all effects on the
382 ERF are accounted for here, for example if the impact on clouds is different between the single-species
383 experiments and the combined piClim-aer experiment we may be seeing a discrepancy due to cloud effects. As
384 we assume that the change in ERF in the single species experiment is directly related to the change in AOD of
385 that species in order to calculate the scaling, we investigated whether small changes in other species might also
386 contribute to the ERF. We found that the changes in the other species were negligible in terms of their contribution
387 to the ERF, so that the scaling derived from these experiments is reasonable (see figures in the Supplemental
388 material).

389 Using the burden as a scaling factor following the same analysis as described for the AOD (fig 5) results in a
390 largely similar result for the scaling factor, although interestingly the burden scaling for SO₂ in the Nor-ESM2
391 model is similar to the other models.
392

393 **4.2 Reactive gases**

394 The different Earth system models include different degrees of complexity in their chemistry, so their responses
395 to changes in reactive gas concentrations or emissions differ. NorESM2 has no atmospheric chemistry, so there is
396 no change to ozone (tropospheric or stratosphere) or to aerosol oxidation following changes in methane or N₂O
397 concentrations. CNRM-ESM2 includes stratospheric ozone chemistry and no changes to aerosol oxidation.
398 UKESM1, GFDL-ESM4, CESM2-WACCM, BCC-ESM1, GISS-E2 and MRI-ESM2 all include tropospheric and
399 stratospheric ozone chemistry as well as changes to aerosol oxidation rates. The ERFs calculated for the reactive
400 gases for several models are shown in Fig. 6, with the multimodel means given in Table 6.

401 The contributions from gas-phase and aerosol changes to the ERF can be pulled apart to some extent by using the
402 clear-sky and aerosol-free radiation diagnostics (Table 7). The direct aerosol forcing (ERF_{ari}) is diagnosed as for
403 the aerosol experiments (section 3.1.3). For gas-phase experiments the diagnosed cloud interactions (ERF_{af}-
404 ERF_{csaf}) comprise the ERF_{aci} from effects on aerosol chemistry (as in section 3.1.3) but also any cloud
405 adjustments to the gas-phase species, and effects of cloud masking on the gas-phase forcing. The clear-sky
406 aerosol-free diagnostic (ERF_{csaf}) is an indication of the gas-phase forcing (ignoring cloud masking effects).

N₂O	0.23	0.05	4
HC	0.04	0.24	5

413

4.2.1 ERF vs SARF

414

For methane the ERFs are largest for those models that include tropospheric ozone chemistry reflecting the increased forcing from ozone production. The tropospheric adjustments are negative for all models except UKESM1 (Fig 7). The negative cloud adjustment comes from an increase in the LW emissions, possibly due to less high cloud. In UKESM1 O'Connor et al (Submitted a) show that methane decreases sulfate new particle formation, thus reducing cloud albedo and hence a positive cloud adjustment in that model.

419

For N₂O results are available for models CNRM-ESM2, NorESM2, MRI-ESM2, and GISS-E2. NorESM2 does not include any ozone depletion from N₂O, although the ERF and SARF are higher than for CNRM-ESM2. There appears little net rapid adjustment to N₂O. Note that due to the method of calculating the all-sky IRF (section 3.1.2), the IRF and the adjustment terms do not sum to give the ERF.

