

46 property of matter, k is independent of size. When the iron oxide content exceeds >3%, the SSA linearly
47 decreases with increasing fraction of coarse particles at short wavelengths (< 600 nm).

48 We recommend that source-dependent values of the SW spectral refractive index and SSA are used
49 in models and remote sensing retrievals instead of generic values. In particular, the close relationships
50 found between k /SSA and the iron content in dust enable establishing predictive rules for spectrally-
51 resolved SW absorption based on particle composition.

52

53 Introduction

54 With teragrams of annual emissions, a residence time of about 1–2 weeks in the atmosphere, and a
55 planetary-scale transport, mineral dust aerosols are a global phenomenon (Uno et al., 2009; Ginoux et
56 al., 2012), and contribute significantly to the global and regional aerosol loading (Ridley et al., 2016)
57 and direct radiative effect (Miller et al., 2014).

58 However, large uncertainties still persist on the magnitude and overall sign of the dust direct radiative
59 effect (Boucher et al., 2013; Highwood and Ryder, 2014; Kok et al., 2017). One of the major sources of
60 this uncertainty is our insufficient knowledge of the dust's absorption properties in the shortwave (SW)
61 and longwave (LW) spectral ranges (e.g., Balkanski et al., 2007; Samset et al., 2018), given that mineral
62 dust contains large particles and a variety of minerals absorbing over both spectral regions (e.g. iron
63 oxides, clays, quartz and calcium-rich species, Sokolik and Toon, 1999; Lafon et al., 2006; Di Biagio
64 et al., 2014a, b). Global and regional scale mapping of dust absorption remains limited and more infor-
65 mation is required (Samset et al., 2018).

66 Aerosol absorption is represented both by the imaginary part (k) of the complex refractive index ($m=n-ik$)
67 of its constituent material, and by the single scattering albedo (SSA, i.e., the ratio of the scattering
68 to extinction coefficient) of the particle population, as well as by the mass absorption efficiency (MAE,
69 units of $\text{m}^2 \text{g}^{-1}$), i.e., the absorption coefficient per unit of aerosol mass concentration.

70 In the shortwave spectral range, absorption by dust accounts for up to ~10–20% of its total extinction.
71 Dust absorption is highest in the UV–VIS, and almost nil towards the near IR (Cattrall et al., 2003;
72 Redmond et al., 2010), due to the combined contribution of large particles in the size distribution and
73 the dust's mineralogy, notably the presence of iron oxides (Karickhoff and Bailey, 1973; Lafon et al.,
74 2006; Derimian et al., 2008; Moosmüller et al., 2012; Formenti et al., 2014a; 2014b; Engelbrecht et al.,
75 2016; Caponi et al., 2017). The mineralogy of mineral dust varies according to that of the parent soils
76 (Nickovic et al., 2012; Journet et al., 2014). Consequently, dust aerosols of different origins should be
77 more or less absorbing in the SW, and have different imaginary spectral refractive index and SSA. Field
78 and laboratory measurements, including ground-based and spaceborne remote sensing, show that k
79 varies at a regional scale by almost two orders of magnitude (0.0001–0.008 at 550 nm) with corre-
80 sponding SSAs between 0.80 and 0.99 at 550 nm (Volz 1972; Patterson et al., 1977; Shettle and Fenn,
81 1979; Dubovik et al., 2002; Haywood et al., 2003; Sinyuk et al., 2003; Linke et al., 2006; Osborne et al.,
82 2008; Müller et al., 2009; Otto et al., 2009; Petzold et al., 2009; Schladitz et al., 2009; McConnell et al.,
83 2010; Formenti et al., 2011; Wagner et al., 2012; Ryder et al., 2013a; Engelbrecht et al., 2016; Rocha-

84 Lima et al., 2018). Albeit some variability being instrumental or analytical (differences in the sampled
85 size fraction or in the method used to retrieve optical parameters), differences persist when the same
86 measurement approach and retrieval method are applied, e.g., in AERONET inversions, supporting the
87 dependence of dust k and SSA with location (Dubovik et al., 2002; Koven and Fung, 2006; Su and
88 Toon, 2011). In contrast, the real part (n) of the dust refractive index, mostly related to particle scatter-
89 ing, is estimated to be less variable than the imaginary part, with values between 1.47–1.56 at 550 nm
90 (i.e., Volz, 1972; Patterson et al., 1977; Balkanski et al., 2007; Petzold et al., 2009).

91 Differences in k or SSA caused by the spatial variability of the iron content may affect the sign of the
92 dust radiative effect (heating vs cooling) (Liao and Seinfeld, 1998; Claquin et al. 1999; Miller et al.,
93 2014), and its global and regional implications (Myhre and Stordal, 2001; Colarco et al., 2014; Das et
94 al., 2015; Jin et al., 2016; Bangalath and Stenchikov, 2016; Strong et al., 2018). For instance, various
95 studies suggest that the direct radiative effect of dust has a strong impact on the Western African Mon-
96 soon (Yoshioka et al., 2007; Konaré et al., 2008) and the Indian Summer Monsoon (Vinoj et al., 2014;
97 Das et al., 2015; Jin et al., 2016). However, there is no consensus whether dust increases or decreases
98 precipitation over these regions (Solmon et al., 2008; Jin et al., 2016; Strong et al., 2018). As an exam-
99 ple, Solmon et al. (2008) indicate that dust reduces precipitation over most of the Sahelian region, but
100 increases it over the Northern Sahel–Southern Sahara. This pattern is, however, very sensitive to the
101 dust absorbing properties, and a decrease of few percent in dust absorption may even cancel out the
102 increase of precipitation over the Sahel. Similarly, Jin et al. (2016) show that by varying k from zero to
103 0.008 at 600 nm (i.e., the highest value currently used in models) the dust effect on the Indian Summer
104 Monsoon may shift from negative (reduction of precipitation) to positive (increase of precipitation) val-
105 ues.

106 In spite of this sensitivity, present climate models adopt a globally–constant spectral complex refractive
107 index (and SSA) for dust, and hence still implicitly assume the same dust mineralogical composition at
108 the global scale. Reference values for the refractive index are usually taken from Volz (1972), Patterson
109 et al. (1977), D’Almeida et al. (1991), Shettle and Fenn (1979), Sokolik et al. (1993), Sinyuk et al. (2003),
110 or OPAC (Hess et al., 1998; Koepke et al., 2015). A parameterization of the spectrally–resolved dust
111 refractive index as a function of the mineralogical composition of the particles is desirable to replace
112 the globally constant values in current climate models, in particular for those models that started to
113 incorporate the representation of dust mineralogy into their schemes (Scanza et al., 2015; Perlwitz et
114 al., 2015a, 2015b).

115 Improving our knowledge of the spectral SW refractive index of mineral dust and its relation to particle
116 composition and origin is also key for the detection of dust aerosols in the atmosphere and the quanti-
117 fication of its mass loading, and total and absorption spectral optical depth from active and passive
118 remote sensing (e.g., Ridley et al., 2016). As an example, the retrieval of the dust SSA and optical depth
119 over bright desert surfaces with the MODIS (Moderate Imaging Resolution Spectroradiometer) Deep
120 Blue algorithm (Hsu et al., 2004) applies the Critical Surface Reflectance Method (Kaufman, 1987) to
121 retrieve dust properties from measured Top of Atmosphere (TOA) spectral reflectance. This algorithm
122 depends critically on a priori information on the spectral refractive index (Kaufman et al., 2001; Yoshida

123 et al., 2013). Similarly, active remote sensing techniques (lidar, light detection and ranging) require the
124 knowledge of the extinction-to-backscatter ratio (the lidar ratio), which is also a strong function of the
125 complex index of refraction or SSA of the aerosol particles (e.g., Gasteiger et al., 2011; Shin et al.,
126 2018). Gasteiger et al. (2011) have shown in fact that a 5% change in the SSA at 532 nm can modify
127 by up to 20% the lidar ratio of dust, which means a 20% change in the estimated profile of the dust
128 extinction coefficient and retrieved optical depth from lidar measurements.

129 In this paper we address these issues by reporting the results of a new laboratory investigation of the
130 shortwave refractive index and SSA of dust from various source regions worldwide, in the framework
131 of the RED–DUST project (Di Biagio et al., 2017a; hereafter DB17; Caponi et al., 2017; hereafter C17).
132 Dust optical properties at discrete wavelengths between 370 and 950 nm are derived in conjunction
133 with the particle elemental and mineralogical composition, including total elemental iron and iron oxides.
134 We investigate the relationship of k and SSA to the iron content to provide a parameterization of the
135 dust absorption as a function of its mineralogy, which can be applied to climate models. The depend-
136 ence of dust absorption on the particle coarse size fraction is also investigated to evaluate the change
137 of dust absorption with atmospheric transport time.

