15

16 **Abstract**

17 Designing effective control policies requires efficient quantification of the nonlinear response of air
18 pollution to emissions. However, neither the current observable indicators nor the current indicators based
19 on response-surface modeling (RSM) can fulfill this requirement. Therefore, this study developed new
20 observable RSM-based indicators and applied them to ambient fine **particle** (PM_{2.5}) and ozone (O₃)
21 pollution control in China. The performance of these observable indicators in predicting O₃ and PM_{2.5}
22 chemistry was compared with that of the current RSM-based indicators. H₂O₂×HCHO/NO₂ and total
23 ammonia ratio, which exhibited the best performance among indicators, were proposed as new observable
24 O₃- and PM_{2.5}-chemistry indicators, respectively. Strong correlations between RSM-based and traditional
25 observable indicators suggested that a combination of ambient concentrations of certain chemical species
26 can serve as an indicator to approximately quantify the response of O₃ and PM_{2.5} to changes in precursor

27 emissions. The observable RSM-based indicator for O₃ (observable peak ratio) effectively captured the
28 strong NO_x-saturated regime in January and the NO_x-limited regime in July, as well as the strong NO_x-
29 saturated regime in northern and eastern China and their key regions, including the Yangtze River Delta
30 and Pearl River Delta. The observable RSM-based indicator for PM_{2.5} (observable flex ratio) also captured
31 strong NH₃-poor condition in January and NH₃-rich condition in April and July, as well as NH₃-rich in
32 northern and eastern China and the Sichuan Basin. Moreover, analysis of these newly developed
33 observable response indicators suggested that the simultaneous control of NH₃ and NO_x emissions
34 produces greater benefits in provinces with higher PM_{2.5} exposure by up to 12 μg m⁻³ PM_{2.5} per 10 % NH₃
35 reduction compared with NO_x control only. Control of volatile organic compound (VOC) emissions by as
36 much as 40 % of NO_x controls is necessary to obtain the co-benefits of reducing both O₃ and PM_{2.5}
37 exposure at the national level when controlling NO_x emissions. However, the VOC-to-NO_x ratio required
38 to maintain benefits varies significantly from 0 to 1.2 in different provinces, suggesting that a more
39 localized control strategy should be designed for each province.

41 **Keywords:** nonlinear response, precursor emissions, response surface model, ozone, PM_{2.5}, indicator

42

43 **1. Introduction**

44 Air pollution has attracted great attention because of its harmful effects on human health (Cohen et
45 al., 2017), climate (Myhre et al., 2013), agriculture and ecosystems (Fuhrer et al., 2016), and visibility
46 (Friedlander et al., 1977). In particular, ambient fine **particles** (PM_{2.5}) and ozone (O₃) are among the top
47 risk factors for global mortality (Forouzanfar et al., 2015; Cohen et al., 2017) and have increased the need
48 to effectively control anthropogenic sources in order to reduce the ambient concentrations of PM_{2.5} and
49 O₃ (Wang et al., 2017). The challenge is that the dominant contributions to ambient PM_{2.5} and O₃ arise
50 from a series of chemical reactions among precursors, including sulfur dioxide (SO₂), nitrogen oxides
51 (NO_x), ammonia (NH₃) and volatile organic compounds (VOCs) (**Seinfeld and Pandis, 2012**). The
52 complexity of the chemical reactions and pathways associated with variations in meteorological
53 conditions and precursor levels results in strong nonlinear responses of PM_{2.5} and O₃ to their precursor
54 emission changes (West et al., 1999; Hakami et al., 2004; Cohan et al., 2005; Pun et al., 2007; Megaritis
55 et al., 2013). Such nonlinearity issues are a major challenge for policy-makers to design an effective
56 control strategy.

57 **Chemical species in the atmosphere are often highly correlated with one another, since their**
58 **concentrations are affected by common atmospheric physical processes (e.g., mixing and transport) and**
59 **chemical reactions. Concentrations of pollutants such as O₃ and PM_{2.5} are typically determined based on**
60 **the ambient levels of their gaseous precursors, implying that O₃ and PM_{2.5} chemistry can be identified**
61 **through a combination of concentrations of some of their related chemical species (i.e., indicators).** The
62 empirical kinetic modeling approach (EKMA) developed by the U.S. EPA quantifies the relationships of
63 O₃ with its precursor concentrations based on O₃ chemistry (Freas et al., 1978; Gipson et al., 1981). The
64 EKMA plot can aid inference of control strategy effectiveness (e.g., NO_x or VOC control) according to
65 VOC-to-NO_x ratios. Several studies have developed “observable” indicators by relating O₃ to reactive

66 nitrogen concentrations and species related to atmospheric oxidation. Such indicators include NO_y ,
67 $\text{H}_2\text{O}_2/\text{HNO}_3$, HCHO/NO_2 and $\text{H}_2\text{O}_2/(\text{O}_3+\text{NO}_2)$ (Milford et al., 1994; Sillman, 1995; Tonnesen and Dennis,
68 2000; Sillman and He, 2002), which can be used to identify NO_x -saturated or -limited regimes. The O_3
69 indicators can be derived from surface-monitoring observations (Peng et al., 2006), modeling simulations
70 (Wang et al., 2010), or even satellite retrievals (Jin et al., 2017; Sun et al., 2018), and then examined using
71 three-dimensional chemical transport models (CTMs) (Jiménez et al., 2004; Zhang et al., 2009; Liu et al.,
72 2010; Ye et al., 2016). Regarding $\text{PM}_{2.5}$ chemistry (more specifically for inorganic $\text{PM}_{2.5}$ sensitivities to
73 NH_3 and NO_x), indicators such as the degree of sulfate neutralization (DSN), gas ratio (GR), and adjusted
74 gas ratio (AdjGR) have been developed (defined in Text S1) to identify NH_3 -poor or -rich conditions
75 (Ansari and Pandis, 1998; Takahama et al., 2004; Pinder et al., 2008; Dennis et al., 2008). The indicator-
76 based method can be efficient in determining the chemical regime in the current scenarios and in
77 qualitatively estimating O_3 and $\text{PM}_{2.5}$ sensitivities to small perturbations in precursor emissions or ambient
78 concentrations without involving complex CTMs. However, traditional indicator methods are unable to
79 quantify the extent of the chemistry regime (Pinder et al., 2008); hence, the traditional observable
80 indicators provide policy-makers limited information for reducing O_3 and $\text{PM}_{2.5}$ pollution.

81 The sensitivity of O_3 and $\text{PM}_{2.5}$ to precursor emissions can be explored by running multiple brute-
82 force CTM simulations. For instance, the response surface model (RSM) developed from brute-force
83 simulations can generate a wide range of O_3 and $\text{PM}_{2.5}$ responses to precursor emissions ranging from
84 fully controlled to doubled emissions (i.e., -100 % to 100 % change relative to the baseline emission)
85 (Xing et al., 2011; Wang et al., 2011). Based on the RSM, the chemical response indicators of Peak Ratio
86 (PR) and Flex Ratio (FR) have been designed to identify regimes of O_3 and $\text{PM}_{2.5}$ chemistry, respectively
87 (see Xing et al., 2018 for detailed description of PR and FR). In contrast to the observable indicators, the
88 PR and FR are meaningful values that represent the exact transition point at which a chemistry regime

89 converts to another regime. With the recent development of the polynomial function-based RSM (pf-
90 RSM), the PR and FR can be easily calculated (Xing et al., 2018). However, this method is built on at
91 least 20 CTM simulations; in other words, the estimating the PR and FR requires considerable computing
92 resources. As a result, RSM use remains limited despite recent improvements in RSM efficiency (Xing et
93 al., 2017).

94 Over the preceding decade, China's air quality has undergone substantial changes. In particular, the
95 enactment of the *Air Pollution Prevention and Control Action Plan* from 2013 to 2017 greatly reduced
96 PM_{2.5} exposure (Zhao et al., 2018; Ding et al., 2019a). However, during this period, significant increases
97 in O₃ concentrations were observed in most Chinese cities (Li et al., 2018). The rate of increase in O₃
98 concentration (based on the 90th percentile of daily maximum of 8-hr running average) was approximately
99 27 %, 19 %, and 8 % in the North China Plain (NCP), Yangtze River Delta (YRD), and Pearl River Delta
100 (PRD), respectively (Ding et al., 2019b). Greater control over anthropogenic sources must be enforced to
101 reduce PM_{2.5} and O₃ concentrations (Lu et al., 2018). Notably, accurate quantification of the nonlinear
102 responses of O₃ and PM_{2.5} to their precursor emissions is critical and a prerequisite for effective mitigation
103 of **air pollution** in China.

104 **The design of an effective O₃ and PM_{2.5} control strategy requires efficient quantification of air**
105 **pollutant sensitivity to precursor emissions.** Indicator studies have demonstrated that the nonlinear
106 response of O₃ and PM_{2.5} to precursors can be estimated by using ambient concentrations of related
107 chemical species. It is expected that the response indicators originally derived from RSM predictions (i.e.,
108 PR and FR) can also be calculated using a combination of ambient concentrations of certain chemical
109 species, enabling these indicators to become “observable” indicators rather than being dependent on
110 numerous CTM simulations. To support the needs of policy design for O₃ and PM_{2.5} control, this study
111 developed effective indicators that not only represent O₃ and PM_{2.5} chemistry but also aid in determining

112 the most feasible emission reduction path, similar to the benefits provided by RSM-based indicators. The
113 flow of this study is presented in Fig. 1. The new observable response indicators were developed by
114 investigating the link between observable and RSM-based indicators in China.