422

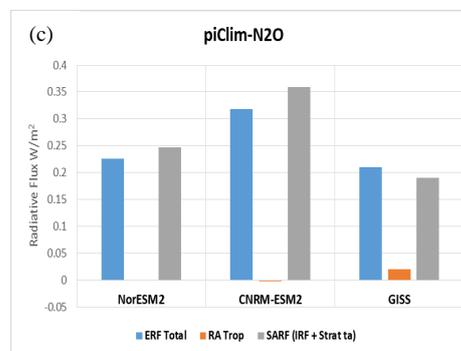

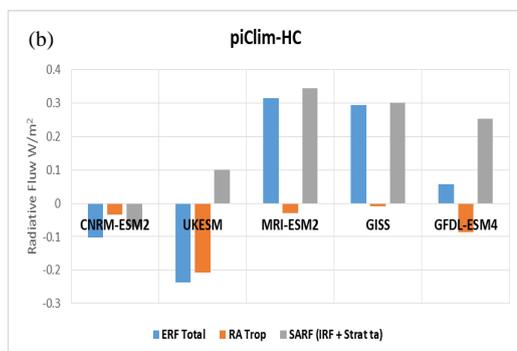

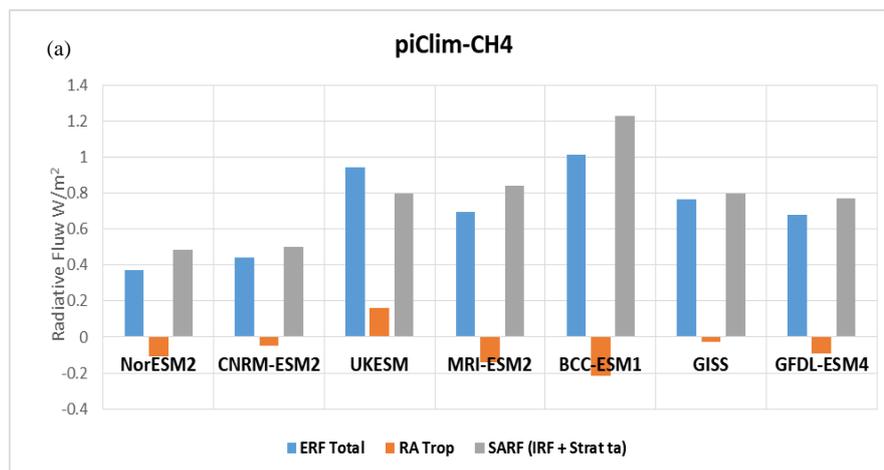

Fig. 7 Breakdown of the ERF into SARF and tropospheric rapid adjustments for the chemically reactive species (a) for piClim-CH4 experiments, (b) for piClim-HC experiments, (c) for piClim-N2O experiments.

423 The models respond very differently to changes in halocarbons. For CNRM-ESM2, UKESM1 and GFDL-ESM4
 424 the ERFs are negative or only slightly positive (see also Morgenstern et al. submitted), whereas for GISS-E2 and
 425 MRI-ESM2 the ERFs and SARF are both strongly positive. The differences in stratospheric ozone destruction in
 426 these models is not sufficient to explain the intermodel differences.

427

428 **Table 7** Calculations of ERFari, ERFaci (cloud) and ERFcs,af for the chemically reactive species

	UKESM			GFDL-ESM4			CNRM-ESM2			NorESM2			MRI-ESM2		
	ERFari	csaf	cloud	ERFari	csaf	cloud	ERFari	csaf	cloud	ERFari	csaf	cloud	ERFari	csaf	cloud

429

430 4.2.2 Ozone changes

431 To understand the contribution of ozone to the diagnosed ERFs, the column changes are diagnosed (figure 8).
432 Increased CH_4 concentrations increases both tropospheric and stratospheric ozone by 2.6 ± 0.3 and 3.3 ± 1.2 Dobson
433 Units respectively. Scaling these by the assumed radiative efficiency give a SARF for ozone produced by methane
434 of $0.25 \pm 0.05 \text{ W m}^{-2}$. Results are similar across all the models that include tropospheric chemistry. VOC emissions
435 increase tropospheric ozone. For GFDL-ESM4 and MRI-ESM2 stratospheric ozone increases too, however it
436 decreases in GISS-E2. The impact of NO_x emissions is predominantly on tropospheric ozone, although MRI-
437 ES2 also has a large stratospheric response to NO_x (and also to O_3 and NTCF). The O_3 experiment comprised
438 both NO_x and VOC emission changes. The tropospheric ozone column in this experiment is slightly larger than
439 the sum of the NO_x and VOC experiments due to non-linearities in the chemistry (Stevenson et al. 2013). The
440 ozone changes when aerosol emissions are included too (NTCF) is slightly smaller than in O_3 , showing that these
441 aerosols act to slightly depress the tropospheric ozone.