138 2. Experimental set-up and instrumentation

139 All experiments discussed here and previously described in DB17 and C17 were conducted in the
140 4.2 m³ stainless-steel CESAM chamber (French acronym for Experimental Multiphase Atmospheric
141 Simulation Chamber) (Wang et al., 2011). Mineral dust aerosols were generated by mechanical shaking
142 of parent soils using about 15 g of soil sample (first sieved to <1000 μm and then dried at 100 °C)
143 placed in a 1 L Büchner flask and shaken for about 30 min at 100 Hz by means of a sieve shaker
144 (Retsch AS200). The dust suspension in the flask was injected into the chamber by flushing with N₂ at
145 10 L min⁻¹ for about 10–15 min. After injection in the chamber, the largest fraction of the dust aerosol
146 (>1.5 μm diameter) remained in suspension for approximately 60 to 120 min thanks to a four-blade
147 stainless steel fan located at the bottom of the chamber, which also ensured homogeneous conditions
148 within the chamber volume. The submicron dust fraction, instead, remained constant with time during
149 experiments, as shown in Fig. 3 reporting the timeline of the measured effective dust fine diameter. The
150 evolution of the physico-chemical and optical properties of the suspended dust was measured by dif-
151 ferent instruments connected to the chamber. The spectral particle volume dry scattering (β_{sca}) and
152 absorption (β_{abs}) coefficients were measured, respectively, by a 3-wavelength nephelometer (TSI Inc.
153 model 3563, operating at 450, 550, and 700 nm; 2 L min⁻¹ flow rate, 2-s time resolution) and a 7-
154 wavelength aethalometer (Magee Sci. model AE31, operating at 370, 470, 520, 590, 660, 880 and 950
155 nm; 2 L min⁻¹ flow rate, 2-min time resolution). The size distribution of aerosols was measured by
156 means of a scanning mobility particle sizer (SMPS, TSI, DMA Model 3080, CPC Model 3772; mobility
157 diameter range 0.019–0.882 μm ; 2.0/0.2 L min⁻¹ sheath-aerosol flow rates, 135-s time resolution), a
158 WELAS optical particle counter (OPC) (PALAS, model 2000, white light source between 0.35 and 0.70
159 μm ; optical-equivalent diameter range 0.58–40.7 μm ; 2 L min⁻¹ flow rate, 1-min time resolution) and a
160 SkyGrimm OPC (Grimm Inc., model 1.129, 0.655 μm operating wavelength; optical-equivalent diameter
161 range 0.25–32 μm ; 1.2 L min⁻¹ flow rate, 6-s time resolution). Aerosol elemental and mineralogical

162 composition, including iron oxides, was derived by analysis of dust samples collected on polycarbonate
163 filters (47-mm diameter Nuclepore, Whatman, nominal pore size 0.4 μm) mounted on a custom-made
164 stainless-steel sample holder (operated at 6 L min^{-1}) for most of the duration of each experiment.

165 All instruments (size, SW optics, filters) sampled air from the chamber. To equalize the airflow extracted
166 by the different instruments, a particle-free N_2/O_2 mixture airflow was continuously injected into the
167 chamber. Inlets for all extractive measurements consisted of a stainless steel tube located inside
168 CESAM, and an external connection of silicone tubing (TSI Inc.) from the chamber to the instruments,
169 for a total length varying between 0.4 and 1.2 m. As detailed in DB17 and shown in Fig. S1 in the
170 supplement, the transmission efficiency due to aspiration and transmission in the sampling lines as a
171 function of particle diameter was estimated to calculate the effective dust fraction sensed by each in-
172 strument, taking into account the sampling flow rate, tubing diameter, tubing geometry, and particle
173 shape and density. For the nephelometer and the aethalometer, the length of the sampling line from
174 the intake point in the chamber to the instrument entrance was about 1.2 m, which resulted in a 50%
175 cutoff of the transmission efficiency at 3.9 μm particle geometric diameter and 100% cutoff at 10 μm .
176 For the filter sampling system, the length of the sampling line of about 0.5 m resulted in a 50% (100%)
177 cutoff at 6.5 μm (15 μm) particle diameter. For the WELAS, the only OPC considered for size distribution
178 in the coarse fraction (see Sect. 2.2), the 50% (100%) cutoff was reached for particles of 5 μm (8 μm)
179 diameter.

180 All experiments were conducted at ambient temperature and relative humidity <2%. In addition to over-
181 night evacuation, the chamber was manually cleaned between experiments to avoid contaminations
182 from remaining dust. Background concentrations of aerosols in the chamber were less than 2.0 $\mu\text{g m}^{-3}$
183 (that is 10^2 to 10^5 times less than the concentration of dust aerosols in suspension in the chamber
184 during experiments)

185 A flowchart of the procedure used to treat and combine optical, size, and compositional data, and the
186 algorithm for SSA and complex refractive index retrieval is shown in Fig. 1. Full details of data treatment
187 for size distribution measurements and filter compositional data are provided in DB17 and C17, and in
188 the following we only mention the main points of interest for the present paper. Full details on the data
189 treatment of the SW optical data are provided in Sect. 2.1 and 3.

190 The optical and size datasets were acquired at different temporal resolutions and then averaged over
191 compatible 10-min intervals, whereas the compositional data represent the experiment integral. The
192 SSA and complex refractive index data were retrieved both at 10-min resolution and as experiment
193 averages to relate them to both size and compositional data. Table 1 summarizes the uncertainties on
194 the measured and derived parameters described in the following.

195 **2.1 SW optical measurements**

196 **2.1.1 Aerosol scattering coefficient**

197 The aerosol scattering coefficients (β_{sca}) at 450, 550, and 700 nm are measured by the nephelometer
198 at angles between 7° and 170° and need to be corrected for the restricted field-of-view of the instru-
199 ment (truncation correction) to retrieve β_{sca} at 0°–180°. The truncation correction factor (C_{trunc}), i.e., the

200 ratio of the β_{sca} at 0° – 180° and 7° – 170° , was estimated by Mie calculations for homogeneous spherical
201 particles using the size distribution measured simultaneously behind SW inlets (see Sect. 2.2). In the
202 calculations, the real part of the complex refractive index of dust was assumed to be wavelength-inde-
203 pendent and fixed at a value of 1.53, while the imaginary part was set to 0.003 at 450 and 550 nm and
204 to 0.001 at 700 nm, according to pre-existing information (Sinyuk et al., 2003; Schladitz et al., 2009;
205 Formenti et al., 2011; Rocha-Lima et al., 2018). For the different dust samples, C_{trunc} ranged between
206 1.2 and 1.7 and decreased with wavelength and the dust residence time in the chamber, following the
207 relative importance of the coarse component in the dust population (Anderson and Ogreen, 1998). The
208 uncertainty on C_{trunc} , calculated by repeating the optical calculations by using the size distribution of
209 dust within its error bars as input to the optical code, is less than $\pm 5\%$ at all wavelengths (in the approx-
210 imation of Mie spherical and homogeneous particles). In order to assess the consistency of the derived
211 truncation correction, we made a sensitivity study in which we recalculated C_{trunc} by varying the refrac-
212 tive index at input to Mie calculations in the range of n and k values obtained in this study (i.e., values
213 at the 10% and 90% percentile as reported in Table 5 for the whole dataset, that is n between 1.49 and
214 1.54 and k between 0.001 and 0.006 at 450, 550, and 700 nm). The results of this sensitivity study
215 indicate that, for fixed dust size distribution, the truncation correction C_{trunc} varies less than 1% for n
216 between 1.49 and 1.54, and $<5\%$ for k between 0.001 and 0.006, and so that it is quite insensitive to
217 the exact assumed n and k values.

218 Once corrected for truncation, the spectral β_{sca} was extrapolated at the aethalometer wavelengths. With
219 this aim, the Scattering Ångström Exponents, $\text{SAE}_{450-550}$ and $\text{SAE}_{550-700}$, were calculated as the linear
220 fit of β_{sca} vs λ at 450–550 nm and 550–700 nm, respectively. The $\text{SAE}_{450-550}$ and $\text{SAE}_{550-700}$ coefficients
221 were used to extrapolate β_{sca} at wavelengths respectively lower and higher than 550 nm. Extrapolated
222 β_{sca} values were used to derive an average SAE of dust for the entire investigated spectral range.

223 2.1.2 Aerosol absorption coefficient

224 The aerosol absorption coefficient (β_{abs}) at 370, 470, 520, 590, 660, 880, and 950 nm was retrieved
225 from aethalometer measurements. The aethalometer measures the attenuation (ATT) through an aer-
226 osol-laden quartz filter, related to the spectral attenuation coefficient (β_{ATT}) as:

$$227 \quad \beta_{\text{ATT}}(\lambda) = \frac{\Delta \text{ATT}(\lambda)}{\Delta t} \frac{A}{V} \quad (1)$$

228 where A is the area of the aerosol collection spot (0.5 ± 0.1) cm^2 and V the air sample flow rate (0.002
229 $\text{m}^3 \text{min}^{-1}$). The slope $\frac{\Delta \text{ATT}(\lambda)}{\Delta t}$ is the linear fit of the measured attenuation as a function of time calcu-
230 lated over 10-min intervals. The spectral attenuation coefficient was converted into an absorption co-
231 efficient β_{abs} following the formula by Collaud Coen et al. (2010):

$$232 \quad \beta_{\text{abs}}(\lambda) = \frac{\beta_{\text{ATT}}(\lambda) - \alpha(\lambda)\beta_{\text{sca}}(\lambda)}{C_{\text{ref}}R(\lambda)} \quad (2)$$

233 The $\alpha(\lambda)\beta_{\text{sca}}(\lambda)$ term accounts for the fraction of the measured attenuation due to side and backward
234 scattering and not to light absorption. The Collaud–Coen correction scheme has been recently shown
235 to yield quite accurate values of the absorption coefficients and absorption Ångström exponents from
236 aethalometer data (Saturno et al., 2017). The value of $\alpha(\lambda)$ was calculated with the formula by Arnott et
237 al. (2005) and varied between 0.002 and 0.02 ($<\pm 1\%$ from formal error propagation on the Arnott for-
238 mula), while $\beta_{\text{sca}}(\lambda)$ is the scattering coefficient from the nephelometer extrapolated to the aethalometer
239 wavelengths. C_{ref} accounts for multiple scattering by the filter fibers, aerosol laden or not. Its spectral
240 value, obtained by the linear extrapolation of C_{ref} at 450 and 660 nm estimated for mineral dust by Di
241 Biagio et al. (2017b), varied between 4.30 at 370 nm to 3.32 at 950 nm. We assume for the extrapolated
242 C_{ref} an uncertainty of $\pm 10\%$ as estimated in Di Biagio et al. (2017b). The correction factor, R, accounts
243 for the decrease in the aethalometer sensitivity with the increase of the aerosol filter loading. The value
244 of R depends on the absorptivity properties of the sampled aerosol and can be calculated as a function
245 of the particle SSA. In this study, we calculated R by estimating a first-guess SSA* as the ratio of the
246 nephelometer-corrected β_{sca} and β_{ext} obtained as the sum of β_{sca} and the β_{abs} non-corrected for filter
247 loading effect. The R was estimated by using the Collaud–Coen et al. (2010) formulation. For the range
248 of estimated SSA* (about 0.60 to 0.99), R varied between 0.5 and 1.0 ($\pm 1-10\%$).