115 The remainder of this paper is structured as follows: Section 2 presents the detailed methods for
116 CTM modeling, RSM configuration and response indicator development. Section 3 presents the
117 evaluation of the performance of observable indicators in predicting the chemistry regime and the
118 development of the observable response indicators and discusses their policy implications. Section 4
119 summarizes the main conclusions of this study.

120 **2. Method**

121 **2.1. Configuration of the CTM and RSM**

122 In this study, the Community Multi-scale Air Quality (CMAQ) model (version 5.2) was used to
123 simulate the baseline concentrations of O₃ and PM_{2.5} and their responses in numerous emission control
124 scenarios with different emission change ratios. The simulation was conducted on a domain covering
125 China with 27 km × 27 km horizontal resolution (Fig. 2). In 2017, January, April, July, and October were
126 simulated to represent winter, spring, summer, and fall, respectively. An annual level was estimated as the
127 average of the levels in these four months. The concentration data was analyzed based on the monthly
128 average for afternoon O₃ (12:00–18:00 China Standard Time when O₃ was the highest across a day), and
129 monthly average for 24-h PM_{2.5}. To approximate exposure concentrations, we also estimated population-
130 weighted O₃ and PM_{2.5} at the regional or national level by averaging the gridded concentrations weighted
131 by the population in each grid cell. The gridded population data were obtained from the 1 km × 1 km
132 LandScan population dataset in 2016 (Oak Ridge National Laboratory, 2013).

133 The anthropogenic emission data were developed by Tsinghua University by using a bottom-up
134 method (Ding et al., 2019a), with updated activity data from the 2017 China statistical yearbook as well

135 as the latest application rates of end-of-pipe control technologies based on the governmental bulletin and
136 reports. The anthropogenic emissions were gridded into $27\text{ km} \times 27\text{ km}$ horizontal resolution to match the
137 CMAQ model (Fig. S1). The 2017 biogenic emissions over China were generated using the Model for
138 Emissions of Gases and Aerosols from Nature (MEGAN; version 2.04). The meteorology field, driven by
139 the Weather Research and Forecasting Model (WRF; version 3.7), followed the same configuration as that
140 in our previous study (Ding et al., 2019a,b), and thus included the Morrison double-moment microphysics
141 scheme, the RRTMG radiation scheme, Kain-Fritsch cumulus cloud parameterization, the Pleim-Xiu land-
142 surface physics scheme, and the ACM2 PBL physics scheme. We used NCEP FNL (Final) Operational
143 Global Analysis data for the initial and boundary conditions in the WRF. The comparison with observation
144 data from the National Climatic Data Center suggested agreeable performance of the WRF model for
145 simulating wind speed, humidity and temperature (Table S1). The CMAQ model performance in
146 reproducing O_3 and $\text{PM}_{2.5}$ concentrations was evaluated by comparison with the ground-based
147 observations (Fig. S2), which suggested acceptable CMAQ model performance that met the recommended
148 benchmark (Ding et al., 2019a,b). **The normalized mean biases of CMAQ in predicting $\text{PM}_{2.5}$ and O_3 are**
149 **-16.4% and -12.5% compared with monitoring data obtained from the China National Environmental**
150 **Monitoring Centre. The mean fractional biases for $\text{PM}_{2.5}$ and O_3 prediction are -14.2% and -11.1%,**
151 **respectively (within the benchmark of $\pm 60\%$). The mean fractional errors for $\text{PM}_{2.5}$ and O_3 prediction are**
152 **21.6% and 17.0% respectively (within the benchmark of 75%).** The RSM was developed based on multiple
153 CTM simulations for various emission-control scenarios according to the brute-force method. Identical to
154 our previous RSM studies (Xing et al., 2017, 2018), the responses of O_3 and $\text{PM}_{2.5}$ to precursor emissions
155 were analyzed using the baseline case and 40 control scenarios using the Latin Hypercube Sample method
156 for four control variables, namely the emission ratios of NO_x , SO_2 , NH_3 , and VOCs. **Though the responses**
157 **of O_3 and $\text{PM}_{2.5}$ to local or regional emissions vary significantly as suggested in our previous study (Xing**

158 et al., 2011), we applied the same change ratio of each pollutant emission to all regions across China in
159 this study. This approach is consistent with the implementation of a multi-regional joint control strategy,
160 which is reasonable for China. The same level of local and regional emission reduction has been
161 recommended to achieve China's aggressive air quality goals (Xing et al., 2019).

162 The control matrix is provided in Table S2. The range of emission changes is set as 0 to 2 to be
163 consistent with our previous studies in which the pf-RSM performance has been well examined (Xing et
164 al., 2011; Wang et al., 2011; Xing et al., 2018; Ding et al., 2019b). The pf-RSM performance in predicting
165 PM_{2.5} and O₃ responses has been evaluated in detail using leave-one-out cross validation as well as the
166 out-of-sample validation method, with normalized errors all within 5% for both PM_{2.5} and O₃ across the
167 domain. Relatively large biases occurred for marginal cases, where emissions are controlled by nearly
168 100% and predicted concentrations are very small. These cases have limited influence on the shape of
169 nonlinear curve of the response function. However, the RSM is developed from a suite of CMAQ
170 simulations, and so uncertainties in the chemical mechanism used in CMAQ might influence the O₃ and
171 PM_{2.5} predictions.

172 2.2. RSM-based indicators of O₃ and PM_{2.5} chemistry

173 Based on the developed pf-RSM, the nonlinear responses of O₃ and PM_{2.5} concentrations to
174 precursor emissions can be represented as follows:

$$175 \quad \Delta Conc = \sum_{i=1}^n X_i \cdot (\Delta E_{NOx})^{a_i} \cdot (\Delta E_{SO2})^{b_i} \cdot (\Delta E_{NH3})^{c_i} \cdot (\Delta E_{VOCs})^{d_i} \quad (1)$$

176 where $\Delta Conc$ is the change in O₃ or PM_{2.5} concentration from the baseline concentration calculated from
177 a polynomial function of four variables (ΔE_{NOx} , ΔE_{SO2} , ΔE_{NH3} , ΔE_{VOCs}); ΔE_{NOx} , ΔE_{SO2} , ΔE_{NH3} , and ΔE_{VOCs}
178 are the change ratios of NO_x, SO₂, NH₃, and VOC emissions (i.e., $\Delta Emissions / Baseline_Emissions$),
179 respectively, relative to the baseline emissions (baseline = 0); and a_i , b_i , c_i , and d_i are the nonnegative
180 integer powers of ΔE_{NOx} , ΔE_{SO2} , ΔE_{NH3} , and ΔE_{VOCs} , respectively. X_i is the coefficient of term i for the 14

181 (n) terms listed in Table 1.

182 The terms used to represent PM_{2.5} and O₃ responses were determined in designing the pf-RSM
183 (Table 1). The high-degree terms of NO_x, VOCs and NH₃ represent their strong nonlinear contributions to
184 O₃ or PM_{2.5}. The interaction terms of NO_x and VOC for PM_{2.5} and O₃ represent the nonlinearity in
185 atmospheric oxidations, whereas those of NO_x and NH₃ for PM_{2.5} represent aerosol thermodynamics (Xing
186 et al., 2018).

187 X_i was fitted by 40 CTM control scenarios for each spatial grid cell. The X_i values in the pf-RSM
188 for annual-averaged population-weighted O₃ and PM_{2.5} concentrations in 31 provinces in China are
189 provided in Table S3 and Table S4, respectively. The terms with first degree for NO_x, SO₂, NH₃, and
190 VOCs represent the first derivative of PM_{2.5} and O₃ response to each precursor emission. O₃ was more
191 sensitive to NO_x (term X₅) and VOCs (term X₆) than to SO₂ (term X₁₃) or NH₃ (term X₁₄), and O₃
192 sensitivity was negative to NO_x but positive to VOCs in most provinces. PM_{2.5} sensitivities to the four
193 precursors (terms X₁, X₂, X₅ and X₁₁ for VOCs, NH₃, SO₂, and NO_x, respectively) were comparable,
194 whereas PM_{2.5} sensitivity to NO_x could be negative or positive.

195 The nonlinearities of O₃ and PM_{2.5} to precursors were mainly determined by high-order and
196 interaction terms. To illustrate such nonlinearities further, we used a series of isopleths, as shown in Fig.
197 3, as an example to present the national-averaged PM_{2.5} response to SO₂ and NH₃, NO_x and NH₃, as well
198 as PM_{2.5} and O₃ responses to NO_x and VOCs in different months. Strong nonlinearity was noted in PM_{2.5}
199 sensitivity to NH₃, and in O₃ and PM_{2.5} sensitivities to NO_x. PM_{2.5} sensitivity to NH₃ increased alongside
200 the transition of PM_{2.5} chemistry from the NH₃-rich condition (typically at high NH₃ emission ratios) to
201 the NH₃-poor condition (typically at low NH₃ emission ratios). O₃ and PM_{2.5} sensitivities to NO_x were
202 negative under the NO_x-saturated regime (typically at high NO_x emission ratios) but became positive
203 under the NO_x-limited regime (typically at low NO_x emission ratios). In addition, the transition points

204 (corresponding to the NO_x or NH₃ ratios at which the chemical regime for O₃ or PM_{2.5} chemistry changed)
 205 varied by time (Fig. 3) and space (see the isopleths at different provinces in Figs S3-S6). In general, the
 206 NH₃-poor condition appears in winter because of low NH₃ evaporation and little agriculture activity which
 207 is a dominant NH₃ source. The strong NO_x-saturated condition appears in winter when photolysis is less
 208 active than in other seasons, and concentrates in industrial regions with abundant NO_x emissions.

