11
12 **Abstract**

13
14 Nitrous acid (HONO), an important precursor of the hydroxyl radical (OH), has been
15 long-standing recognized to be of significance to atmospheric chemistry, but its
16 sources are still debate. In this study, we conducted continuous measurement of
17 HONO from November 2017 to November 2018 at the SORPES station in Nanjing of
18 eastern China. The yearly average mixing ratio of observed HONO was 0.69 ± 0.58
19 ppb, showing a larger contribution to OH relative to ozone with a mean OH
20 production rate of 1.16 ppb/h. To estimate the effect of combustion emissions of
21 HONO, the emitted ratios of HONO and NO_x were derived from 55 fresh plumes
22 (NO/NO_x > 0.85), with a mean value of 0.79%. During the nighttime, the chemistry of
23 HONO was found to depend on RH, and heterogeneous reaction of NO₂ on aerosol
24 surface was presumably responsible for HONO production. The average nighttime
25 NO₂-to-HONO conversion frequency (C_{HONO}) was determined to be 0.0055 ± 0.0032
26 h⁻¹ from 137 HONO formation cases. The missing source of HONO around noontime
27 seemed to be photo-induced with an average P_{unknown} of 1.04 ppb h⁻¹, based on a
28 semi-quantitative HONO budget analysis. An over-determined system of equations
29 was applied to obtain the monthly variations in nocturnal HONO sources. Except for
30 burning-emitted HONO (approximately 23% of total measured HONO), the
31 contribution of heterogeneous formation on ground surfaces was an approximately

32 constant proportion of 36% throughout the year. The soil emission revealed clear
33 seasonal variation, and contributed up to 40% of observed HONO in July and August.
34 A higher propensity for generating HONO on aerosol surface occurred in heavily
35 polluted period (about 40% of HONO in January). Our results highlight
36 ever-changing contributions of HONO sources, and encourage more long-term
37 observations to evaluate the contributions from varied sources.

38

39 **1. Introduction**

40

41 Nitrous acid (HONO) is a vital constituent of nitrogen cycle in the atmosphere, first
42 observed in the field by Perner and Platt (1979). The concentrations of HONO varied
43 from dozens of ppt in remote regions (Villena et al., 2011b;Meusel et al., 2016) to
44 several ppb in polluted urban regions (Yu et al., 2009;Tong et al., 2015). The
45 photolysis of HONO (R1) has been long standing as a momentous source of the
46 hydroxyl radicals (OH) especially during the early morning when other OH sources
47 are minor (Platt et al., 1980;Alicke, 2002, 2003). Even during the daytime, recent
48 studies have recognized the photolysis of HONO as a potentially stronger contributor
49 to daytime OH radicals than that of O₃ (Kleffmann, 2005;Elshorbany et al., 2009;Li et
50 al., 2018). Meanwhile, HONO has been found to affect adversely human health (Jarvis
51 et al., 2005;Sleiman et al., 2010).

52

53 Although the significance of HONO has been given much weight, the sources of
54 ambient HONO are complicated and have been debated for decades. HONO can be
55 emitted from combustion, including vehicle exhaust, industrial exhaust and biomass
56 burning (Table 1).Tunnel experiments with tests for different engine types have
57 determined an emission ratio of HONO/NO_x for traffic source, ranged in 0.3-0.8%
58 (Kirchstetter et al., 1996;Kurtenbach et al., 2001). The release from soil nitrite
59 through acidification reaction and partitioning is considered to be another primary
60 source of atmospheric HONO (Su et al., 2011). Soil nitrite could come from
61 biological nitrification and denitrification processes (Canfield et al., 2010;Oswald et
62 al., 2013), or be enriched via reactive uptake of HONO from the atmosphere