249 The Absorption Ångström Exponent (AAE) was calculated as the power-law fit of β_{abs} versus λ .

250 Due to an instrumental problem, aethalometer data were not always available, with a typical 30-min
251 interruption usually 10 to 30 minutes after the beginning of experiments.

252 2.2 Size distribution

253 The aerosol number size distribution was obtained from SMPS, WELAS and SkyGrimm measurements
254 over different diameter ranges. The measured electrical mobility and optical equivalent diameters from
255 the SMPS and the OPCs were first converted into geometrical diameters (D_g) as described in DB17
256 and summarized in Table 1. The OPCs conversion assumes for dust a complex refractive index that in
257 our study was set in the range 1.47–1.53 for n and 0.001–0.005 for k for both the SkyGrimm and the
258 WELAS (following DB17). After conversion, the estimated D_g range was 0.01–0.50 μm for the SMPS,
259 0.65–73.0 μm for the WELAS, and 0.29–68.2 μm for the SkyGrimm. Due to a calibration issue, data for
260 the SkyGrimm in the range $D_g > 1\mu\text{m}$ were discarded, so that the WELAS is the only instrument consid-
261 ered in the super-micron range. A very low counting efficiency was observed for the WELAS below 1
262 μm and data in this size range were also discarded.

263 The SMPS, WELAS, and SkyGrimm data were combined, as detailed in DB17, to obtain the full size
264 distribution of the dust aerosols suspended in the CESAM chamber, $(dN/d\log D_g)_{\text{CESAM}}$, and the size
265 distribution behind SW optical instruments inlets, $(dN/d\log D_g)_{\text{SWoptics}}$, after taking into account particle
266 losses along sampling lines (see Supplementary material and Fig. S1). As previously discussed, due
267 to the particle losses in the sampling line from the chamber to the nephelometer/aethalometer, the
268 $(dN/d\log D_g)_{\text{SWoptics}}$ size distribution is cut at 10 μm , so no particles above this diameter reach the SW
269 instruments.

270 The measured size distributions, $(dN/d\log D_g)_{\text{CESAM}}$ and $(dN/d\log D_g)_{\text{SWoptics}}$, were used to estimate the
271 mass concentration of aerosols and their effective diameter (D_{eff}) in the CESAM chamber and behind
272 the SW instrument inlets as:

$$273 \quad \text{Mass concentration} = \int \frac{\pi}{6} D_g^3 \frac{dN}{d\log D_g} \rho \cdot d\log D_g \quad (3)$$

$$274 \quad D_{\text{eff}} = \frac{\int D_g^3 \frac{dN}{d\log D_g} d\log D_g}{\int D_g^2 \frac{dN}{d\log D_g} d\log D_g} \quad (4)$$

275 The effective dust density ρ in Eq. (3) was set at 2.5 g cm^{-3} , a value that is approximately in the middle
276 of the range of desert dust densities reported in the literature, i.e., $2.1\text{--}2.75 \text{ g cm}^{-3}$ (Maring et al., 2000;
277 Iwasaka et al., 2003; Reid et al., 2003). The effective diameter was evaluated separately for the fine
278 and coarse fractions of dust by integrating Eq. (4) for diameters $\leq 1 \mu\text{m}$ ($D_{\text{eff, fine}}$) and $> 1 \mu\text{m}$ ($D_{\text{eff, coarse}}$),
279 respectively.

280 The dust size distribution, $(dN/d\log D)_{\text{SWoptics}}$, measured at each 10-min time step for each sample was
281 fitted with a sum of five lognormal functions. For each mode, the parameters of the lognormal functions,
282 i.e., the total number concentration (N_i), the geometric median diameter ($D_{g,i}$), and the geometric stand-
283 ard deviation of the distribution (σ_i), were retrieved. The uncertainties in the retrieved parameters were
284 estimated by repeating the fit using size data within their uncertainties. The resulting parameters of the
285 fits at the peak of the injection in the chamber are reported in Table S1, and an example of size fitting
286 is shown in Fig. S2.

287 The procedure described here to estimate $(dN/d\log D_g)_{\text{CESAM}}$ and $(dN/d\log D_g)_{\text{SWoptics}}$ implies that as-
288 sumptions are made on the values of n and k to correct OPCs data, and this may introduce a circularity
289 in the estimates of the refractive index of dust that use $(dN/d\log D_g)_{\text{SWoptics}}$ as input in optical calculations
290 (see Sect. 3.2). In order to analyze the dependence of the results on this assumption, we made a
291 sensitivity calculation by varying the values of n and k used for OPCs corrections within the range of
292 values retrieved in this study (10% and 90% percentiles in Table 5, i.e., 1.49–1.54 for n and 0.001–
293 0.006 for k). We concluded that changing n and k in this range has a very low impact on the retrieved
294 number size distribution behind the SW inlets $(dN/d\log D_g)_{\text{SWoptics}}$ compared to the original assumptions
295 made in our calculations (<5% changes in the retrieved size number distribution at the different diame-
296 ters between the original correction and the correction by varying n and k). This is due to the fact that
297 when changing D_g due to changes in the n and k in the OPCs correction, the loss function also modifies
298 to values corresponding to the new D_g . Given that the loss function increases/decreases for increas-
299 ing/decreasing D_g , the combined changes in D_g and the loss function compensate so that the net num-
300 ber concentration behind the SW inlets varies less than a few percent. These results therefore suggest
301 that the procedure to estimate the complex refractive index of dust is nearly independent of the assumed
302 OPC correction.

303 2.3 Dust elemental and mineralogical composition and iron content

304 The elemental and mineralogical composition of the dust aerosols was estimated by combining different
305 techniques: X-ray diffraction (XRD, Panalytical model Empyrean diffractometer) to estimate the parti-
306 cles' mineralogical composition in terms of clays, quartz, calcite, dolomite, gypsum, and feldspars;
307 wavelength dispersive X-ray fluorescence (WD-XRF, Panalytical PW-2404 spectrometer) to deter-
308 mine the dust elemental composition (Na, Mg, Al, Si, P, K, Ca, Ti, Fe); and X-ray absorption near-edge
309 structure (XANES) to retrieve the content of iron oxides and their speciation between hematite and
310 goethite. The dust mass collected on Nuclepore filters during the experiments varied between 0.3 and
311 6 mg m^{-3} as calculated from elemental concentrations according to Lide (1992).

312 Full details on the XRD, WD-XRF, and XANES measurements and data analysis are provided in DB17
313 and C17. In this study, we discuss the dust elemental iron mass concentration, $\text{MC}_{\text{Fe}\%}$, i.e., the percent
314 mass of elemental iron with respect to the total dust mass concentration, and the iron oxides mass
315 concentration, $\text{MC}_{\text{Fe-ox}\%}$, i.e., the percent mass fraction of iron oxides with respect to the total dust mass
316 concentration, estimated as the sum of goethite ($\text{MC}_{\text{Goet}\%}$) and hematite ($\text{MC}_{\text{Hem}\%}$) species.

317 3. Strategy for data analysis

318 3.1 Calculation of the spectral extinction coefficient and SSA from scattering and absorption 319 coefficients

320 The spectral scattering and absorption coefficients, $\beta_{\text{sca}}(\lambda)$ and $\beta_{\text{abs}}(\lambda)$, measured by the nephelometer
321 and the aethalometer were used to estimate 10-min averages of the spectral extinction coefficient, β_{ext}
322 (λ), at the 7- λ of the aethalometer between 370 and 950 nm as:

$$323 \quad \beta_{\text{ext}}(\lambda) = \beta_{\text{abs}}(\lambda) + \beta_{\text{sca}}(\lambda) \quad (5).$$

324 The Extinction Ångström Exponent (EAE) was calculated as the power-law fit of β_{ext} versus λ .

325 The spectral single scattering albedo of dust at 10-min resolution ($\text{SSA}_{10\text{-min}}$) was retrieved as:

$$326 \quad \text{SSA}_{10\text{-min}}(\lambda) = \frac{\beta_{\text{sca}}(\lambda)}{\beta_{\text{ext}}(\lambda)} \quad (6).$$

327 The experiment-averaged SSA (λ) was calculated for each soil type based on the following formula
328 (Moosmüller et al., 2012):

$$329 \quad \text{SSA}(\lambda) = \left(1 + \frac{1}{m(\lambda)} \right)^{-1} \quad (7)$$

330 where $m(\lambda)$ represents the slope of the linear fit between the 10-min averages of $\beta_{\text{sca}}(\lambda)$ and $\beta_{\text{abs}}(\lambda)$
331 measured along the whole duration of each experiment. An example of $\beta_{\text{sca}}(\lambda)$ versus $\beta_{\text{abs}}(\lambda)$ fitting to
332 retrieve the spectral SSA is shown in Fig. S3 in the Supplement. The correlation coefficient R^2 of the
333 β_{sca} versus β_{abs} fit usually ranges between 0.97 and 1 at all wavelengths. As will be discussed later in
334 the paper, the single scattering albedo of dust depends on the particle coarse size fraction, and during
335 our experiments $\text{SSA}_{10\text{-min}}$ was not derived continuously for the different samples due to the aethalom-
336 eter measurement interruptions. The application of Eq. (7) avoids any bias in the calculated averaged
337 SSA for different soils due to size effects. For two of the analyzed samples (Tunisia and Namib-2),

338 however, the linear fitting procedure was not applicable due to the fact that, respectively, only two and
339 one absorption measurements from the aethalometer were available just after the peak of the injection,
340 with no data afterwards. Average SSA data for Tunisia were thus estimated as the mean of the two
341 available SSA_{10-min} data points, while the single SSA_{10-min} measurement at the peak of the injection was
342 reported for Namib-2. This difference in time sampling should be kept in mind when comparing SSA
343 data for these two samples to the rest of the dataset.