209 To further quantify the aforementioned nonlinearity, two RSM-based response indicators (i.e., the
 210 PR for O₃ and FR for PM_{2.5}) were calculated as described in our previous studies (Xing et al., 2011, 2018;
 211 Wang et al., 2011).

212 For O₃, the PR can be directly calculated as follows:

$$213 \quad PR = 1 + \Delta E_{NOx} \Big|_{\frac{\partial \Delta Conc_{O_3}}{\partial \Delta E_{NOx}}=0} E_{NOx} \in [a, b] \quad (2)$$

214 where $\frac{\partial \Delta Conc_{O_3}}{\partial \Delta E_{NOx}}$ is the first derivative of the $\Delta Conc_{O_3}$ to ΔE_{NOx} , which can be derived as follows:

$$215 \quad 5 * X_1 * \Delta E_{NOx}^4 + 4 * X_2 * \Delta E_{NOx}^3 + 3 * X_3 * \Delta E_{NOx}^2 + 2 * X_4 * \Delta E_{NOx} + X_5 = 0 \quad (3)$$

216 The PR is the NO_x emissions (represented as $1 + \Delta E_{NOx}$) that produce maximum O₃ concentration
 217 under the baseline VOC emissions. For $PR < 1$, the baseline condition is NO_x saturated, and the level of
 218 simultaneous control of VOCs to prevent an increase in O₃ levels from the NO_x controls must be
 219 understood. This level is defined by the ratio of VOCs to NO_x (i.e., VNr) corresponding to the PR and is
 220 calculated as follows:

$$221 \quad VNr = r \Big|_{\frac{\partial \Delta Conc_{O_3}}{\partial \Delta E_{NOx}}=0} \quad \text{when } PR < 1, \quad r = \Delta E_{VOC} / \Delta E_{NOx} \quad (4)$$

222 where $\frac{\partial \Delta Conc_{O_3}}{\partial \Delta E_{NOx}}$ is the first derivative of the $\Delta Conc_{O_3}$ to ΔE_{NOx} . When $\Delta E_{VOC} = r \times \Delta E_{NOx}$, and ΔE_{SO_2}

223 and ΔE_{NH_3} are 0, $\frac{\partial \Delta Conc_{O_3}}{\partial \Delta E_{NOx}}$ can be written as follows:

$$224 \quad 5 * X_1 * \Delta E_{NOx}^4 + 4 * X_2 * \Delta E_{NOx}^3 + 3 * X_3 * \Delta E_{NOx}^2 + 2 * X_4 * \Delta E_{NOx} + X_5 + X_6 * r + 2 * X_7 *$$

$$r^2 * \Delta E_{NOx} + 3 * X_8 * r^3 * \Delta E_{NOx}^2 + 2 * X_9 * r * \Delta E_{NOx}^2 + 4 * X_{10} * r^3 * \Delta E_{NOx}^3 + 6 * X_{11} * r * \Delta E_{NOx}^5 + 3 * X_{12} * r * \Delta E_{NOx}^2 = 0 \quad (5)$$

Since the ΔE_{NOx} is close to 0 when the controls are taken from the baseline, we ignore the terms of ΔE_{NOx} in the first derivative function above, then it can be written as follows,

$$X_5 + X_6 * r = 0 \quad (6)$$

The VNr therefore can be calculated using the following equation:

$$VNr = - \frac{X_5}{X_6} \quad (7)$$

For PM_{2.5}, the FR can be directly calculated from the polynomial function of PM_{2.5} by estimating the second derivative of the PM_{2.5} response to NH₃ emissions without considering interaction with other pollutants (Xing et al., 2018). In this study, we selected a simplified method to calculate the FR, estimated as the corresponding NH₃ emission ratio when the PM_{2.5} sensitivity to NH₃ and NO_x emissions is equal under the baseline conditions (similar to the definition in Wang et al (2011), but here we calculated the sensitivity of PM_{2.5} instead of nitrate in this study):

$$FR = 1 + \Delta E_{NH3} \left| \frac{\partial \Delta Conc_{PM}}{\partial \Delta E_{NH3}} = \frac{\partial \Delta Conc_{PM}}{\partial \Delta E_{NOx}} \right. \Delta E_{NH3} \in [a, b], \Delta E_{NOx} = 0, \quad (8)$$

where $\frac{\partial \Delta Conc_{PM}}{\partial \Delta E_{NH3}}$ and $\frac{\partial \Delta Conc_{PM}}{\partial \Delta E_{NOx}}$ are the first derivatives of the $\Delta Conc_{PM}$ to ΔE_{NH3} and ΔE_{NOx} , respectively, and ΔE_{NH3} can be obtained as follows:

$$3 * X_4 * \Delta E_{NH3}^2 + (2 * X_3 - X_{10}) * \Delta E_{NH3} + X_2 - X_{11} = 0 \quad (9)$$

The FR is the NH₃ emissions (represented as $1 + \Delta E_{NH3}$) that correspond to the inflection point between NH₃-rich and -poor conditions under baseline NO_x emissions. A FR greater than 1 indicates that the baseline condition is NH₃ poor, and a FR less than 1 indicates that the baseline condition is NH₃ rich. The extra benefit in PM_{2.5} reduction (denoted as ΔC_{NH3}) from simultaneous NH₃ controls in the same percentage as the required NO_x controls can be quantified as follows:

247
$$\Delta C_{NH_3} = \left(\frac{\partial \Delta Conc_{PM_{2.5}}}{\partial \Delta E_{NO_x}} \Big|_{\Delta E_{NH_3} = \Delta E_{NO_x}} \right) - \left(\frac{\partial \Delta Conc_{PM_{2.5}}}{\partial \Delta E_{NO_x}} \Big|_{\Delta E_{NH_3} = 0} \right) \quad (10)$$

248 where

249 $\frac{\partial \Delta Conc_{PM_{2.5}}}{\partial \Delta E_{NO_x}} \Big|_{\Delta E_{NH_3} = \Delta E_{NO_x}}$ is the first derivative of the $\Delta Conc_{PM_{2.5}}$ response to ΔE_{NO_x} when $\Delta E_{NH_3} =$

250 ΔE_{NO_x} , and

251 $\frac{\partial \Delta Conc_{PM_{2.5}}}{\partial \Delta E_{NO_x}} \Big|_{\Delta E_{NH_3} = 0}$ is the first derivative of the $\Delta Conc_{PM_{2.5}}$ response to ΔE_{NO_x} when $\Delta E_{NH_3} = 0$.

252 ΔC_{NH_3} can be calculated as follows:

253
$$\Delta C_{NH_3} = X_2 \quad (11)$$

254 **2.3. Observable indicators of O₃ and PM_{2.5} chemistry**

255 Zhang et al. (2009) summarized the various observable indicators with their corresponding transition
 256 values to identify O₃ and PM_{2.5} chemistry: O₃ indicators were H₂O₂/HNO₃, H₂O₂/(O₃+NO₂), NO_y, O₃/NO_x,
 257 O₃/NO_y, O₃/NO_z, HCHO/NO_y, and HCHO/NO₂, and the PM_{2.5} indicators were the DSN, GR, and AdjGR
 258 (defined in Text S1); these indicators have been used extensively in previous research (Liu et al., 2010;
 259 Wang et al., 2011; Ye et al., 2016). In the current study, we evaluated all the aforementioned indicators
 260 except DSN (DSN is included in the definition of the AdjGR, thus it was not considered as a separate
 261 indicator in this study). The original transition values, summarized by Zhang et al (2009), are listed in
 262 Table 2. In the present study, we examined these transition values and compared their performance in
 263 predicting O₃ and PM_{2.5} chemistry. Because the RSM-based indicators, PR and FR, are calculated using
 264 the multiple CTM simulations that use state-of-the-science representations of O₃ and PM_{2.5} chemistry,
 265 these indicators were assumed to represent the true condition for comparison with the condition predicted
 266 using observable indicators. The performance of each observable indicator is described by its success rate,
 267 which is the ratio of the number of correct predictions to the total number of predictions. A correct
 268 prediction is indicated by the observable indicator providing consistent results for O₃ or PM_{2.5} chemistry

269 as suggested by PR or FR. The comparison is only conducted for spatial grid cells with valid PR or FR
270 values within the range of 0 (fully controlled emissions) to 2 (double emissions).

271 As RSM-based indicators, the PR and FR have meaningful values that can be used to illustrate the
272 extent of the chemistry regime. The linkage of observable indicators with the PR and FR was investigated
273 by performing a linear-log regression of the value of the original observable indicator and the values of
274 the PR or FR as follows:

$$275 \quad \log(Y) = A \cdot X + B \quad (12)$$

276 where Y is an observable indicator for O_3 or $PM_{2.5}$, X is the RSM-based indicator (i.e., PR for O_3 or FR
277 for $PM_{2.5}$), and the coefficients A and B are estimated based on statistical regression. Therefore, the
278 observable response indicators (X') can be calculated as follows:

$$279 \quad X' = \frac{\log(Y) - B}{A} \quad (13)$$

280 The observable response indicators have the same policy implication as that of PR or FR, but they
281 can be directly calculated from the baseline concentrations of certain chemical species rather than being
282 derived from multiple CTM simulations. Therefore, these indicators are considerably more efficient than
283 are traditional RSM-based indicators.