63 (VandenBoer et al., 2014a;VandenBoer et al., 2014b). In addition to direct emissions,
64 the vast majority of HONO is produced chemically. The recombination of NO and
65 OH (R3) is the main homogeneous reaction for supplying HONO (Pagsberg et al.,
66 1997;Atkinson, 2000), whose contribution may be significant under conditions of
67 sufficient reactants at daytime. During the nighttime, with low OH concentrations,
68 other larger sources, i.e. heterogeneous reactions of NO₂ on various surfaces, are
69 required to explain elevated mixing levels of HONO. Laboratory studies indicate that
70 NO₂ can be converted to HONO on humid surfaces (R4), being first order in NO₂ and
71 depending on various parameters including the gas phase NO₂ concentration, the
72 surface water content, and the surface area density (Kleffmann et al.,
73 1998;Finlayson-Pitts et al., 2003). Besides, the heterogeneous reduction of NO₂ with
74 surface organics (R5) is proposed to be another effective pathway to generate HONO
75 (Ammann et al., 1998;Ammann et al., 2005;Aubin and Abbatt, 2007), observed in
76 freshly emitted plumes with high concentrations of NO_x and BC (Xu et al., 2015).
77 Notably this reaction rate is drastically reduced after the first few seconds due to
78 consumption of the reactive surfaces (Kalberer et al., 1999;Kleffmann et al., 1999),
79 but this reaction could be strongly enhanced by light on photo-activated surface
80 (George et al., 2005;Stemmler et al., 2006;Stemmler et al., 2007). During the daytime,
81 heterogeneous HONO formation from the photolysis of adsorbed nitric acid (HNO₃)
82 and particulate nitrate (NO₃⁻) at UV wavelengths has been found in experiments and
83 observations (Zhou et al., 2003;Zhou et al., 2011;Ye et al., 2016;Ye et al., 2017).
84 Heterogeneous processes are typically considered as the primary sources of HONO in
85 many regions yet are the most poorly understood. For NO₂ conversion to HONO on
86 surfaces (R4,R5), the uptake coefficients of NO₂ derived from different experiments
87 vary from 10⁻⁹ to 10⁻² (Ammann et al., 1998;Kirchner et al., 2000;Underwood et al.,
88 2001;Aubin and Abbatt, 2007;Zhou et al., 2015). The key step to determine the
89 uptake of NO₂ or the reaction rate is still ill-defined, and we are also not certain if and
90 how the ambient natural surfaces can be reactivated by radiation. Furthermore, it has
91 become a main concern to compare the contributions of ground and aerosol surfaces
92 to HONO formation. It is so far, not well explained for the observed HONO,

93 especially during daytime. Large unknown sources of HONO were identified by many
94 studies (Su et al., 2008b;Sörgel et al., 2011;Michoud et al., 2014;Lee et al., 2016).

95

96 Benefitting from more and more studies, particularly the observations under different
97 environments (Lammel and Cape, 1996;Li et al., 2012), understanding of HONO
98 chemistry in the atmosphere has been greatly improved during the last decade.
99 However, most HONO observations were short-term campaigns with studies ranging
100 from several weeks to several months. For example, Reisinger (2000) found a linear
101 correlation between the HONO/NO₂ ratio and aerosol surface density in the polluted
102 winter atmosphere; and Nie et al. (2015) showed the influence of biomass burning
103 plumes on HONO chemistry, according to observed data during late April–June 2012;
104 while Wong et al. (2011) believed that NO₂ to HONO conversion on the ground was
105 the dominant source of HONO by analyzing vertical profiles from 15 August to 20
106 September in 2006. Moreover, a theory that HONO from soil emission explained the
107 strength and diurnal variations of the missing source has been presented by Su et al.
108 (2011) based on data measured from 23 to 30 October 2004. In case the HONO
109 sources possibly exhibit temporal variability, especially seasonal differences, it is
110 challenging to draw a full picture on the basis of these short-term observations. More
111 than a year of continuous observation is needed, yet rather limited.

112

113 The Yangtze River Delta (YRD) is one of the most developed regions in eastern
114 China. Rapid urbanization and industrialization have induced severe air pollution over
115 the last three decades, particularly high concentrations of reactive nitrogen (Richter et
116 al., 2005;Rohde and Muller, 2015), including HONO (Wang et al., 2013;Nie et al.,
117 2015). In this study, we conducted HONO observations continuously from November
118 2017 to November 2018, at the Station for Observation Regional Processes and the
119 Earth System (SORPES), located in the western part of the YRD, a place that can be
120 influenced by air masses from different source regions of anthropogenic emissions,
121 biomass burning, dust and biogenic emissions (Ding et al., 2013;Ding et al., 2016).
122 Our one-year observation showed well-defined diurnal patterns and obvious season

123 variations of HONO concentrations at relatively high levels. We discussed the
124 potential mechanism of HONO production based upon semiquantitative analysis and
125 correlation studies, and paying special attention to changes in major sources of
126 HONO during different seasons.