344 3.2 Retrieval of the spectral complex refractive index

345 An optical calculation was performed to estimate the complex refractive index ($m=n-ik$) of dust aerosols
346 based on optical and size data. The retrieval algorithm consisted in recalculating the spectral scattering
347 $\beta_{sca}(\lambda)$ and absorption $\beta_{abs}(\lambda)$ coefficients measured at each 10-min interval by using the fitted
348 $(dN/d\log D)_{SWoptics}$ size distribution as input and by varying the real and imaginary parts of the complex
349 refractive index in the calculations until the best agreement between measurements and calculations
350 was found. At each wavelength the root mean square deviation (RMSD) was calculated as:

$$351 \quad RMSD(\lambda) = \sqrt{\left[\frac{\beta_{sca,measured}(\lambda) - \beta_{sca,calculated}(\lambda)(n,k)}{\beta_{sca,calculated}(\lambda)(n,k)} \right]^2 + \left[\frac{\beta_{abs,measured}(\lambda) - \beta_{abs,calculated}(\lambda)(n,k)}{\beta_{abs,calculated}(\lambda)(n,k)} \right]^2}$$

352 (8)

353 The RMSD was minimized at each wavelength to obtain $n-k$ pairs that most closely reproduce the
354 measured scattering and absorption coefficients. Optical calculations were performed at the 7 wave-
355 lengths of the aethalometer between 370 and 950 nm using Mie theory for homogeneous spherical
356 particles. In the calculations, the real part of the refractive index was varied in the range 1.40–1.60 at
357 steps of 0.01, while the imaginary part was varied in the range 0.0001–0.050 at steps of 0.0001. For
358 each sample, this resulted in 10500 computations per wavelength and per 10-min time step. The un-
359 certainty on the real and imaginary parts of the refractive index was estimated with a sensitivity study.
360 For this purpose, the values of n and k were also obtained by using as input the observed $\beta_{sca}(\lambda)$, β_{abs}
361 (λ) , and $(dN/d\log D)_{SWoptics}$, plus or minus one standard deviation on their measurement. The deviations
362 of the values of n and k retrieved in the sensitivity study with respect to those obtained in the first
363 inversions were assumed to correspond to the one standard deviation uncertainty of 10-min retrieved
364 values.

365 Experiment-averaged values of the spectral n and k were estimated as the average of single n and k
366 values retrieved at 10-min steps (indicated as n_{10-min} and k_{10-min}). In fact, differently from the SSA, the
367 refractive index did not seem to depend on the particle coarse size fraction (Sect. 4.5).

368 A control experiment was performed with submicron ammonium sulphate aerosols (see DB17 and sup-
369plementary Fig. S4) with the aim of validating the proposed methodology to estimate the aerosol com-
370plex refractive index for a non-absorbing aerosol type. For ammonium sulphate particles with a mono-
371modal size distribution centered at 0.06 μm , as measured with the SMPS, the retrieved real part of the
372refractive index was 1.56 (± 0.01) in the 450–700 nm wavelength range, as expected from literature
373(Toon et al., 1976; Flores et al., 2009; Denjean et al., 2014).

374 3.3 Assumptions on the retrieval of SSA and complex refractive index

375 The approach used to retrieve the SSA and the complex refractive index of dust and the accuracy of
376 the results depend on the accuracy of the input data and the assumptions in the optical calculations.
377 We discuss here two points of the applied procedure, in part already mentioned in the previous para-
378 graphs.

379 1/ The size distribution from OPCs and also the scattering coefficient from the nephelometer used as
380 input to the n and k retrieval procedure and SSA calculation depend more or less directly on the dust
381 refractive index. These instruments need in fact to be corrected for instrumental artefacts and these
382 corrections require an a priori knowledge of the n and k , which in our approach were set to fixed values
383 (1.47–1.53 for n and 0.001–0.005 for k for OPCs optical to geometrical diameter conversion, and 1.53
384 for n and 0.001–0.003 for k for nephelometer truncation correction). This choice may in principle intro-
385 duce a certain degree of uncertainty and circularity into the derived n , k , and SSA for dust. Nonetheless,
386 we note that the range of refractive index values used to correct OPCs and nephelometer data falls in
387 the range of variability of the refractive index values obtained in this study (see Sect. 4.3), which sug-
388 gests that the values used for the corrections are appropriate. Additionally, as previously discussed,
389 both the size distribution ($dN/d\log D_g$)_{SWoptics} and the scattering coefficient are not very sensitive to the
390 assumptions about n and k used for the calculations (less than 5% changes in both the number size
391 distribution behind SW inlets and the scattering coefficient from changing n and k within the range of
392 estimated values in this study) which further demonstrates the robustness of the proposed approach.

393 2/ The retrieval procedure for n and k , as well as the calculations for OPCs optical-to-geometrical
394 diameter and the nephelometer truncation correction, simplifies the non-spherical heterogeneous dust
395 aerosols (e.g., Chou et al. 2008; Okada et al., 2011; Nousiainen and Kandler, 2015) into homogeneous
396 spherical particles that can be represented by Mie theory. In the present study, we decided not to use
397 a more advanced shape-representing theory, given that the shape distribution and morphology of the
398 dust samples was not measured during experiments. Improper assumptions on the particle shape and
399 morphology may in fact induce even larger errors than using Mie theory, in particular for super-micron
400 aerosols (Kalashnikova and Sokolik, 2004; Nousiainen and Kandler, 2015). It should be pointed out,
401 however, that dust is usually assumed to be spherical in global climate models (e.g., Myhre and Stordal,
402 2001; Balkanski et al., 2007; Jin et al., 2016), and different studies still show contrasting results on the
403 true impact of dust non-sphericity on radiative fluxes and heating rates from global model simulations
404 (Mishchenko et al., 1995; Yi et al., 2011; Räisänen et al., 2012; Colarco et al., 2014). On the other hand,
405 shape effects can be important for the retrieval of aerosol properties from remote sensing techniques
406 using spectral, angular, and polarized reflectance measurements (e.g., Feng et al., 2009).

407 4. Results

408 Nineteen soil samples from different desert areas in Northern Africa, Sahel, Eastern Africa and the
409 Middle East, Central Asia, Eastern Asia, North America, South America, Southern Africa, and Australia
410 were selected for experiments from a collection of 137 soil samples from source areas worldwide. The
411 main information on the provenance of these soils is provided in Table 2. The nineteen selected soils,
412 the same as analyzed in DB17, represent the major dust source regions depicted in Ginoux et al. (2012).

413 Amongst the database of 137 samples from all the world regions that constitute significant dust emitters,
414 this range in mineralogical composition represents the largest variability in iron oxides contents that can
415 be found worldwide. This is illustrated in Fig. 2 where we represent the variability of hematite and goe-
416 thite content in the nineteen selected soils and compare it with the range of variability of the global
417 desert soils from the database of Journet et al. (2014).

418 4.1 Physical and chemical properties of analysed dust samples

419 4.1.1 Dust mass concentration and size distribution

420 Figure 3 shows a typical example of a time series of aerosol mass concentration and effective fine and
421 coarse diameters measured inside the CESAM chamber and behind the SW instruments inlets during
422 the experiments, as well as the corresponding β_{sca} and β_{abs} at 370 nm. The Figure shows the rapid
423 increase of the mass concentration within CESAM during dust injection in the chamber, and its subse-
424 quent decrease during experiments due to both size-selective gravitational settling, occurring mostly
425 within the first 30 min of experiments, and dilution by sampling. The scattering and absorption coeffi-
426 cients of dust decrease with time after injection in tandem with the decrease of the mass concentration
427 and the size-dependent depletion in the chamber. The dust mass concentration inside CESAM at the
428 peak of the injection is between 2 mg m^{-3} (Mali) and 310 mg m^{-3} (Bodélé) and falls to values between
429 0.9 mg m^{-3} (Mali) and 20 mg m^{-3} (Bodélé) behind SW instruments inlets. These values are comparable
430 to those measured close to sources during dust storms (Rajot et al., 2008; Kander et al., 2009). After a
431 2-hour experiment, the dust mass concentration has decreased to values of 0.2 to 2.5 mg m^{-3} (inside
432 CESAM) and of 0.1 to 1.9 mg m^{-3} (behind the SW inlets), within a range of values comparable to what
433 has been measured after medium- to long-range dust transport in the real atmosphere (Weinzerl et
434 al., 2011; Denjean et al., 2016b). These data therefore indicate that in a 2-hour experiment in CESAM
435 it is possible to reproduce the temporal changes of the mass load observed in the real atmosphere for
436 dust from its emission to a receptor site.