284 **3. Results**

285 **3.1. Evaluating observable indicator performance in predicting chemistry regimes**

286 **3.1.1. O_3**

287 Observable indicators and the PR are compared in Fig. 4, and the performance of observable
288 indicators in predicting O_3 chemistry is summarized in Table 2. In general, strong correlation was noted
289 between the observable indicators and PR. The indicator with the highest annual success rate was
290 H_2O_2/HNO_3 approximately 73.4 %, with a value of 0.2 for the transition from NO_x -saturated to NO_x -

291 limited conditions. However, the original transition value of 0.2 for $\text{H}_2\text{O}_2/\text{HNO}_3$ tended to be too low,
292 particularly in April, July, and October (see Fig. 4a). This study found that the annual success rate of
293 $\text{H}_2\text{O}_2/\text{HNO}_3$ could be increased to 80.5 % if 0.3 was used as the transition value. This finding was
294 consistent with corresponding findings in previous studies, which have suggested the transition values of
295 $\text{H}_2\text{O}_2/\text{HNO}_3$ within the range of 0.2-3.6 at different locations and in different seasons (Sillman, 1995;
296 Sillman et al, 1997; Lu and Chang, 1998; Tonnesen and Dennis, 2000; Hammer et al, 2002; Liang et al,
297 2006; Zhang et al., 2009). $\text{H}_2\text{O}_2/(\text{O}_3+\text{NO}_2)$, with a transition value of 0.02, also exhibited a high annual
298 success rate of 66.4 %; this rate could be increased to 71.1 % by applying a transition value of 0.005
299 because the original transition value was too high, particularly in January, April, and October (see Fig. 4b).
300 HCHO/NO_y and HCHO/NO_2 exhibited relatively low performance, particularly in April and July, because
301 the original transition values appeared to be too high (Fig. 4h and i). **However, the performance of**
302 **HCHO/NO_y and HCHO/NO_2 could be greatly improved by using lower transition values, with increased**
303 **annual success rates as high as 76 %. The change of the transition values implies that such indicators**
304 **cannot fully consider all factors that determine the O_3 chemistry by using concentrations of just two**
305 **species.** The transition values of the indicators NO_y , O_3/NO_x , O_3/NO_y , and O_3/NO_z were suitable for
306 estimating annual levels if only one unique transition value was applied for all months (apparently, these
307 transition values for O_3/NO_x , O_3/NO_y and O_3/NO_z in January, and NO_x in April and July may have been
308 too low). However, their success rates (all < 70 %) were not as high as those of other indicators. The
309 inferior performance of the three O_3 -involved indicators (O_3/NO_x , O_3/NO_y and O_3/NO_z) may have been
310 associated with the considerable effects of background O_3 , which cannot be removed easily.

311 Because $\text{H}_2\text{O}_2/(\text{O}_3+\text{NO}_2)$ and HCHO/NO_2 exhibited good performance in predicting O_3 chemistry,
312 this study proposed a new indicator combining these two indicators, namely $\text{H}_2\text{O}_2 \times \text{HCHO}/\text{NO}_2$, with a
313 transition value of 0.3. The results suggested that this new indicator has the highest annual success rate,

314 namely 87.3 %, among all the indicators. Studies (Sillman, 1995; Tonnesen and Dennis, 2000) have
315 suggested that HCHO is approximately proportional to the VOC reactivity (i.e., the weighted sum of the
316 reactions of VOCs with OH) and that HCHO/NO₂ closely approximates the competition between OH
317 reactions with VOC and NO₂ that is central to O₃ chemistry. H₂O₂ derives from a key radical termination
318 pathway under low NO_x conditions (HO₂ + HO₂ → H₂O₂ + O₂). Comparison of H₂O₂ with NO_y or HNO₃,
319 which derives from a key radical termination pathway under high NO_x conditions, OH + NO₂ → HNO₃)
320 represents the relative abundance of VOCs to NO_x. The new hybrid indicator incorporates information
321 from the two individual indicators and could potentially be more robust.

322 3.1.2 PM_{2.5}

323 We selected the GR and AdjGR as observable indicators for PM_{2.5} chemistry to identify NH₃-poor
324 or NH₃-rich conditions. Comparison of GR and AdjGR with the FR is detailed in Fig. 5. AdjGR
325 performance was much higher than that of the GR, with a larger annual success rate of 74.1 % compared
326 with the GR's 55.6 % (see Table 3). The transition value of the GR appeared to be too low in all months
327 (Fig. 5a). This result was consistent with those of previous studies; the AdjGR tends to be a more robust
328 indicator because in contrast to the GR, it does not require an assumption of full sulfate neutralization
329 (Zhang et al., 2009). The improvement of AdjGR compared to GR is the greatest in January and the
330 smallest in July (Table 3). This is consistent with Pinder et al. (2008) who showed that accounting for
331 DSN is important under cold temperatures but GR and AdjGR converge for higher temperatures.

332 This study designed a new indicator, total ammonia ratio (TAR), where the sulfate concentration is
333 involved in the calculation, as follows:

$$334 \quad TAR = \frac{[TA]^2}{[TN] \times [TS]} = \frac{[NH_3] \times [NH_4^+]}{([HNO_3] + [NO_3^-]) \times [SO_4^{2-}]}, \quad (14)$$

335 where [TN] and [TS] are the total molar concentrations of nitrate ([HNO₃] + [NO₃⁻]) and sulfate

336 ($[SO_4^{2-}]$), respectively, and TAR is the relative abundance of total ammonia to nitrate and sulfate, regarded
337 as the product of $[TA]/[TN]$ and $[TA]/[TS]$. To simplify the calculation, $[TA]^2$ is assumed to be the
338 product of the molar concentration of ammonia gas $[NH_3]$ and ammonium $[NH_4^+]$.

339 The performance of TAR in predicting $PM_{2.5}$ chemistry was slightly higher than that of AdjGR, as
340 demonstrated by the higher success rate of TAR than that of AdjGR in all months. The annual success rate
341 of TAR was 79.6 %, with a transition value of 10 (Table 3).

342 3.2 Developing the observable responsive indicators

343 3.2.1 O_3

344 Fig. 6 presents the log-linear regressions of the O_3 observable indicators on the PR indicator derived
345 from the RSM. In general, all observable indicators exhibited strong correlations with the PR (all except
346 NO_y presented positive correlations with the PR), with varying R^2 values (0.08 – 0.75). The indicators
347 including NO_y , O_3/NO_x , O_3/NO_y , and O_3/NO_z , which had relatively low success rates, exhibited weaker
348 correlation with the PR ($R^2 < 0.31$; Fig. 6c-f). The newly developed $H_2O_2 \times HCHO/NO_2$ indicator exhibited
349 the strongest correlation with the PR ($R^2 = 0.75$), implying that the log-linear combination of the H_2O_2 ,
350 $HCHO$, and NO_2 baseline concentrations could approximate the responsive PR indicator to quantify O_3
351 chemistry. Other indicators can also be used to approximately estimate the PR based on the regression
352 coefficients shown in Fig. 6; however, their correlations with the PR were not as strong as those with
353 $H_2O_2 \times HCHO/NO_2$.

354 To evaluate the ability of the observable PR (oPR; estimated based on $H_2O_2 \times HCHO/NO_2$) to
355 represent the spatial and temporal variation of O_3 chemistry, the spatial distribution of the PR and oPR in
356 the four study months was compared across the simulated domain (Fig. 7). The oPR successfully captured
357 the strong NO_x -saturated regime in January ($PR < 1$) and the NO_x -limited ($PR > 1$) regime in July.

358 In addition, the PR and oPR suggested a consistently strong NO_x-saturated regime in northern and
359 eastern China and key regions such as the YRD and PRD. The domain-averaged oPRs were 0.97, 1.52,
360 1.73, and 1.37 in January, April, July, and October, respectively; these values are similar to the PRs (0.77,
361 1.24, 1.38, and 1.17, respectively). Thus, the oPR may approximate the PR to quantify the O₃ chemistry,
362 even on a large spatial and temporal scale.

363 3.2.2. PM_{2.5}

364 The correlations between PM_{2.5} observable indicators and the responsive FR indicator derived from
365 the RSM were investigated (Fig. 8). The AdjGR has the lowest R² (0.40) because of its high variations for
366 the NH₃-poor condition (Fig. 5b). A stronger positive correlation was noted between the GR and FR (R²
367 = 0.57); however, the success rate of the GR was the lowest among all the indicators (the success rate of
368 the GR increased when the transition value was set as the median value of the GR, namely 5, at an FR of
369 1). The TAR exhibited the strongest positive correlation with the FR (R² = 0.60), implying that the FR can
370 be approximately estimated by the log-linear combination of baseline concentrations of ammonia gas,
371 nitric acid gas, particulate ammonium, sulfate, and nitrate.