442 There is a larger variation across models in the stratospheric ozone depletion from halocarbons -38.8 DU in
443 UKESM1 to -10.6 DU in CESM2-WACCM.

444

445

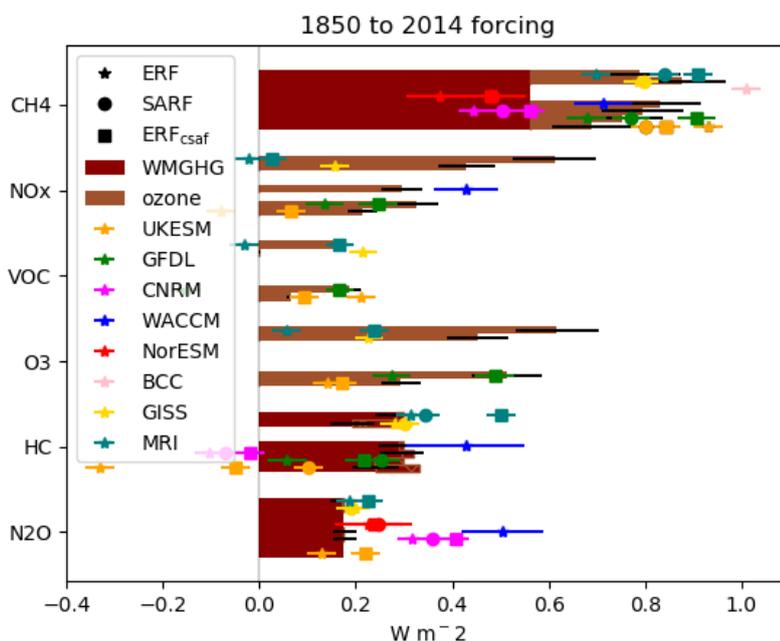

446 Fig. 8 Changes in column in Dobson Units (DU) of tropospheric (dark bars) and stratospheric ozone (light bars) for
447 each experiment. Error bars show error on the mean due to interannual variability in each model.

448 4.2.3 Comparison with greenhouse gas forcings

449 The ERFs diagnosed for the gas-phase changes are compared with the expected radiative forcings in figure 9. The
450 SARF from the well-mixed gases are given by Etminan et al. (2016) for CH_4 and N_2O , and by WMO (2018) for

451 the halocarbons (the halocarbon changes are slightly different in each model). The SARF for tropospheric ozone
452 is estimated to be $0.042 \pm 0.005 \text{ W m}^{-2} \text{ DU}^{-1}$ (Stevenson et al. 2013). The SARF for stratospheric ozone is strongly
453 dependent on its altitude. For the CH_4 , NO_x and VOC experiments we assume that stratospheric ozone changes
454 are close to the tropopause and the tropospheric ozone SARF can be used. For the N_2O and HC experiment we do
455 not have a means to estimate the SARF from ozone changes.
456 For methane the ERFs are all lower than the expected GHG SARF (except for UKESM1) which is likely due to
457 the negative cloud adjustments (although BCC-ESM1 included ozone chemistry the column ozone changes were
458 not provided). The diagnosed ERFcsaf and SARF agree better with the expected SARF though it is notable that
459 in NorESM2 and CNRM-ESM2 these are still lower than expected. For N_2O the modelled radiative forcing (of
460 all kinds) is larger than expected for NorESM2, CNRM-ESM2 and CESM-WACCM. For UKESM1 the modelled
461 N_2O ERF is lower than the expected SARF due to increased aerosol forcing (O'Connor et al. submitted b), whereas
462 the ERFcsaf is slightly higher. For halocarbons the estimate for GFDL agrees quite well with the modelled SARF.
463 The SARF for CNRM-ESM2 and ERFcsaf for UKESM1 is less than expected, partly due to stratospheric ozone
464 depletion which is not accounted for here. The modelled ERF for UKESM1 is strongly negative due to increased
465 aerosols ((O'Connor F. M., 2019) submitted, Morgenstern et al. submitted). The estimated ozone SARF from
466 the NO_x , VOC and O_3 experiments agrees with the ERFcsaf for GFDL, but it strongly overestimates the ERFcsaf
467 for MRI-ESM2. MRI-ESM2 has a very strong stratospheric ozone response to NO_x and it is likely that using the
468 tropospheric ozone radiative efficiency to scale this is inappropriate.