437 Concurrently with the mass concentration, the effective diameter, $D_{\text{eff,coarse}}$, of the coarse fraction of the
438 dust aerosol also rapidly decreases with time due the progressive deposition of the coarsest particles
439 in the chamber. For the different analyzed soils, $D_{\text{eff,coarse}}$ varies in the range of $4\text{--}8 \mu\text{m}$ (peak of injection)
440 to $3\text{--}4 \mu\text{m}$ (after 2 hours) inside the CESAM chamber, and in the range of $3\text{--}4 \mu\text{m}$ (peak of injection) to
441 $2\text{--}3 \mu\text{m}$ (after 2 hours) behind the SW inlets. In contrast, $D_{\text{eff,fine}}$ remains quite constant during the ex-
442 periments, with a value between 0.6 and $0.7 \mu\text{m}$ for all soils. The values of $D_{\text{eff,coarse}}$ obtained in this
443 study inside the CESAM chamber are in line with those measured close to African sources ($4\text{--}12 \mu\text{m}$,
444 Rajot et al., 2008; Weinzerl et al., 2009; Ryder et al., 2013a) and for dust transported across the Medi-
445 terranean ($5\text{--}8 \mu\text{m}$, Denjean et al., 2016a). Conversely, the values of $D_{\text{eff,coarse}}$ behind the SW instru-
446 ments inlets are mostly in agreement with those reported for dust transported across the Atlantic ocean
447 ($\sim 3 \mu\text{m}$, Maring et al., 2003; Müller et al., 2011; Denjean et al., 2016b). Our values of $D_{\text{eff,fine}}$ are higher
448 compared to values reported by Denjean et al. (2016a) for dust aerosols transported over the Mediter-
449 ranean (0.2 to $0.5 \mu\text{m}$), reflecting the fact that we analyse pure dust whereas these authors often en-
450 countered dust externally mixed with pollution particles.

451 The comparison of $D_{\text{eff,coarse}}$ values suggests that while the size of dust in CESAM is mostly representa-
452 tive of dust close to sources, as already pointed out in DB17, the size measured behind the SW instru-
453 ments inlets is mostly representative of transport conditions. Figure 4 illustrates this point by showing
454 the volume size distributions of the generated dust aerosols at the peak of injection seen by the SW
455 optical instruments, compared to the average size of dust measured in CESAM (DB17) and field obser-
456 vations close to sources (e.g., Niger) and after long-range transport (Cape Verde, Suriname, and
457 Puerto Rico). The size distribution of dust inside CESAM includes a coarse mode up to tenths of micro-
458 metres and well reproduces field observations close to sources, as shown in comparison to the Niger
459 case. Due to particle losses along tubes, the coarsest particles above $10\ \mu\text{m}$ diameter are not seen by
460 the SW instruments. The overall shape of the dust size distribution sensed by the SW instruments is
461 comparable to that measured during atmospheric long-range transport, even if the fraction of particles
462 above $10\ \mu\text{m}$ diameter is significantly under-represented compared to observations. (i.e., Betzer et al.,
463 1988; Formenti et al., 2001; Maring et al., 2003; Ryder et al., 2013b; Jeong et al., 2014; Denjean et al.,
464 2016b).

465 4.1.2 Iron and iron oxide dust content

466 The mass concentrations of iron oxides, hematite, goethite, and total elemental iron for the different
467 analysed samples are reported in Table 3. There is a considerable variability in the iron and iron oxide
468 content for our samples. Total iron in the dust samples is in the range from 2.4% (Namib-1) to 10.6%
469 (Australia). Iron oxides account for 11% and 62% of the iron mass, whereas the percent of iron oxides
470 to the total dust mass varies between 0.7% (Bodélé Depression) and 5.8% (Niger). These data are in
471 the range of values reported in the literature (Reid et al., 2003; Scheuven et al., 2013; Formenti et al.,
472 2011, 2014a). For the samples from the Sahara and the Sahel, goethite is the dominant iron oxide
473 species, in agreement with Lafon et al. (2006) and Formenti et al. (2014a; 2014b). In contrast, over
474 other regions, hematite dominates over goethite, as already reported by some studies (Arimoto et al.,
475 2002; Shen et al., 2006; Lu et al., 2011).

476 4.2 Spectral- and time-dependent dust extinction and absorption coefficients, complex refrac- 477 tive index, and SSA

478 Figure 5 illustrates a typical spectral- and time-dependent set of measured optical properties. The
479 spectral extinction coefficient, absorption coefficient, SSA, and real and imaginary parts of the complex
480 refractive index obtained at 10-min resolution for the Morocco and Algeria samples are shown at the
481 peak of the dust injection in CESAM and 30 and 90 min after the peak. Figure 5 shows that absorption
482 decreases with wavelength, but not extinction. The SSA increases from 370 to 590 nm while it shows
483 almost constant values between 590 and 950 nm. The imaginary refractive index decreases with λ
484 following the decrease of β_{abs} . The real part of the refractive index is almost constant with wavelength.

485 The extinction and absorption coefficients decrease in absolute value with time, as already shown in
486 Fig. 3, but their spectral dependence remains quite constant with time, even if it varies from soil to soil.
487 The experiment-averaged Absorption, Scattering, and Extinction Ångström Exponents, representing
488 the spectral variation of the absorption, scattering and extinction coefficients, vary between the values
489 of 1.5 and 2.4 (AAE), -0.4 and 0.4 (SAE), and -0.2 and $+0.5$ (EAE) for the different samples. These

490 values are in line with those previously reported by Moosmüller et al. (2012) and C17 for dust from
491 various locations. The retrieved n and k also show negligible changes of their spectral shape with time
492 and their magnitude remains approximately constant. In contrast, the SSA increases with time, in par-
493 ticular below 600 nm wavelength, and so its spectral shape changes. This is mostly due to the decrease
494 of the coarse size fraction with residence time in the chamber, as will be analysed in Sect. 4.5. Similarly
495 to the absorption, scattering, and extinction coefficients, the spectral shape of k and SSA is somewhat
496 different between the various samples, with the sharpest spectral variations observed for the most ab-
497 sorbing samples and a less pronounced spectral variation for the less absorbing ones, as evident, for
498 example, by comparing the SSA data for Morocco and Algeria in Fig. 5.

499 **4.3 Spectral complex refractive index and SSA for the different source regions and comparison** 500 **to literature data**

501 Figure 6 shows the experiment-averaged n , k , and SSA between 370 and 950 nm for the nineteen
502 aerosol samples analyzed in this study. Data of n , k , and SSA and their uncertainties for each sample
503 are reported in Tables 4 and 5 together with the average values for each of the eight different source
504 regions and for the full dataset. Figure 6 shows that there are significant differences, both in magnitude
505 and spectral shape, between the imaginary refractive index and SSA for the different samples. The
506 highest values of k (and lowest values of SSA) are obtained for the Niger, Mali, Namib-2 and Australia
507 samples, which also show the highest values of both the iron oxide content between 3.6% and 5.8%
508 and hematite content between 2.0% and 4.8% (k is in the range 0.0048–0.0088 at 370 nm and 0.0012–
509 0.0021 at 950 nm, and SSA is in the range 0.70–0.75 at 370 nm and 0.95–0.97 at 950 nm). The lowest
510 values are obtained for the Bodélé, Namib-1, and Arizona samples, which have iron oxide contents
511 between 0.7% and 1.5% (k is 0.001 at 370 and 0.0003 at 950 nm, and SSA is in the range 0.91–0.96
512 at 370 nm and 0.97–0.99 at 950 nm). Both k and SSA vary from region to region, with the largest
513 absorptions (highest k , lowest SSA) for the Sahel and Australia and the lowest absorption (lowest k ,
514 highest SSA) in North and South America and the Middle East; k and SSA values also vary within the
515 same region, as illustrated in Fig. 6 for the Sahelian and Southern African samples. The real part of the
516 refractive index, on the other hand, is not only almost wavelength-independent, as anticipated, but also
517 relatively invariant from sample to sample. Its average over the 370–950 nm spectral range is between
518 1.48 (Gobi) and 1.55 (Ethiopia and Namib-2).

519 The full envelope of n , k , and SSA obtained for the entire set of analysed samples is shown in Fig. 7a
520 and 7b (left panels). The real refractive index is relatively invariant, the spectral k varies by up to an
521 order of magnitude (0.001–0.009 at 370 nm and 0.0003–0.002 at 950 nm). The SSA changes accord-
522 ingly for the different dust samples at the different wavelengths (30% change at 370 nm corresponding
523 to values between 0.70–0.96 and 4% change at 950 nm for values within 0.95–0.99). The population
524 mean is 1.52 for n (as spectral average) and varies in the range 0.0033–0.0009 for k and 0.85–0.98 for
525 the SSA between 370 and 950 nm (0.0016 and 0.94 as spectral averages for k and SSA) (Fig. 7 and
526 Tables 4 and 5).

527 The comparison between the full envelope of n , k , and SSA in this study with literature data is shown
528 in Fig. 7a and 7b (right panels). Literature values considered for comparison include estimates from

529 ground-based, aircraft, and satellite observations, laboratory studies, AERONET inversions, and esti-
530 mates from mixing rules based on the dust mineralogical composition. Given that the sample selection
531 in our experiments fully envelopes the global variability of mineralogy of natural dust, we could expect
532 that our dataset would also fully envelope the global-scale variability of the dust absorption and scat-
533 tering properties in the SW. When comparing with available literature data we found that our n and SSA
534 datasets very well envelope the range of values indicated in the literature, with only a few outlier points.
535 In contrast, for the imaginary refractive index the reported range of variability from the literature is sig-
536 nificantly larger than that found in our study, with our range of k being mostly at the lower bound of
537 previous results. Nonetheless, our range of k values fully envelopes the ensemble of remote sensing
538 and field campaign data on airborne dust from the previous literature reported in Fig. 7a. The global
539 average spectral values for k in our study (thick black line) perfectly match the Dubovik et al. (2002)
540 dataset from a synthesis of AERONET observations from various locations worldwide. Likewise, our k
541 average is also very close to the dataset by Balkanski et al. (2007), estimated from mineralogical com-
542 position assuming 1.5% in volume of hematite in dust (a value similar to our population average of 1.8%
543 (in mass) for the dust hematite content), a value shown to allow a reconciliation of climate modelling
544 and satellite observations of the dust direct SW radiative effect. Looking at Fig. 7a, the datasets which
545 show the largest deviations from our estimated range of k are the ones by: (i) Volz (1972), Patterson et
546 al. (1977) and Hess et al. (1998; i.e., the OPAC database, which is the same k dataset used in the new
547 OPAC 4.0 version, Koepke et al., 2015), which are also amongst the most commonly used references
548 for the dust imaginary refractive index in many climate models; (ii) the dataset by Wagner et al. (2012),
549 from laboratory chamber experiments; and (iii) the dataset by Steigmann and Yang (2017), estimated
550 from a machine learning technique. The reasons for these discrepancies in the k values are difficult to
551 assess, since they can be related to both instrumental and analytical aspects. In the studies by Volz
552 (1972) and Patterson et al. (1977), for instance, the complex refractive index was obtained by transmit-
553 tance and diffuse reflectance on pellet samples, a technique that requires the dust to be pressed in a
554 matrix of non-absorbing material. In this case a discrepancy arises from the different optical behaviour
555 between dust compressed in a pellet and the airborne particles. Moreover, Volz (1972) and Patterson
556 et al. (1977) analyse dust aerosols collected after mid- to long- transport, so after the dust have been
557 possibly mixed with absorbing species. For the case of Wagner et al. (2012), the choice of the optical
558 theory to retrieve k (T-matrix instead of Mie theory as used in our work, but also used in the majority of
559 past field and remote sensing literature studies considered) is expected to cause the observed differ-
560 ences with our dataset.