372 The capability of the observable FR (oFR; estimated based on the TAR indicator) in representing
373 the spatial and temporal variation of PM_{2.5} chemistry is illustrated in Fig. 9. Both the FR and oFR
374 suggested strong NH₃-poor condition (FR > 1) in January and NH₃-rich condition (FR < 1) in April and
375 July. The oFR suggested strong NH₃-rich condition in northern and eastern China and the Sichuan Basin;
376 these findings were consistent with those for the FR. The domain-averaged oFRs were 1.56, 1.05, 0.86,
377 and 1.24 in January, April, July, and October, respectively, with the strongest NH₃-poor condition in
378 January and NH₃-rich condition in July. These findings were comparable with the FRs of 1.47, 1.16, 0.95,
379 and 1.19 for the four study months, respectively, suggesting that the oFR can approximate the FR to
380 quantify the PM_{2.5} chemistry and its spatial and temporal variations.

381 3.3. Policy implications

382 3.3.1. O₃

383 The responsive PR indicator may help policy-makers to understand the status and extent of O₃
384 chemistry in the current scenarios. A lower PR (< 1) suggested a NO_x-saturated regime. Moreover, the
385 VNr could be used to inform policy-makers about the level of simultaneous control of VOCs required to
386 prevent an increase in O₃ levels from NO_x controls. In general, the VNr is negatively correlated with the
387 PR because a lower PR implies a stronger NO_x-saturated regime, which in turn requires more simultaneous
388 VOC control with NO_x. By contrast, a higher PR implies a weaker NO_x-saturated or even NO_x-limited
389 regime, which requires less or no simultaneous control of VOCs with NO_x. The negative correlation
390 between VNr and the PR was quantified by the simple linear regression of VNr on PR (Fig. S7). A high
391 R² (approximately 0.82) suggested that the VNr originally derived from the RSM can also be
392 approximately estimated from the PR or oPR.

393 Figure 10 presents a comparison of the VNr derived from the RSM, with the VNr calculated based
394 on the oPR, estimated by the H₂O₂×HCHO/NO₂ indicator and denoted as oVNr. Consistent spatial and
395 temporal variations were found for VNr and oVNr. Additional simultaneous VOC control is required in
396 January and in northern and eastern China, and is highly correlated with the low PR (Fig. 7). The domain-
397 averaged oVNr values were estimated to be 0.95, 0.43, 0.38, and 0.47 in January, April, July, and October,
398 respectively, with the highest and lowest oVNr values noted in January and July, respectively. That is
399 comparable with VNr in the four study months (i.e., 0.82, 0.46, 0.34, and 0.57, respectively).

400 The annual-averaged VNr and PR were also calculated for each province in China (Fig. 11). VNr
401 was negatively correlated with the PR at the provincial level. The northern provinces, namely Heilongjiang,
402 Xinjiang, and Liaoning required the highest VNr (1-1.2) because their PRs were very low (0.3-0.4). In the
403 NCP, including the province of Tianjin, Hebei, Henan, Shandong, Shanxi, Inner Mongolia, and Beijing,

404 high VNr (0.7-0.9) was required to overcome the stronger NO_x-saturated regime (PR = 0.4-0.6). The
405 coastal provinces, namely Fujian, and Guangdong, and middle-eastern provinces, namely Jiangxi and
406 Hunan, also demonstrated relatively high PRs (>0.7) and low VNr (<0.3).

407 3.3.2. PM_{2.5}

408 Using the responsive FR indicator or its observable oFR indicator can rapidly identify NH₃-rich or
409 NH₃-poor conditions, and this information can aid policy-makers in estimating the additional PM_{2.5} benefit
410 associated with simultaneous control of NH₃ and NO_x emissions (ΔC_{NH_3}). As discussed in Section 2.2,
411 ΔC_{NH_3} can be calculated from the RSM using the first derivative of the PM_{2.5} responsive function to
412 NH₃. Therefore, ΔC_{NH_3} must be strongly associated with the secondary inorganic aerosol (SNA)
413 concentration, as suggested in Fig. S8, which demonstrates a strong correlation between SNA
414 concentration and ΔC_{NH_3} . The linear regression with high R² (>0.71) implies that the ΔC_{NH_3} can be
415 approximately calculated based on the SNA concentration.

416 The ΔC_{NH_3} estimated based on the SNA concentration (o ΔC_{NH_3} ; based on the regression
417 function in Fig. S8) was compared with that derived from the RSM (Fig. 12). The o ΔC_{NH_3} typically
418 captured the spatial and temporal variation of ΔC_{NH_3} , suggesting large benefits in January and October,
419 particularly in eastern China and the Sichuan Basin. The domain-averaged ΔC_{NH_3} values were
420 approximately 0.31, 0.22, 0.16, and 0.38 $\mu\text{g m}^{-3}$ PM_{2.5} per 10 % NH₃ reduction in January, April, July, and
421 October respectively. In April and July, o ΔC_{NH_3} presented consistent results approximately 0.21 and
422 0.16 $\mu\text{g m}^{-3}$ PM_{2.5}, respectively, per 10 % NH₃ reduction, but slightly underestimated the benefits in
423 January and October (0.24 and 0.22 $\mu\text{g m}^{-3}$ PM_{2.5}, respectively, per 10 % NH₃ reduction).

424 At the annual level, ΔC_{NH_3} was compared with the population-weighted PM_{2.5} concentration in
425 each province (Fig. 13). ΔC_{NH_3} ranged from 2 to 12 $\mu\text{g m}^{-3}$ PM_{2.5} per 10 % NH₃ reduction. In addition,
426 the provinces with higher PM_{2.5} exposure exhibited additional benefits from NH₃ reductions (i.e., high

427 ΔC_{NH_3}), particularly in Hunan, Shandong, Tianjin, Jiangxi, Anhui, Henan, and Hubei where ΔC_{NH_3}
428 was $> 8 \mu\text{g m}^{-3}$ $\text{PM}_{2.5}$ per 10 % NH_3 reduction. These benefits from simultaneous NH_3 control were
429 substantial enough to be considered in these regions for achieving the national ambient $\text{PM}_{2.5}$ target (35
430 $\mu\text{g m}^{-3}$).

431 3.3.3. Cobenefits of NO_x and VOC control in reducing O_3 and $\text{PM}_{2.5}$

432 NO_x and VOCs are major precursors for O_3 and $\text{PM}_{2.5}$, and effectively controlling their emissions
433 can lead to cobenefits in reducing O_3 and $\text{PM}_{2.5}$. The PR results suggest strong NO_x -saturated regimes in
434 northern and eastern China including key regions such as the Sichuan Basin, YRD, and PRD, where
435 simultaneous VOC control with a certain VOC-to- NO_x ratio is required to prevent increases in O_3 levels
436 from the NO_x controls. $\text{PM}_{2.5}$ sensitivity to NO_x can be negative under a strong NO_x -saturated regime; this
437 effect is not as significant as it is for O_3 (Fig. 3). We quantified the nonlinearity of $\text{PM}_{2.5}$ sensitivity to NO_x
438 by using the same PR concept but for $\text{PM}_{2.5}$ response (Text S2); Fig. S9 presents the spatial distribution
439 of the PR to identify $\text{PM}_{2.5}$ sensitivity to NO_x emission in the four study months. The PR values for $\text{PM}_{2.5}$
440 were > 1 in April, July, and October in all grid cells across China, suggesting that NO_x control is always
441 beneficial for $\text{PM}_{2.5}$ reduction during these months. Even in January, the PR for $\text{PM}_{2.5}$ (0.4-0.8 in eastern
442 and northern China) remains larger than that for O_3 (0.2-0.6 in eastern and northern China), implying that
443 the suggested VNr for O_3 was high enough to overcome the potential limitations on $\text{PM}_{2.5}$ reduction from
444 NO_x control.

445 To explore the cobenefits of reducing O_3 and $\text{PM}_{2.5}$ after simultaneous control of NO_x and VOCs,
446 we investigated the effectiveness of six control pathways with various VOC-to- NO_x ratios including 0,
447 0.2, 0.4, 0.6, 0.8 and 1.0 (Fig. 14). In general, O_3 and $\text{PM}_{2.5}$ concentrations can be reduced in all months
448 through simultaneous control of NO_x and VOC emissions, although different VNr and control levels are
449 required in different months. In January (under strongly NO_x -saturated conditions), reductions in $\text{PM}_{2.5}$

450 and O₃ require VOC emission controls in addition to NO_x controls to prevent potential disbenefits
451 associated with the nonlinear chemistry. The smaller VNr required for PM_{2.5} (~0.4) than for O₃ (~1.0) in
452 this case might be associated with the smaller PR for PM_{2.5} as well as the additional benefit of VOC
453 controls in reducing secondary organic aerosols. Apparently, a larger VNr control ratio and greater
454 emission control is required in January compared with other months. In Fig. 14(a), only one pathway can
455 achieve simultaneous reduction in O₃ and PM_{2.5} concentrations (i.e., the pathway with VNr equal to 1 and
456 at the far end of the pathway, with reduction rates > 80%). In April and October, simultaneous VOC
457 controls were still required for O₃ (VNr = 0.2-0.6) but not for PM_{2.5}. In July when NO_x-limited regime
458 was dominant, the NO_x control was critical because the VOC controls had little effect on either O₃ or
459 PM_{2.5}. At the annual level, the simultaneous VOC controls (40 % of the NO_x controls) led to cobenefits in
460 reducing both O₃ and PM_{2.5} at the national level. However, VNr varied significantly in different seasons,
461 suggesting that considering the seasonality of O₃ and PM_{2.5} chemistry is necessary for design of a season-
462 specific control strategy.