469
470 **Fig. 9** Estimated SARF from the greenhouse gas changes (WMGHGs and ozone) using Etminan et al. 2016 for the
471 WMGHG radiative efficiencies. Hatched bars show decreases in tropospheric ozone (not stratospheric). Symbols show
472 the modelled ERF, SARF and ERFcsaf (estimate of gas-phase clear-sky ERF) – see key. Uncertainties on the bars are
473 due to uncertainties in radiative efficiencies. Uncertainties on the symbols are errors in the mean due to interannual
474 variability in the model diagnostic.

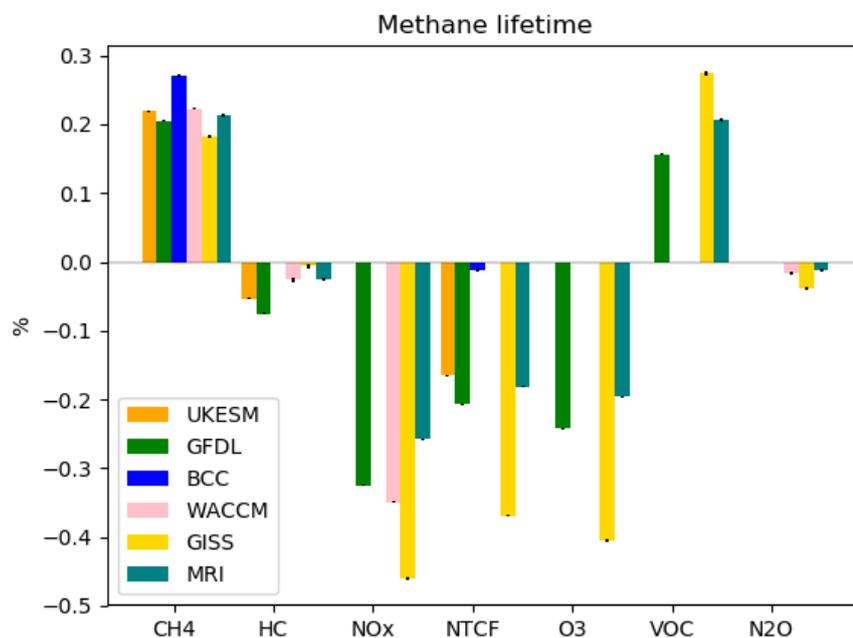

475 4.2.4 Methane Lifetime

476 In the CMIP6 setup the modelled methane concentrations do not respond to changes in oxidation rates. The
477 methane lifetime is diagnosed (which includes stratospheric loss as parameterised within each model) and
478 assuming a loss to soil with a lifetime of 120 years (Myhre et al., 2013b) and this can be used to infer the methane
479 changes that would be expected if methane were allowed to vary. Figure 10 shows the methane lifetime response
480 is large and negative for NO_x emissions, with a smaller positive change for VOC emissions. Halocarbon
481 concentration increases decrease the methane lifetime, as ozone depletions leads to increased UV in the
482 troposphere and increased methane loss to chlorine in the stratosphere (Stevenson et al. submitted). The lifetime
483 response to changing methane concentrations can be used to diagnose the methane lifetime feedback factor f (Fiore
484 et al. 2009). The results here give $f=1.32, 1.30, 1.41, 1.33, 1.25, 1.31$ (mean 1.32 ± 0.05) for UKESM1, GFDL-
485 ESM4, BCC-ESM1, CESM-WACCM. This is in very good agreement with AR5.