561 4.4 Imaginary refractive index and SSA versus iron and iron oxide content

562 The sample-to-sample variability of the imaginary part of the refractive index k and the SSA observed
563 in Fig. 6 and 7 is related to the dust composition by investigating the dependence on the particle iron
564 content. In Fig. 8 we show the experiment-averaged k and SSA at 370, 520, and 950 nm versus the
565 mass concentration of iron oxides (hematite+goethite, $MC_{Fe-ox\%}$), hematite ($MC_{Hem\%}$), goethite
566 ($MC_{Goeth\%}$), and total elemental iron ($MC_{Fe\%}$) measured for the different dust samples analyzed in this
567 study. The data are linearly fitted to relate k and SSA to $MC_{Fe-ox\%}$, $MC_{Hem\%}$, $MC_{Goeth\%}$, and $MC_{Fe\%}$. The
568 results of the fits at all wavelengths between 370 and 950 nm are reported in Table 6, together with the

569 statistical indicators of the goodness of fit (correlation coefficient, R^2 , and reduced chi square, χ^2_{red} , i.e.,
570 the obtained chi square divided by the number of degrees of freedom). The data in Fig. 8 and Table 6
571 indicate that there is an excellent correlation between both k and SSA and $\text{MC}_{\text{Fe-ox}\%}$ at the different
572 wavelengths ($R^2 > 0.75$). A weaker correlation is found when relating k and SSA to $\text{MC}_{\text{Hem}\%}$ and $\text{MC}_{\text{Fe}\%}$
573 (R^2 between 0.40 and 0.74 for k and between 0.49 and 0.78 for the SSA), and $\text{MC}_{\text{Goeth}\%}$ (R^2 between
574 0.17 and 0.62). The better correlation of k and SSA to $\text{MC}_{\text{Fe-ox}\%}$ compared to $\text{MC}_{\text{Fe}\%}$ is expected since
575 dust optical properties in the visible wavelengths are mostly sensitive to the fraction of iron oxides,
576 rather than to iron incorporated into the crystal structure of silicates (i.e., Karickhoff and Bailey, 1973;
577 Lafon et al., 2006; Moosmüller et al., 2012; Klaver et al., 2011; Engelbrecht et al., 2016; C17). The
578 quantities that most robustly satisfy a linear relationship are k and $\text{MC}_{\text{Fe-ox}\%}$, as indicated by the reduced
579 chi square χ^2_{red} that is around 1 at all different wavelengths. The χ^2_{red} increases to values also larger
580 than 2 in the other cases, indicating the poorer robustness of the fit in these cases.

581 We also investigated the dependence of the spectral k and SSA on the mass concentration of other
582 minerals contained in dust, such as clays, calcite, quartz, and feldspars, and also on the mass concen-
583 tration of different elements. We found that there is no statistically significant correlation between k and
584 SSA and the mass concentration of any of these compounds (not shown), with R^2 values between 0.002
585 and 0.46 at the different wavelengths for all cases.

586 These results therefore clearly show that iron, particularly in the form of iron oxides, is the main driver
587 of dust shortwave absorption.

588 4.5 Imaginary refractive index and SSA versus dust coarse size fraction

589 The dependence of the spectral k and SSA on the dust coarse fraction is investigated by relating it to
590 the $D_{\text{eff,coarse}}$ calculated from the size distribution data behind the SW instruments inlets. The $k_{10\text{-min}}$ and
591 $\text{SSA}_{10\text{-min}}$ at 370, 520, and 950 nm versus $D_{\text{eff,coarse}}$ are shown in Fig. 9 for all experimental data, which
592 we separated into three classes based on their iron oxide content ($\text{MC}_{\text{Fe-ox}\%} \leq 1.5\%$, $1.5\% < \text{MC}_{\text{Fe-ox}\%}$
593 $< 3\%$, $\text{MC}_{\text{Fe-ox}\%} \geq 3\%$). Figure 9 shows that even if the correlation is not very strong ($R^2 < 0.54$), there is
594 a clearly decreasing tendency for the $\text{SSA}_{10\text{-min}}$ with increasing $D_{\text{eff,coarse}}$, particularly at 370 and 520 nm
595 for strongly absorbing samples with iron oxide content larger than 3%. The $\text{SSA}_{10\text{-min}}$ is mostly inde-
596 pendent of changes of $D_{\text{eff,coarse}}$ at 950 nm. Conversely, $k_{10\text{-min}}$ has a very poor correlation with $D_{\text{eff,coarse}}$
597 ($R^2 < 0.35$) and thus does not depend on size. Similar results were also obtained for the real part (not
598 shown).

599 These results confirm previous observations (Sokolik and Toon, 1999; McConnell et al., 2008, 2010;
600 Kandler et al., 2011; Ryder et al., 2013a; 2013b) that the refractive index, an intrinsic property of matter,
601 is independent of size, while the SSA increases as the coarse dust size fraction decreases. This is due
602 to the fact that absorption efficiency for a single particle (Q_{abs}) increases with particle diameter while the
603 scattering efficiency (Q_{sca}) decreases. Ryder et al. (2013a) also showed that the dependence of SSA
604 on size is linear, but important only when the coarse fraction is high (if particles larger than about 3 μm
605 in diameter are present), otherwise the SSA depends mainly on composition.

606 5. Summary and concluding remarks

607 In this paper we presented new measurements of the spectral SW complex refractive index ($m=n-ik$)
608 and single scattering albedo (SSA) for nineteen mineral dust aerosols generated in the laboratory from
609 natural soil samples from major desert dust source areas in northern Africa, the Sahel, Middle East,
610 eastern Asia, North and South America, southern Africa, and Australia, and selected to represent the
611 heterogeneity of the dust composition at the global scale, in particular the range of iron oxide concen-
612 trations. The envelope of refractive indices and SSA data obtained in this study can thus be taken as
613 representative of the variability of the global dust aerosol.

614 Experiments described here were conducted in the 4.2 m³ CESAM chamber, a realistic and dynamic
615 environment where dust aerosols can be generated and maintained in suspension for few hours while
616 monitoring the evolution of their physical, chemical, and optical properties. The generated dust aerosols
617 are characterized by a realistic size distribution, including both the sub-micron and the super-micron
618 fraction, and they have an atmospherically representative mass concentration and composition, includ-
619 ing iron oxides and elemental iron content.

620 The results of the present study can be summarized as follows:

- 621 1. The spectral k and SSA retrieved in this study vary from sample to sample within the same region
622 but also from a region to another. For k , values vary between 0.001–0.009 at 370 nm and 0.0003–
623 0.002 at 950 nm. For SSA, values vary from 0.70 to 0.96 at 370 nm and from 0.95 at 0.99 at 950
624 nm. In contrast, n is wavelength-independent and almost uniform for the different sources, with
625 values between 1.48 and 1.55. Values for n and SSA fall within the range of published literature
626 estimates, while for k we obtain a much narrower range of variability than the ensemble of literature
627 results, as illustrated in Fig. 7. In particular, we found lower values of k compared to most of the
628 literature values currently used in climate models, such as Volz et al. (1972), Patterson et al. (1977),
629 and the OPAC database (Hess et al., 1998; Koepke et al., 2015). Miller et al. (2014) state that the
630 values of Dubovik et al. (2002) from AERONET, Patterson et al. (1977) for far-travelled dust, and
631 OPAC probably bracket the global solar absorption by dust. In contrast, our results indicate that
632 dust absorption is lower than previously thought, and its average is close to the values reported by
633 Dubovik et al. (2002) from AERONET observations and Balkanski et al. (2007) for a dust with a
634 1.5% volume fraction of hematite. Our range of variability of an order of magnitude for k and be-
635 tween 4% and 30% for the spectral SSA is actually large enough to change the sign of the global
636 dust direct effect at the TOA (Miller et al., 2004), as well as its regional implications (e.g., Solmon
637 et al., 2008; Jin et al., 2016), and has to be taken into account in climate modelling.
- 638 2. The documented changes in k and SSA also impact remote sensing retrievals. To give an example,
639 following Gasteiger et al. (2011), our observed variability of about 10% for the SSA at 532 nm would
640 translate to about 40% variability in the retrieved extinction profiles and optical depths from lidar
641 observations for dust from varying sources.
- 642 3. The sample-to-sample variability observed in this study is mostly related to the iron oxide and
643 elemental iron content in dust. At each investigated wavelength the magnitude of k and SSA is
644 linearly correlated to the mass concentration of total iron oxides, hematite, goethite, and total ele-
645 mental iron. Small variations of these compounds translate into large variations of k and SSA. This

646 suggests that it is sufficient to know the content of iron oxide or elemental iron in dust to predict its
647 spectral k and SSA, which represents a huge simplification for parameterizing their regional and
648 global variability.