463 **4. Summary and conclusion**

464 Compared with conducting multiple CTM simulations, the indicator method proved more efficient
465 in identifying the chemical regime in the current scenarios. However, the traditional indicators are not as
466 useful as the RSM-based PR and FR indicators for policy-makers to infer feasible emission reduction
467 paths. Therefore, this study quantified the relationship between RSM-based and traditional-observable
468 indicators and developed new observable response indicators, the oPR and oFR, which can be used to
469 quantify the nonlinearity of O₃ and PM_{2.5} response to precursor emissions. Similar to the traditional
470 indicators, the oPR and oFR can be easily calculated using a combination of ambient concentrations of
471 certain chemical species obtained from surface-monitored observations, modeling simulations, or even
472 satellite retrievals. In addition, the observable responsive indicators can not only rapidly identify the

473 chemical regime but also provide policy-makers with useful information, such as simultaneous VOC
474 controls to prevent increases in O₃ levels from NO_x controls under the NO_x-saturated regime (i.e., VNr),
475 as well as the additional benefit of simultaneously reducing NH₃ alongside NO_x control in PM_{2.5} reductions
476 (i.e., ΔC_NH₃). Since the indicators are developed from simulations with spatially uniform emission
477 controls across the country, they are especially useful for providing quick estimates of the potential
478 benefits or risks from uniform controls. These estimates can also provide a basis to design more localized
479 control strategies for particular regions.

480 This study proposed a new O₃-chemistry indicator, namely H₂O₂×HCHO/NO₂, and PM_{2.5}-chemistry
481 indicator, namely the TAR, both of which exhibited the highest success rates among all the indicators.
482 This study also suggested that the log-linear combinations of baseline H₂O₂, HCHO, and NO₂
483 concentrations could provide an approximate PR to quantify O₃ chemistry spatially and temporally.
484 Similarly, the log-linear combination of baseline concentrations of ammonia gas, nitric acid gas,
485 particulate ammonium, sulfate and nitrate can be used to approximately estimate the FR for PM_{2.5}
486 chemistry. The VNr was highly correlated with the PR, suggesting that a stronger NO_x-saturated regime
487 requires greater VOC control accompanied by NO_x control. The positive correlation between ΔC_NH₃
488 and the population-weighted PM_{2.5} concentration suggested that a province with high PM_{2.5} exposure can
489 gain greater benefits from NH₃ reduction. Finally, simultaneous control of NO_x and VOC could reduce
490 both O₃ and PM_{2.5} throughout the year, and an effective control pathway (VNr = 0.4) could lead to the
491 cobenefits of reducing both O₃ and PM_{2.5}. However, VNr varied significantly among the seasons and
492 provinces, suggesting the necessity of considering the seasonality of chemistry and of designing a more
493 localized control strategy for each province. We note that the discrepancy between the observable indicator
494 and the responsive indicator might also be influenced by uncertainties in the chemical mechanism of
495 CMAQ as well as prediction errors of the pf-RSM. The new indicators were designed based on the existing

496 chemical mechanism, and the transition values might be refined in the future as our understanding of
497 atmospheric chemical processes improves.

498 In conclusion, the two unique aspects of this study are as follows. First, quantification of the
499 correlation of observable indicators with responsive indicators (Fig. 5 and 7) implied that the traditional
500 observable indicators, based on monitored or satellite-retrieved concentrations, can be used to quantify
501 the nonlinearity of $PM_{2.5}$ and O_3 to precursor emission and provide useful policy implications. Second,
502 this study reported a promising method for efficiently establishing $PM_{2.5}$ - and O_3 - responsive functions to
503 precursors for traditional responsive or reduced-form modeling studies. This study suggested that the PR
504 or FR (a combination of coefficients in the polynomial functions in the pf-RSM) can be approximately
505 estimated using the ambient concentration of certain chemical species. Similarly, all coefficients in
506 polynomial functions can be calculated based on a set of ambient concentrations of certain chemical
507 species. The simple log-linear regression method used in this study demonstrated the possibility that even
508 in the presence of uncertainties in prediction, more advanced data analytics technologies such as deep
509 learning may improve performance in future.