486

487

488

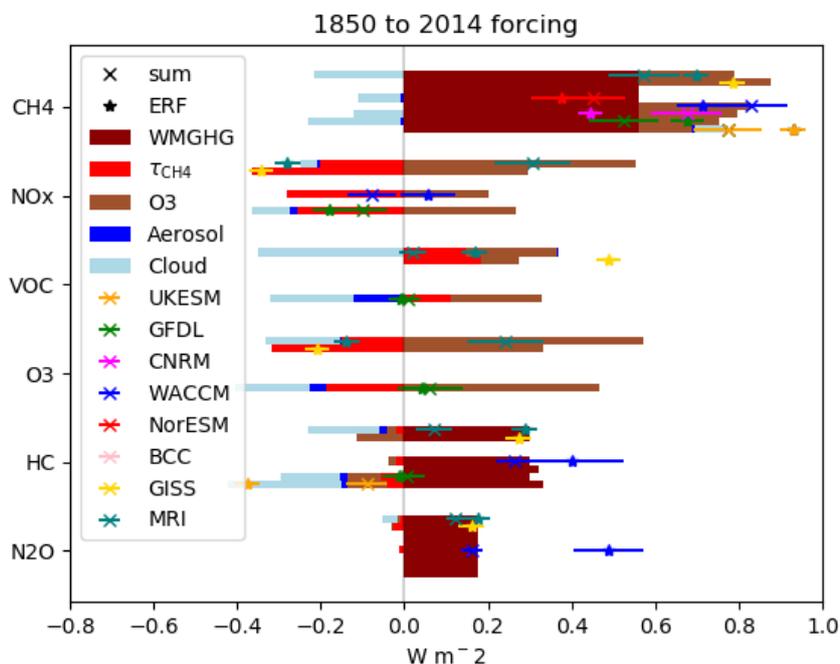

489 **Fig. 10** Changes in methane lifetime (%), for each experiment. Uncertainties are errors on the mean from interannual
490 variability.

491 4.2.5 Total ERFs

492 The methane lifetime changes can be converted to expected changes in concentration if methane were allowed to
493 freely evolve following Fiore et al. (2009), using the f -factors appropriate to each model (section 3.3.4). The
494 inferred radiative forcing is based on radiative efficiency of methane (Etminan et al. 2016). The methane changes

495 also have implications for ozone production, so we assume an ozone SARF per ppb of CH₄ diagnosed for each
496 model from section 3.3.3.
497 The breakdown of the information from the analyses above is shown in Fig. 11, using the SARF calculated for
498 the gases (WMGHGs and ozone), the changes in methane lifetime and the ERFari and cloud contributions for the
499 aerosols for models where this is available. The contributions from methane lifetime changes have also been added
500 to the diagnosed ERF as these aren't accounted for in the models. Differences between the diagnosed ERF (stars)
501 and the sum of the components (crosses) then shows to what extent this decomposition into components can
502 account for the modelled ERF. For many of the species, this breakdown is reasonable, and illustrates that cloud
503 radiative effects make significant contributions to the total radiative impacts of WMGHGs and ozone precursors.
504 This analysis cannot distinguish between cloud effects due to changes in atmospheric temperature profiles or those
505 due to increased cloud nucleation from aerosols. Differences between “sum” and ERF are largest for N₂O and
506 halocarbons. For the halocarbons the “sum” is typically larger than the ERFs, since the radiative impact of
507 stratospheric ozone depletion is ignored in the “sum”. For N₂O the “sum” is typically smaller than the RFs, so this
508 difference would become even larger when including any ozone depletion.

509
510 **Fig. 11 SARF for WMGHGs, ozone and diagnosed changes in methane. Model diagnosed direct aerosol RF and cloud**
511 **radiative effect. Crosses mark the sum of the five terms for each model. Stars mark the diagnosed ERF with the effect**
512 **of methane lifetime (on methane and ozone) added. Differences between stars and crosses shows undiagnosed**
513 **contributions. Uncertainties on the sum are mainly due to the uncertainties in the radiative efficiencies. Uncertainties**
514 **in the ERF are errors on the mean due to interannual variability. Note for WACCM, BCC, GISS the breakdown into**
515 **aerosol and cloud effects is unavailable.**

516 5. Discussion

517 For all of the species shown we see considerable variation in the calculated ERFs across the models, which is due
518 in part to differences in the model aerosol and chemistry schemes; not all models have interactive schemes for all
519 of the species, and whether or not chemistry is considered will impact the evolution of some of the aerosol species.
520 We can use the differences in model complexity from the multimodel approach together with the separation of
521 the effects of the various species in the individual AerChemMIP experiments to understand how the various
522 components contribute to the overall ERFs we have calculated.