649 4. We also investigated the dependence of k and SSA on the size distribution of dust. While k is
650 independent of size (suggesting that a constant value can be used along transport), below 600 nm
651 the SSA linearly decreases for increasing $D_{\text{eff,coarse}}$ for strongly absorbing samples with more than
652 3% iron oxide content. The investigated range of $D_{\text{eff,coarse}}$ is within about 2 and 4 μm , and thus
653 comparable to values obtained along a transport path over the Atlantic Ocean for dust during about
654 2 to 6 days following emission (Denjean et al., 2016a).

655 Based on our results, we recommend that dust simulations, as well as remote sensing retrievals, use
656 source-dependent values of the spectral SW refractive index and SSA instead of generic values. We
657 propose, as a first step, a set of regionally-averaged n , k , and SSA values to represent dust from each
658 of the eight regions analysed here as well as a global average value from the ensemble of our data
659 (Tables 4 and 5). Furthermore, the relationships found between k and SSA and the iron oxides or ele-
660 mental iron content in dust open the perspective to establish predictive rules to estimate the spectrally-
661 resolved SW absorption of dust based on composition. We recommend the use of iron oxide content
662 rather than iron content as it is better correlated with k and SSA. The relationship found in this study,
663 nonetheless, refer to the bulk composition of the dust aerosols and to a size range typical of 2 to 6 days
664 of transport in the atmosphere. As demonstrated in C17 with the mass extinction efficiency, the rela-
665 tionships linking the dust absorption to iron content vary as a function of the analysed size fraction due
666 to the fact that iron bearing minerals are more concentrated in the clay fraction ($<2.0 \mu\text{m}$) than in the
667 coarsest fraction of the dust (Kandler et al., 2009; C17). Further investigation should be therefore ad-
668 dressed to evaluate the dependence of the spectral k and SSA versus iron content as a function of the
669 size distribution of the particles. This will allow to determine if the k and SSA versus iron relationships
670 change or not in different phases of the aerosol lifetime, so from the source areas (when the coarsest
671 fraction is dominant), to long-range transport conditions (when most of the coarse particle fraction
672 above few μm has settled out). We point out, however, that the use of mineralogy to estimate k and
673 SSA based on linear relationships, as obtained in our study, requires nonetheless that the model-pre-
674 dicted dust composition accurately reflects that of the natural atmospheric aerosols. To this aim, realistic
675 soil mineralogy databases and accurate modelling of the soil to aerosol size fractionation need to be
676 developed in model schemes.

677 Finally, this study had the objective to investigate the variability of the dust SW optical properties at the
678 global scale in link to the global variability of the dust composition. It is noteworthy that observations
679 over Southern Africa and the Sahel from the present study indicate that the k and SSA variabilities over
680 these regions are comparable to the ones obtained for the global scale. For other regions, such as
681 North America and Australia, only one sample was analyzed, with no information on the regional-scale
682 variability of k and SSA. Additionally, for some of the analyzed areas, such as the Bodélé depression,
683 even local scale variability (on the order of few km) may be of relevance, given the documented local
684 scale changes of the particles' mineralogy and iron content (Bristow et al., 2010). More efforts should

685 be therefore devoted to better characterize the variability of dust spectral optical properties at the re-
686 gional scale with the aim of better assessing the dust impact on the climate of different areas of the
687 world.

688

689 **Data availability**

690 Complex refractive index and single scattering albedo data for the different analyzed samples are pro-
691 vided in Tables 4 and 5. Processed CESAM data are immediately available upon request to the contact
692 author. They will also soon be made available through the EUROCHAMP–2020 data center
693 (<https://data.eurochamp.org/>). The following IDL routines were used in the analysis: mpfitexy.pro (avail-
694 able at <https://github.com/williamsmj/mpfitexy>) was used to linearly fit data taking into account uncer-
695 tainties on both x and y; mie_single.pro (available at [http://www.atm.ox.ac.uk/code/mie/mie_sin-
696 gle.html](http://www.atm.ox.ac.uk/code/mie/mie_single.html)) was used for optical calculations using Mie theory; mpcurvefit.pro (available at [http://cow.phys-
698 ics.wisc.edu/~craigm/idl/idl.html](http://cow.phys-
697 ics.wisc.edu/~craigm/idl/idl.html)) was used for size lognormal fitting.

699 **Author contributions**

700 C. Di Biagio, P. Formenti, Y. Balkanski, and J. F. Doussin designed the experiments and discussed the
701 results. C. Di Biagio performed the experiments and performed the full data analysis with contributions
702 by P. Formenti, L. Caponi, M. Cazaunau, E. Pangui, and J.F. Doussin. The soil samples used for ex-
703 periments were collected by M. O. Andreae, K. Kandler, T. Saeed, S. Piketh, D. Seibert, and E. Wil-
704 liams. E. Journet participated to the selection of the soil samples for experiments. Sophie Nowak per-
705 formed the XRD measurements. C. Di Biagio and P. Formenti wrote the manuscript with comments
706 from all co–authors.

707

1087 **Table 1.** Measured and retrieved quantities and their estimated uncertainties. For further details, refer
 1088 to Sect. 2, as well DB17 and C17.
 1089

Parameter	Time resolution	Uncertainty	Uncertainty calculation	Comments	
Optical SW	Scattering coefficient at 450, 550, and 700 nm, $\beta_{\text{sca}}(\lambda)$	10-min data	5–12%	Quadratic combination of photon counting and gas calibration uncertainty (5%), angular corrections uncertainty (<5%) and standard deviation over 10-min intervals (2–10%).	The uncertainty on $\beta_{\text{sca}}(\lambda)$ usually decreases with increasing dust residence time in the chamber as a result of the reduction of the coarse component.
	Absorption coefficient at 370, 470, 520, 590, 660, 880, and 950 nm, $\beta_{\text{abs}}(\lambda)$	10-min data	22–30% at 370 nm 23–87% at 950 nm	Error propagation formula ¹ on Eq. (2) considering the uncertainties on $\beta_{\text{ATT}}(\lambda)$ from 10-min fitting procedure (error propagation formula ¹ on Eq. 1, ~20%), and uncertainties on $\alpha(\lambda)$ (1%), $\beta_{\text{sca}}(\lambda)$ (5–12%), C_{ref} (10%), and R (1–10%).	
	Extinction coefficient, $\beta_{\text{ext}}(\lambda) = \beta_{\text{sca}}(\lambda) + \beta_{\text{abs}}(\lambda)$	10-min data	~25%	Sum of $\beta_{\text{sca}}(\lambda)$ and $\beta_{\text{abs}}(\lambda)$ uncertainties	
	Single Scattering Albedo, $\text{SSA}(\lambda) = \beta_{\text{sca}}(\lambda) / (\beta_{\text{sca}}(\lambda) + \beta_{\text{abs}}(\lambda))$	10-min data	9–12%	Error propagation formula ¹ considering single uncertainties on β_{sca} and β_{abs} .	
	Single Scattering Albedo, $\text{SSA}(\lambda) = (1 + 1/m(\lambda))^{-1}$	Experiment averaged	1–12% at 370 nm 1–3% at 950 nm	Error propagation formula ¹ on Eq. (6) considering the uncertainty on $m(\lambda)$, i.e., the slope of the linear fit between β_{sca} and β_{abs} over the whole duration of each experiment.	
	Complex refractive index (n-ik)	10-min data	<5% for n <50% for k	Deviations of the values of n and k retrieved in the sensitivity study (see Sect. 3.2) with respect to those obtained in the first inversions were assumed to correspond to the one standard deviation uncertainty to 10-min retrieved values.	
	Complex refractive index (n-ik)	Experiment averaged	<8% for n 13–75 % for k	Quadratic combination of the standard deviation of n and k over the experiment and the deviation on the experiment-averaged values between those obtained from central inversions and inversions using input data \pm their uncertainty.	
Size distribution	–	–	–	–	The electrical mobility to geometrical diameter conversion was performed by assuming for dust a dynamic shape factor of 1.75 ± 0.10 , as determined by SMPS–SkyGrimm comparison
SMPS geometrical diameter (D_g), $D_g = D_m / \chi$	–	–	–6%	Error propagation formula ¹ considering the uncertainty on the estimated shape factor χ (~6%)	

					in their overlapping range (see DB17)
	SkyGrimm geometrical diameter (D_g)	–	<15.2%	Standard deviation of the D_g values obtained for different refractive indices values used in the optical to geometrical conversion	The conversion of optical to geometrical diameters for the SkyGrimm and the WELAS was performed by Mie calculations by varying the dust refractive index in the range 1.47–1.53 for the real part and 0.001–0.005 for the imaginary part. Then D_g is set at the mean ± 1 standard deviation of the values obtained for the different values of n and k (see DB17). Refractive index is assumed to be constant with particle size and wavelength-independent.
	WELAS geometrical diameter (D_g)	–	<7%	The same as for the SkyGrimm	
	$(dN/d\log D)_{S\text{Woptics}}$	10-min data	~20-90%	Error propagation formula ¹ considering the $dN/d\log D_g$ st. dev. over 10-min and the uncertainty on particle loss function along sampling tubes $L(D_g)$ (~50% at 2 μm , ~10% at 8 μm)	
	$D_{\text{eff, fine}}$	10-min data	<5%	Deviation obtained by repeating the calculations by using the size distribution \pm its uncertainty.	
	$D_{\text{eff, coarse}}$	10-min data	5–40%		
Mineralogical composition	Elemental iron mass concentration ($MC_{\text{Fe}\%}$)	Experiment averaged	10%	Uncertainties calculated as discussed in DB17 and C17	
	Iron oxides mass concentration ($MC_{\text{Fe-ox}\%}$)	Experiment averaged	15%		
	Goethite mass concentration ($MC_{\text{Goeth}\%}$)	Experiment averaged	<10%		
	Hematite mass concentration ($MC_{\text{Hem}\%}$)	Experiment averaged	<10%

 1110

1111 **Table 3.** Chemical characterization of the dust aerosols in the PM_{10.6} size fraction. Column 3 shows
 1112 MC_{Fe%}, the fractional mass of elemental iron with respect to the total dust mass concentration ($\pm 10\%$),
 1113 and column 4 reports MC_{Fe-ox%}, the mass fraction of iron oxides with respect to the total dust mass
 1114 concentration ($\pm 15\%$) and its speciation in hematite MC_{Hem%} and goethite MC_{Goeth%} ($< \pm 10\%$). The iron
 1115 oxide measurements were not made on the Taklimakan sample. Mean values and standard deviations
 1116 based on single sample data are reported for the full dataset.