127

128 **2. Methodology**

129

130 *2.1. Study site and instrumentation*

131

132 Continuous observation was conducted at the SORPES station at the Xianlin Campus
133 of Nanjing University (118°57'E, 32°07'N), located in the northeast suburb of Nanjing,
134 China, from November 2017 to November 2018 (Fig. S1). The easterly prevailing
135 wind and synoptic condition makes it a representative background site of Nanjing and
136 a regional downwind site of the city cluster in the YRD region. Detailed descriptions
137 for the station can be found in previous studies (Ding et al., 2013;Ding et al., 2016).

138

139 HONO was measured with a commercial long path absorption photometer instrument
140 (QUAMA, Model LOPAP-03). The ambient air was sampled in two similar
141 temperature controlled stripping coils in series using a mixture reagent of 100 g
142 sulfanilamide and 1 L HCl (37% volume fraction) in 9 L pure water. In the first
143 stripping coil, all of the HONO and a fraction of interfering substances were absorbed
144 into solution, and the remaining interfering species (NO₂, HNO₃, HO₂NO₂, PAN, etc.)
145 were absorbed in the second stripping coil. After adding a reagent of 0.8 g
146 N-naphtylethylenediamine-dihydrochloride in 8 L pure water to, colored azo dyewas
147 formed in the solutions from 2 stripping coils, which were then separately detected via
148 long path absorption in special Teflon tubing. To minimize the measurement
149 interferences, the real HONO signal was the difference between the signals in the two
150 channels. Further details can be found in (Heland et al., 2001;Kleffmann et al., 2006).
151 To correct for the small drifts in instrument's baseline, the compressed air was
152 sampled every 12 h (flow rate: 1.0 L/min) to make zero measurement. A span check
153 was made using 0.04 mg/m³ nitrite (NO₂⁻) solution each two weeks with a flow rate of

154 0.28 ml/min. The time resolution, detection limit, accuracy of the measurement was 5
155 min, 10 pptv, and 10%, respectively.

156

157 The NO and NO₂ levels were measured using a chemiluminescence instrument (TEI,
158 model 42i) coupled with a highly selective photolytic converter (Droplet
159 Measurement Technologies, model BLC), and the analyzer had a detection limit of 50
160 pptv for an integration time of 5 min, with precision of 4% and an uncertainty of 10%
161 (Xu et al., 2013). Ozone and CO were measured continuously using Thermo-Fisher
162 Scientific TEI 49i and TEI 48i, respectively. The fine particle mass concentration
163 (PM_{2.5}) was continuously measured with a combined technique of light scattering
164 photometry and beta radiation attenuation (Thermo Scientific SHARP Monitor Model
165 5030). Water soluble aerosol ions (NO₃⁻, SO₄²⁻, NH₄⁺ etc.) and ammonia (NH₃) were
166 measured by a Monitor for Aerosols and Gases in ambient Air (designed and
167 manufactured by Applikon Analytical B.V., the Netherlands) with a PM_{2.5} cyclone
168 inlet, in a time resolution of 1 hr. The size distribution of submicron particles (6-820
169 nm) is measured with a DMPS (differential mobility particle sizer) constructed at the
170 University of Helsinki in Finland. Meteorological measurements including relative
171 humidity (RH), wind speed, wind direction, and air temperature were recorded by
172 Automatic Weather Station (CAMPEEL co., AG1000). UVB total radiation was
173 measured by UVB radiometer (UVS-B-T UV Radiometer, KIPP & ZONEN).