523

524 5.1 Aerosols

525 The 1850-2014 mean ERFs for SO₂, OC and BC are: -0.94 +/- 0.15 Wm⁻² for SO₂, -0.27 +/- 0.04 Wm⁻² for OC,
526 and 0.14 +/- 0.08 Wm⁻² for BC. The total ERF for the aerosols is -0.94 +/- 0.08 Wm⁻², within the range of -1.65
527 to 0.6 Wm⁻² reported by (Bellouin et al., 2019).

528 The radiative kernels and double call diagnostics are used to separate the direct and cloud effects of aerosols for
529 those models where all the relevant diagnostics are available. These two methods broadly agree on the cloud
530 contribution for the BC, SO₂ and OC experiments, although we find a smaller cloud adjustment to black carbon
531 compared to other studies (Samset and Myhre, 2015; Stjern et al., 2017; Smith et al., 2018).

532 As the CLISCCP cloud diagnostics become available for more of the CMIP6 models, it will be possible to do a
533 direct calculation of the cloud rapid adjustments using the kernels from (Zelinka et al., 2014) and compare those
534 with the adjustments calculated using the kernel difference method described in (Smith et al., 2018) and used here
535 (Section 3.1.2).

536 The values diagnosed for the ERF_{ari} (for the models we have available diagnostics for) in CMIP6 are similar to
537 those from CMIP5 (Myhre et al., 2013a) where they reported values for sulfate of -0.4 (-0.6 to -0.2) Wm⁻²
538 compared to our -0.36 (-0.19 to -0.48) Wm⁻² for the SO₂ experiment, for OC they found -0.09 (-0.16 to -0.03)
539 Wm⁻² compared to our value of -0.09 (-0.07 to -0.15) Wm⁻² and for BC they had +0.4 (+0.05 to +0.80) compared
540 to our value of 0.28 (0.13- 0.38) Wm⁻², so broadly the ERF_{ari} for the individual species agree with those found in
541 the previous set of models used in CMIP5. The overall aerosol ERF_{ari} from AR5 is reported as in the range -1.5
542 to 0.4 Wm⁻², compared to values reported here in the range -0.16 to 0.03 Wm⁻².

543 The radiative efficiencies per AOD calculated here are generally larger than those from the AeroCom Phase II
544 experiments (Myhre et al., 2013b), with the caveat that the models included here did not have fixed clouds, so
545 that indirect effects would be included; the BC efficiencies are however closer to those in AeroCom Phase II,
546 perhaps indicative of a lesser effect of the cloud effects in the case of BC. The radiative efficiencies per AOD
547 calculated here are generally larger than those from the AeroCom Phase II experiments (Myhre et al., 2013b),
548 with the caveat that the models included here did not have fixed clouds, so that indirect effects would be included;
549 the BC efficiencies are however closer to those in AeroCom Phase II, perhaps indicative of a lesser effect of the
550 cloud effects in the case of BC.

551 5.2 Reactive gases

552 The diagnosed ERFs from methane, N₂O, halocarbons and ozone precursors are: 0.80±0.13, 0.26±0.15, 0.15±0.27
553 and 0.17±0.08 W m⁻² (excluding CNRM-ESM2 and NorESM2 as these do not have tropospheric ozone chemistry)
554 . These compare with 0.79±0.13, 0.17±0.03, 0.18±0.15 and 0.22±0.14 W m⁻² from AR5 (Myhre et al., 2013a) -
555 where the effects on methane lifetime and CO₂ have been removed from the AR5 calculations, and the halocarbons
556 are for CFCs and HCFCs only. Section 3.3.5 show that cloud effects can make a significant contribution to the
557 overall ERF even for WMGHGs. However, clouds cannot explain all the differences. The ERF for N₂O is larger
558 than estimated in AR5. The multi-model ERF for halocarbons is similar to AR5, although the models have a wide
559 spread with some showing significantly lower ERFs and some significantly higher. The difference in halocarbon
560 ERF could be due to strong ozone depletion in these models.