697

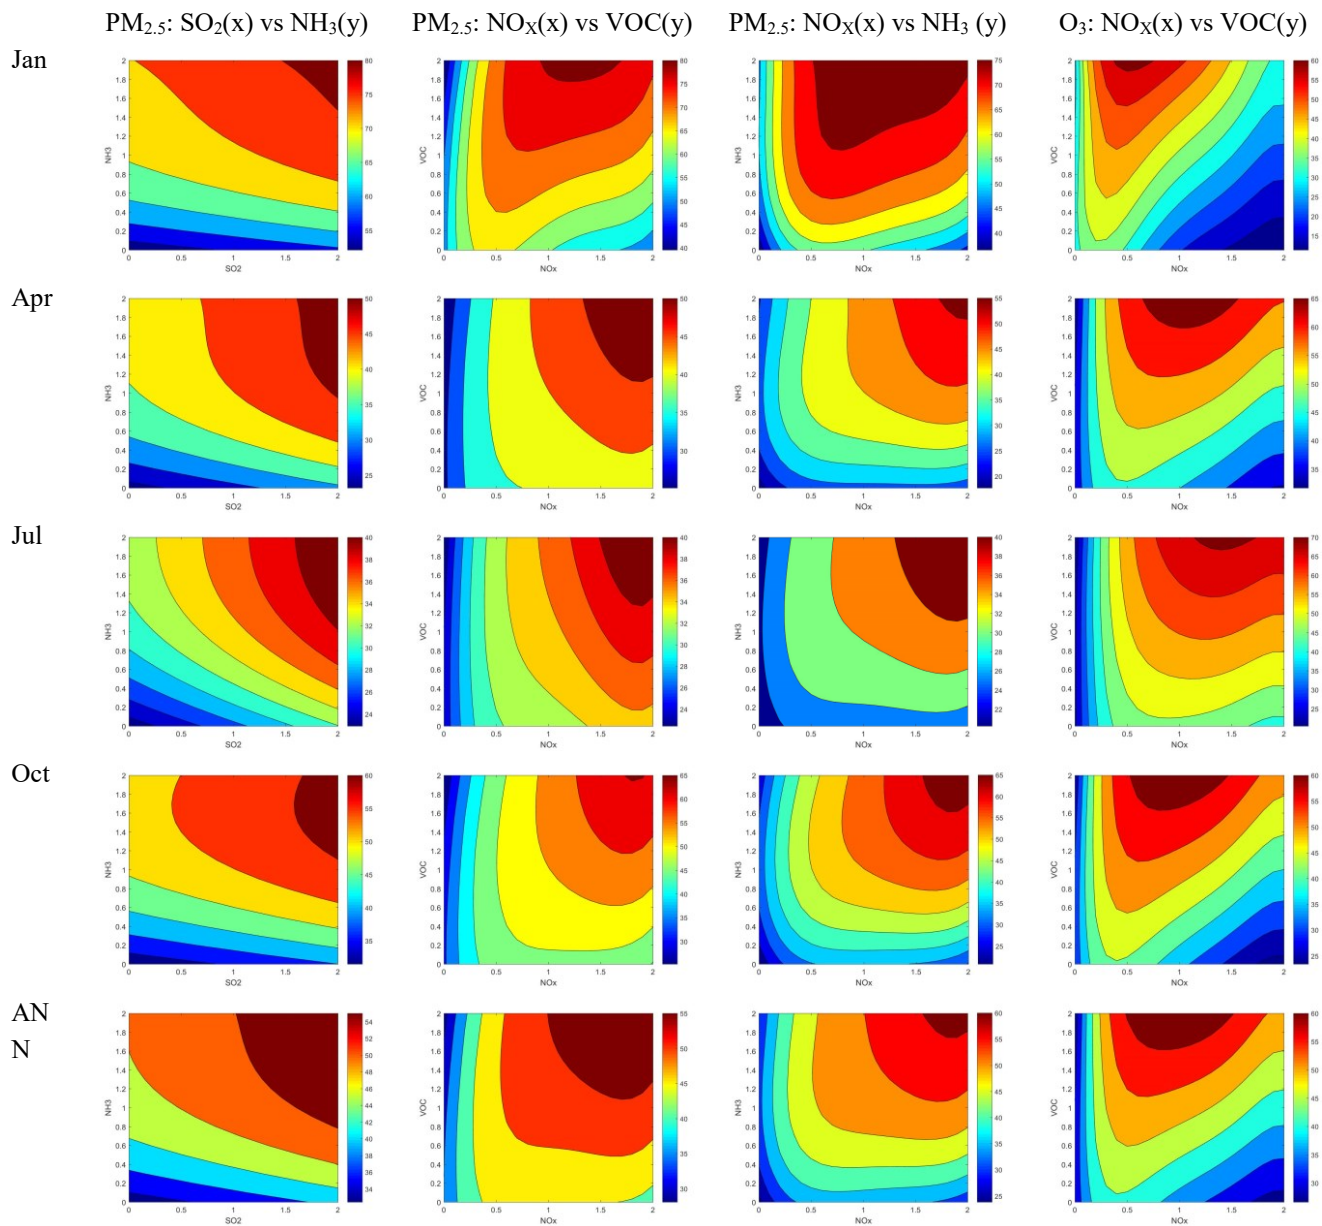

Figure 1. Flow of observable response indicator development and application

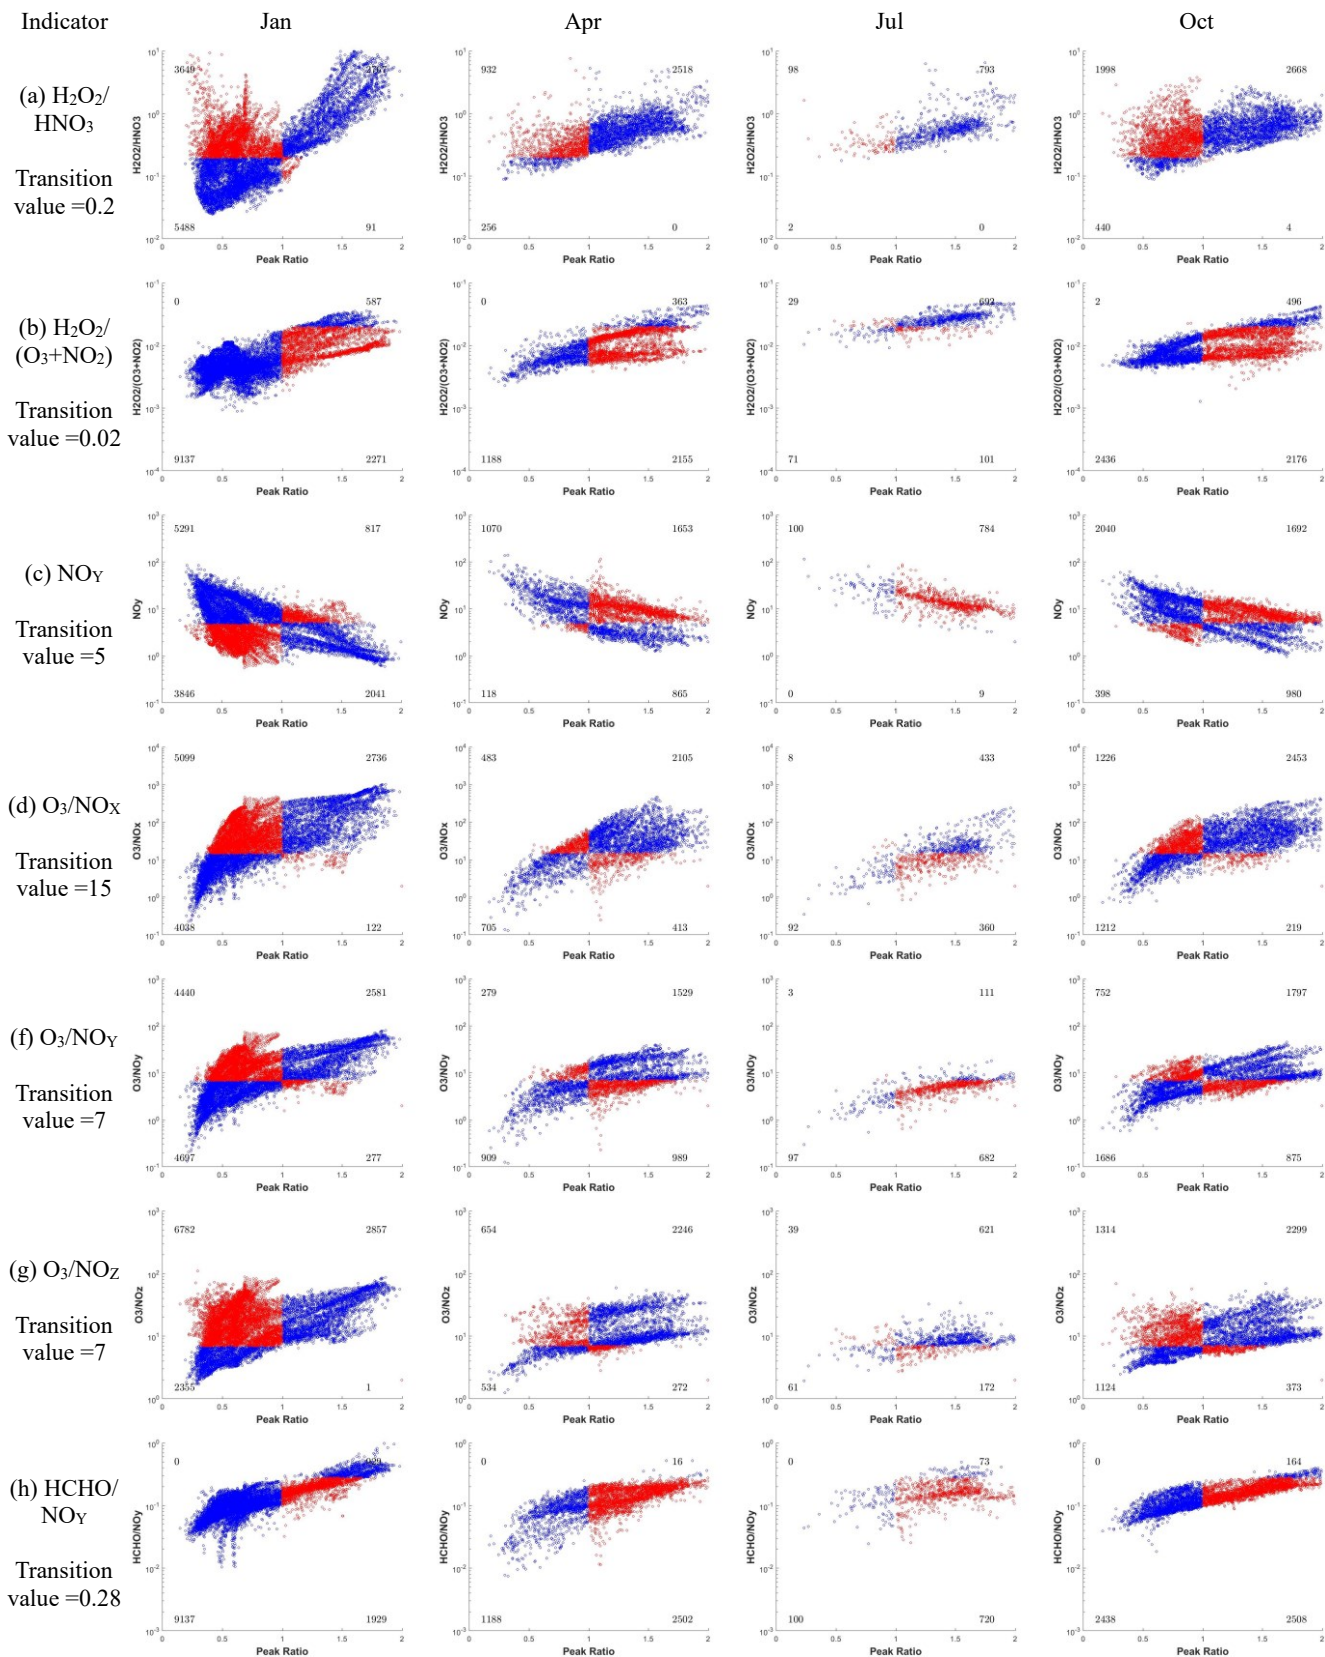

699

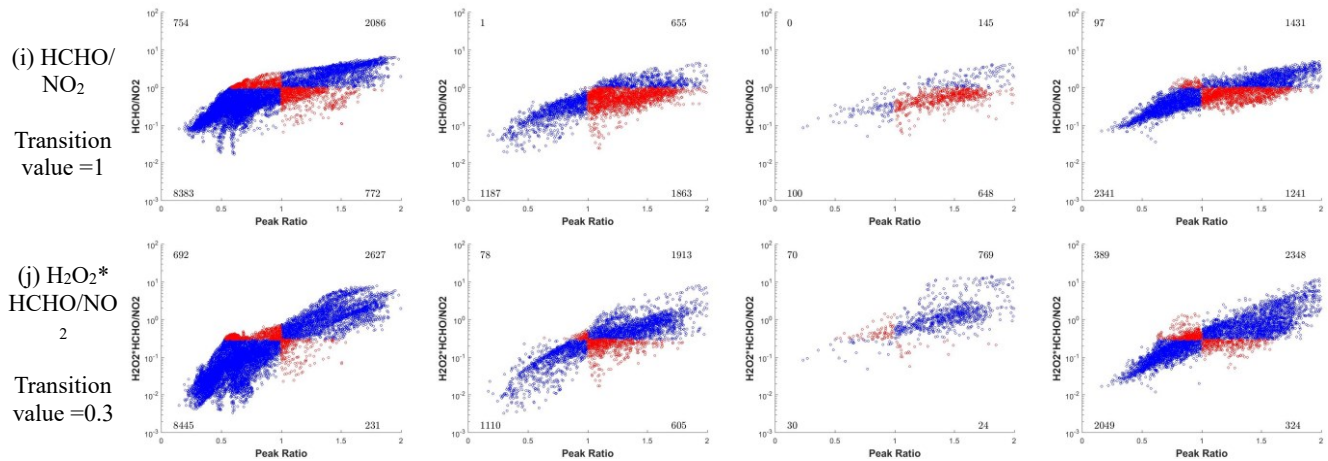

700 **Figure 2.** Simulation domain over mainland China (27×27 -km² resolution, 182×232 grid cells). The
 701 31 provinces are BJ-Beijing; TJ-Tianjin; HEB- Hebei; SX-Shanxi; IM-Inner Mongolia; LN- Liaoning;
 702 JL- Jilin; HLJ-Helongjiang; SH- Shanghai; JS-Jiangsu; ZJ-Zhejiang; AH- Anhui; FJ- Fujian; JX-
 703 Jiangxi; SD- Shandong; HEN- Henan; HUB-Hubei; HUN- Hunan; GD-Guangdong; GX- Guangxi; HN-
 704 Hainan; CQ- Chongqing; SC- Sichuan; GZ-Guizhou; YN- Yunnan; TB- Tibet; SHX-Shaanxi; GS-
 705 Gansu; QH-Qinghai; NX- Ningxia; and XJ-Xinjiang)