1117

Geographical area	Sample	MC _{Fe%}	MC _{Fe-ox%}	MC _{Hem%}	MC _{Goeth%}
Northern Africa – Sahara	Tunisia	4.1	2.2	1.2	1.1
	Morocco	3.6	1.4	0.4	1.0

1118

1119 **Table 4.** Real (n) and imaginary (k) parts of the refractive index estimated for the nineteen analysed
 1120 dust samples and mean values calculated for the eight regions and for the full dataset. Data for single
 1121 soils are reported as experiment-averaged values and their uncertainty is calculated as indicated in
 1122 Table 1. Mean values and standard deviations at each wavelength based on single sample data are
 1123 reported for the eight regions and the full dataset. The median and 10% and 90% percentile values are
 1124 also reported for the full dataset. For North America and Australia, for which only one dust sample was
 1125 analysed, the reported data correspond to the single sample available from these regions. For the real
 1126 part, the average over the whole shortwave range (n_{sw}) is indicated.
 1127

Sample/Region	n_{sw}		k							σ_k

1131 **Table 6.** Results of the linear fit between k and SSA and the mass concentration of iron oxides, $MC_{Fe-ox\%}$,
 1132 hematite, $MC_{Hem\%}$, goethite, $MC_{Goeth\%}$, and elemental iron, $MC_{Fe\%}$ in dust. Column 1 indicates the
 1133 wavelength; $(a \pm \sigma_a)$ indicates the retrieved slope and its estimated uncertainty; $(b \pm \sigma_b)$ indicates the
 1134 retrieved intercept and its estimated uncertainty; R^2 denotes the correlation coefficient and χ^2_{red} is the
 1135 reduced chi-square of the fit.

$k = a MC_{Fe-ox\%} + b$							$SSA = a MC_{Fe-ox\%} + b$						
Wavelength (nm)	$a \pm \sigma_a$	$b \pm \sigma_b$	$R^2; \chi^2_{red}$	$a \pm \sigma_a$	$b \pm \sigma_b$	$R^2; \chi^2_{red}$	Wavelength (nm)	$a \pm \sigma_a$	$b \pm \sigma_b$	$R^2; \chi^2_{red}$	$a \pm \sigma_a$	$b \pm \sigma_b$	$R^2; \chi^2_{red}$

Figure 2. Box and whisker plot showing the full variability of hematite and goethite mass fractions in the clay and silt soil fractions in the dust source regions at the global scale by considering desert source areas as reported in Ginoux et al. (2012) and DB17. Data are from the soil mineralogical database by Journet et al. (2014). Dots indicate hematite and goethite soil content (extracted from Journet et al.) for the nineteen soils used in the CESAM experiments. The Journet database assumes that the iron oxides in the silt fraction consist only of goethite.

1188 **Figure 4.** Comparison of dust size distributions sensed by the SW optical instruments (behind the SW
1189 instruments inlet $(dV/d\log D_g)_{SWOptics}$), with field data for long-range transported dust. The thick black line
1190 represents the mean value of $(dV/d\log D_g)_{SWOptics}$ at the peak of the dust injection in CESAM for experi-
1191 ments with the different samples. The grey shaded area indicates the range of $(dV/d\log D_g)_{SWOptics}$ for all
1192 samples. The dotted black line shows the average of the dust size distribution at the peak of the injection
1193 inside the CESAM chamber from DB17. Field data are from: Formenti et al. (2001) (CLAIRE campaign
1194 in Suriname, South America), Maring et al. (2003) and Denjean et al. (2016b) (PRIDE and DUST-AT-
1195 TACK campaigns in Puerto Rico, Caraibes), Müller et al. (2011) and Chen et al. (2011) (SAMUM2 and
1196 NAMMA campaigns in Cape Verde, eastern Atlantic). For comparison, data taken close to the source
1197 in Niger from Formenti et al. (2011) during the AMMA campaign are also shown. All data are reported
1198 as volume size distributions normalised at the maximum.

1216 **Figure 5.** Spectral extinction coefficient, absorption coefficient, SSA, and real (n) and imaginary (k)
1217 parts of the refractive index at the peak of the dust injection in the chamber and after 30 and 90 minutes
1218 for Morocco and Algeria dust samples. Data are reported at the seven aethalometer wavelengths (370,
1219 470, 520, 590, 660, 880, and 950 nm) as 10-min averages. In the top panel we report the extinction
1220 calculated as the sum of scattering and absorption coefficients. For the sake of clarity error bars are not
1221 shown for SSA, n, and k data.

1236 **Figure 6.** (a) Real (n) and imaginary (k) parts of the dust complex refractive index and (b) single scat-
1237 tering albedo (SSA_{AVG}) at seven wavelengths between 370 and 950 nm obtained for the 19 aerosol
1238 samples analyzed in this study. Data for the refractive index correspond to the time average of the 10
1239 min values obtained between the peak of the injection and 120 min later. The error bar corresponds to
1240 the absolute uncertainty in n and k , estimated to be $<8\%$ for n and between 13 and 75 % for k . SSA_{AVG}
1241 data correspond to the fit of the 10 min values of β_{sca} versus β_{abs} , and the uncertainty is between 1%
1242 and 12% at 370 nm and between 1% and 3% at 950 nm.

1249 **Figure 7.** Comparison of results obtained in this study (a) with literature–compiled values (b) of the dust
1250 real and imaginary parts of the refractive index (n , k) and single scattering albedo (SSA) in the SW
1251 spectral range. The regions in gray in panel a) indicate the full range of variability obtained in this study,
1252 and the gray thick lines are the means of k and SSA obtained for the different aerosol samples. Litera-
1253 ture values in panel b) include estimates from ground-based and aircraft observations during field cam-
1254 paigns, laboratory studies, AERONET inversions, and estimates from dust mineralogical composition.
1255 Data are in some cases for the full dust size distribution, while in other only the fine fraction below about
1256 $2\ \mu\text{m}$ is measured (identified with *).

1257 The main provenance of the dust and datasets from the literature is provided in the following: Volz et
1258 al. (1972) is data for rainout dust collected in Germany; Patterson et al. (1977) is Saharan dust; Hess
1259 et al. (1998) is data from the OPAC database; Colarco et al. (2002) is data for dust from Dakar, Sal,
1260 and Tenerife; Dubovik et al. (2002) included data from Bahrain-Persian Gulf and Solar Village-Saudi
1261 Arabia AERONET stations; Haywood et al. (2003) is dust from Mauritania; Sinyuk et al. (2003) is data
1262 from Cape Verde, Dakar, and Burkina Faso; Clarke et al. (2004) is Asian dust offshore of China, Japan,
1263 and Korea; Linke et al. (2006)-A is dust from Cairo; Linke et al. (2006)-B is dust from Morocco; Balkanski
1264 et al (2007) is calculated from mineralogical composition assuming a 1.5% hematite mass fraction in
1265 dust; Todd et al. (2007) is from Bodélé; Osborne et al. (2008) is from Niger; Otto et al. (2009), Petzold
1266 et al. (2009), Schladitz et al. (2009), and Muller et al. (2010, 2011) is dust originated mostly in Morocco;
1267 McConnell et al. (2008, 2010) is dust from Niger/Senegal; Chen et al. (2011) is dust from Western
1268 Sahara; Formenti et al. (2011) in the k plot is an average of airborne observations for the AMMA cam-
1269 paign in Niger, while for the SSA plot, Formenti et al. (2011)-A is from observations in the Saharan Air
1270 Layer, -B is from Bodélé/Sudan, and -C is a Sahelian uplift episode; Johnson et al. (2011) is dust from
1271 Western Sahara; Moosmüller et al. (2012) analysed samples from Middle East, Mali and Spain, and
1272 here we report the average of their obtained values; Wagner et al. (2012) obtained k values for several
1273 samples from Cairo and Burkina Faso and here we report and average of its results; Ryder et al. (2013)
1274 is dust from Western Sahara and Mauritania and we report in both k and SSA plots the average of their
1275 observations; Engelbrecht et al. (2016) analysed many dust samples from all over the world, here we
1276 report their measured minimum and maximum of the dust SSA that are -A from California and -B from
1277 the Etosha Pan in Namibia; Steigmann and Yang (2017) modelled the refractive index of dust based
1278 on assumed mineralogical compositions typical for Northern and Southern Sahara and Western and
1279 Eastern Asia dust, and here we report the average of their results for both n and k . Uncertainties in the
1280 field observations have been omitted for the sake of clarity. The legend identifies the line styles used in
1281 the plots.

1282 *(The different acronyms spell out as: AERONET = Aerosol Robotic Network; OPAC = Optical Properties*
1283 *of Aerosols and Clouds; SHADE = Saharan Dust Experiment; BODEX = The Bodélé Dust Experiment;*
1284 *DABEX = Dust and Biomass Experiment; SAMUM = Saharan Mineral Dust Experiment; DODO = Dust*