561 The estimated ozone SARFs from the changes in levels of methane, NO_x and VOC from 1850 to 2014 are
562 0.24±0.05, 0.32±0.05, and 0.17±0.06 W m⁻² compared to 0.24±0.13, 0.14±0.09, and 0.11±0.05 W m⁻² in CMIP5
563 (Myhre et al., 2013a). The NO_x contribution stands out as being larger in this study. The CMIP5 results did not
564 account for the radiative impact of ozone changes above the tropopause, but this is not enough to account for the
565 difference in the NO_x-induced ozone compared to AR5.

566 The overall effect of NTCF emissions (excluding methane and other WMGHGs) on the 1850-2014 ERF
567 experienced by models that include tropospheric chemistry is strongly negative (-0.70±0.47 W m⁻²) due to the
568 dominance of the aerosol forcing over that from ozone. There is a large spread in the NTCF forcing due to the
569 different treatment of atmospheric chemistry within these models. Models without tropospheric and/or
570 stratospheric chemistry prescribe varying ozone levels which are not included in the NTCF experiment. Hence
571 the overall forcing experienced by these models due to ozone and aerosols will be different from that diagnosed
572 here.

573 6. Conclusion

574 The experimental setup and diagnostics in CMIP6 have allowed us for the first time to calculate the effective
575 radiative forcing (ERF) for present day reactive gas and aerosol concentrations and emissions in a range of Earth
576 system models. Quantifying the forcing in these models is an essential step to understanding their climate
577 responses.

578 This diagnoses also allows us to quantify the radiative responses to perturbations in individual species or groups
579 of species. These responses include physical adjustments to the imposed forcing as well as chemical adjustments
580 and adjustments related to the emissions of natural aerosols. The total adjustment is therefore a complex
581 combination of individual process, but the diagnosed ERF implicitly includes these and represents the overall
582 forcing experienced by the models.

583 We find that the ERF from well-mixed greenhouse gases (methane, nitrous oxide and halocarbons) is significantly
584 different to the SARF estimated from standard formulae. This indicates that Earth system processes need to be
585 taken into account when understanding the contribution WMGHGs have made to present climate and when
586 projecting the climate effects of different WMGHG scenarios.

587 5. Acknowledgements

588 GT, WC, MM, FO'C, DO, MS, CS acknowledge funding received from the European Union's Horizon 2020
589 research and innovation programme under grant agreement No 641816 (CRESCENDO).

590 FMO'C, JPM were funded by the Met Office Hadley Centre Climate Programme funded by BEIS and Defra
591 (GA01101). GZ was supported by the NZ government's Strategic Science Investment Fund (SSIF) through the
592 NIWA programme CACV.

593 We acknowledge the World Climate Research Programme, which, through its Working Group on Coupled
594 Modelling, coordinated and promoted CMIP6. We thank the climate modeling groups for producing and making
595 available their model output, the Earth System Grid Federation (ESGF) for archiving the data and providing
596 access, and the multiple funding agencies who support CMIP6 and ESGF.

597

598 6. Author Contributions

599 Manuscript preparation was done by GDT, WJC, RJK, DO and additional contributions from all co-authors.
600 Model simulations were set up, reviewed and/or ran by DO, FMO'C, NLA, MD, LE, LH, J-FL, MMichou,
601 MMills, JM, PN, VN, NO, MS, TT, ST, TW, GZ, JZ. Analysis was carried out by GT, WC, RK, DO.

602

603 7. Data Availability

604 All data from the various earth system models used in this paper are available on the Earth System Grid Federation
605 Website, and can be downloaded from there. <https://esgf-index1.ceda.ac.uk/search/cmip6-ceda/>