706

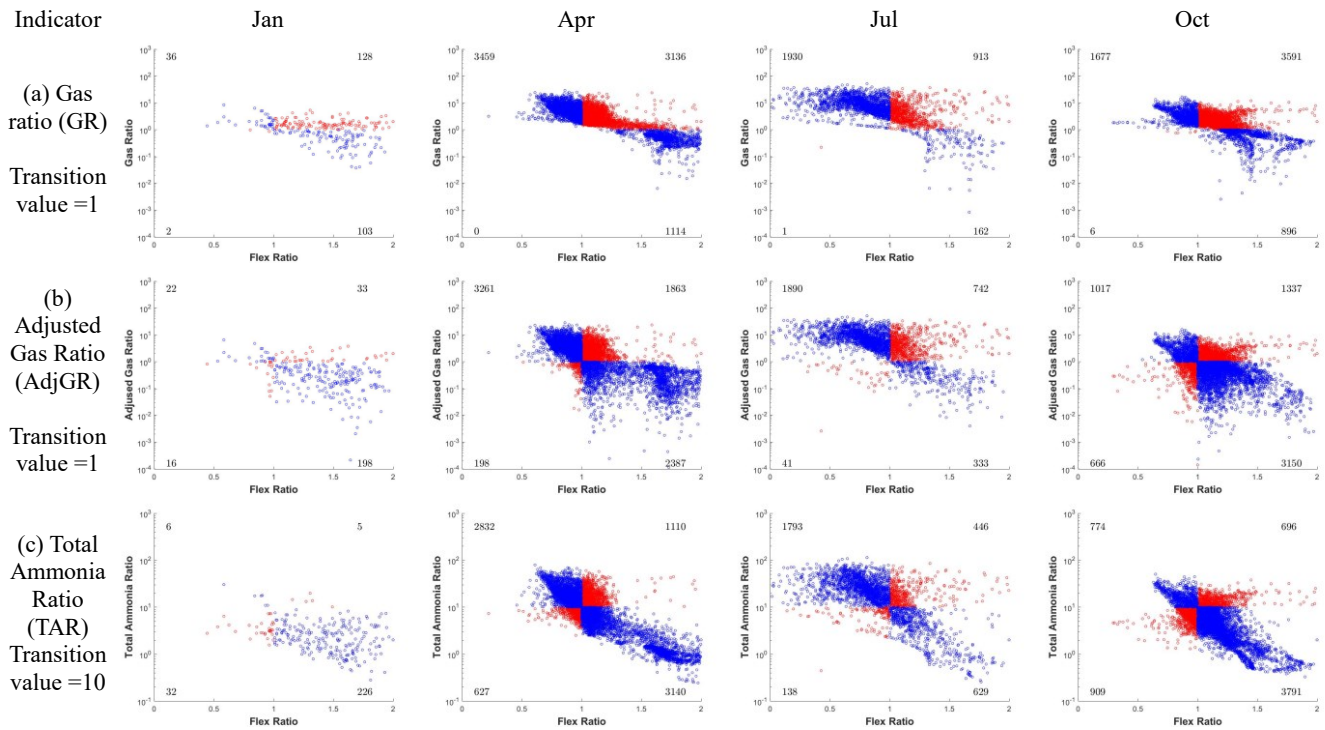

707 **Figure 3.** Isopleth of population-weighted PM_{2.5} and daytime O₃ to precursor emission change in
 708 different months. (The x- and y- axes represent precursor emission rates with a baseline of 1, applied to
 709 all grid cells in China; background colors represent the population-weighted PM_{2.5} and daytime O₃
 710 concentrations in China, with units of $\mu\text{g m}^{-3}$ for PM_{2.5} and ppb for O₃)

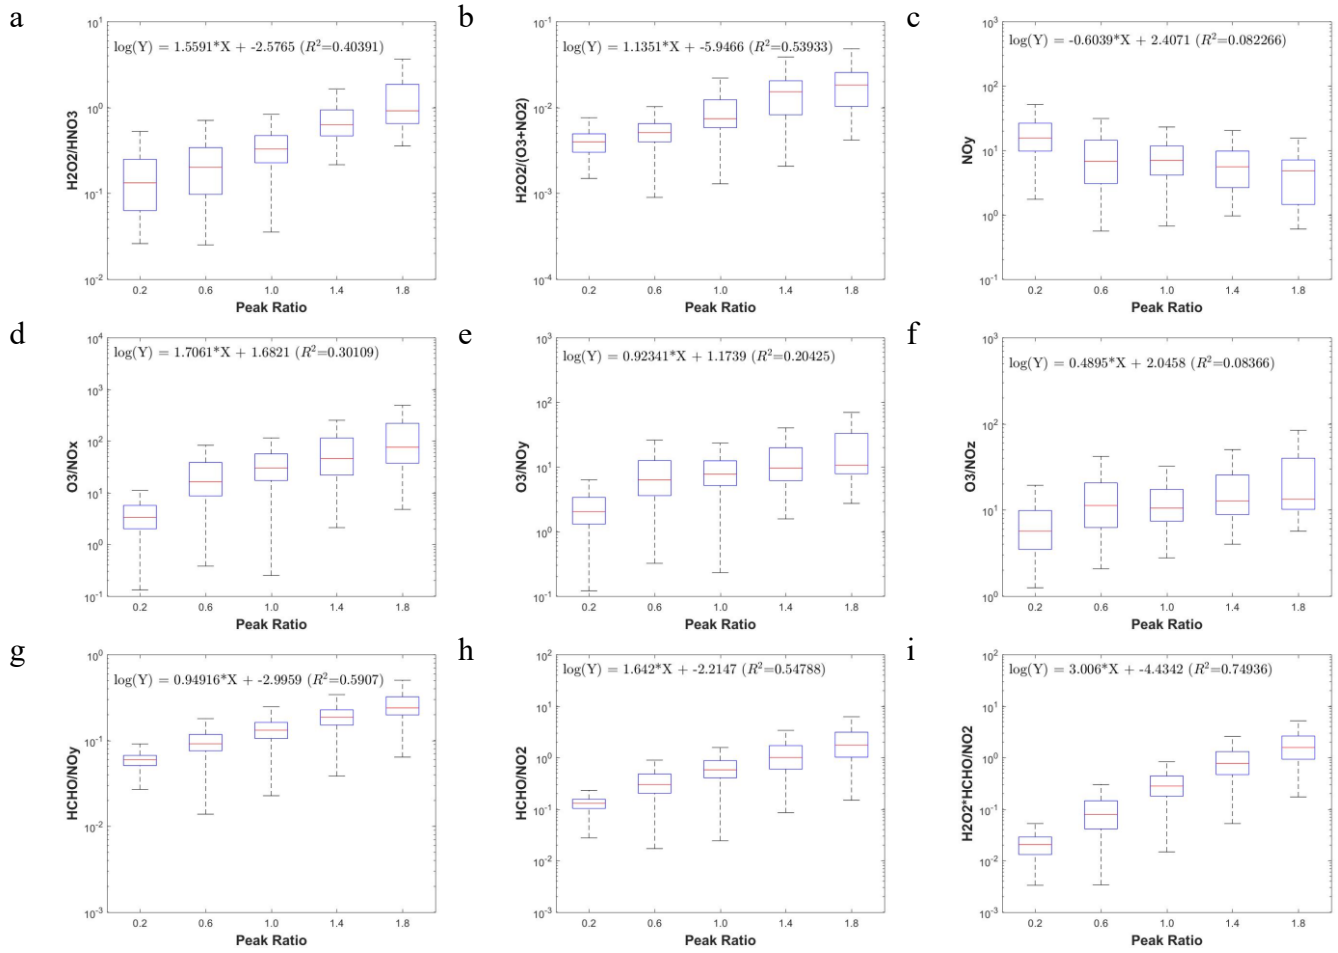

711 **Figure 4.** Performance of observable indicators in predicting O_3 chemistry. The x-axis represents the PR
 712 values where the transition value is 1, and the y-axis represents the observable indicators. The blue dots
 713 represent the grids where O_3 chemistry is successfully predicted by the observable indicator; the red dots
 714 represent the grids where the observable indicator fails to predict O_3 chemistry. The numbers in the four
 715 corners represent the grid number in each section; the number in July is much lower than those in the
 716 other months because most grids are located at the NO_x -limited regime with $\text{PR} > 2$ in July.

717

718 **Figure 5.** Performance of observable indicators in predicting PM_{2.5} chemistry. The x-axis represents the
 719 FR values where the transition value is 1, and the y-axis represents the observable indicators. The blue
 720 dots represent the grids where PM_{2.5} chemistry is successfully predicted by the observable indicator; the
 721 red dots represent the grids where the observable indicator fails to predict PM_{2.5} chemistry. The numbers
 722 in the four corners represent the grid number in each section; the number in January is much lower than
 723 those in the other months because most grids are located at the NH₃-poor condition with FR>2 in
 724 January.