174

175 ***2.2. TUV model and OH estimate***

176

177 The Tropospheric Ultraviolet and Visible (TUV) Radiation Model
178 (<http://www.acd.ucar.edu/TUV>) was adopted to compute the photolysis frequencies,
179 which is most probably accurate in clean and cloudless days. The pivotal parameters
180 of this model were inputted as follows: the ozone density was measured by Total
181 Ozone Mapping Spectrometer (<http://toms.gsfc.nasa.gov/teacher/ozoneoverhead.html>);
182 the typical single scattering albedo (SSA) and Ångström exponent (Alpha) were 0.93
183 and 1.04 (Shen et al., 2018); The mean value of optical depth (AOD) at 550nm was
184 0.64, derived following an empirical relationship with PM_{2.5} in Nanjing (Shao et al.,

185 2017). To reduce the error of model, we used observed UVB to correct simulated
186 results (J_{mod}) by Eq. (1).

187

$$188 \quad J = \frac{\text{UVB}_{\text{obs}}}{\text{UVB}_{\text{mod}}} J_{\text{mod}} \quad (1)$$

189

190 The daytime OH concentration was calculated by applying the empirical model (Eq. 2)
191 proposed by Rohrer and Berresheim (2006), based on strong nearly linear correlations
192 of measured OH concentrations with simultaneously observed $J(\text{O}^1\text{D})$. The coefficient
193 **a** reflects the average influence of reactants (e.g. NO_x , VOCs, ozone, H_2O) on OH at
194 the selected place for research; the exponent **b** represents the combined effects of all
195 photolytic processes on OH, for example, $J(\text{O}^1\text{D})$, $J(\text{NO}_2)$, $J(\text{HONO})$, $J(\text{HCHO})$ and
196 so on; and the parameter **c** counts the light-independent OH sources. The values of
197 coefficients **a**, **b** and **c** in Eq. (2) are adopted from the OH studies in the Pearl River
198 Delta (PRD) and Beijing, China (Rohrer et al., 2014; Tan et al., 2017; Tan et al., 2018).
199 By summarizing the coefficients **a**, **b**, **c** in different OH observation campaigns (Table
200 S1), especially the almost equal slope of the OH- $J(\text{O}^1\text{D})$ relation for different
201 locations and seasons in the polluted areas of China, we can make assumptions that
202 the comprehensive impact of reactants (e.g. NO_x and VOCs) on OH cannot compete
203 with that of UV light to OH, and the chemical environments of OH are similar. This
204 suggest that it can be a reasonable way to derive OH by using Eq. (2) in our study,
205 and the error of derived OH radicals has been assessed as not subverting the relative
206 conclusions in this study (Fig. S1(a) and Fig. S1(d)). The calculated OH
207 concentrations around noon ($J(\text{O}^1\text{D}) > 1 \times 10^{-5} \text{ s}^{-1}$) were in the range of $0.46\text{-}2.0 \times 10^7$
208 cm^{-3} , comparable to observations in Chinese urban or suburban atmospheres (Lu et al.,
209 2012; Lu et al., 2013).

210

$$[\text{OH}] = a \times (\text{J}(\text{O}^1\text{D}) / 10^{-5} \text{s}^{-1})^b + c$$

$$a = 4.2 \times 10^6 \text{ cm}^{-3}, b = 1$$

211 $c = 1.0 \times 10^6 \text{ cm}^{-3}$ in summer (2)

$$c = 0.6 \times 10^6 \text{ cm}^{-3}$$
 in spring, autumn

$$c = 0.2 \times 10^6 \text{ cm}^{-3}$$
 in winter

212

213 **3. Results**

214

215 **3.1. Observation overview**

216

217 We carried out continuous measurements for HONO at the SORPES station in the
218 northeast suburb of Nanjing from November 2017 to November 2018 with a mean
219 measured ambient HONO mixing level of 0.69 ± 0.58 ppb (Fig. S2), within the range
220 of those in or in the vicinity of mega cities (Table 2). Fig.1 shows the seasonal pattern
221 of HONO and related parameters. The highest concentration of HONO was found in
222 winter (1.04 ± 0.75 ppb), followed by spring (0.68 ± 0.48 ppb), autumn (0.66 ± 0.53
223 ppb) and summer (0.45 ± 0.37 ppb). Such seasonal variations in Nanjing are aligned
224 with that in Beijing (Hendrick et al., 2014), and are somewhat similar to those in Jinan
225 (Li et al., 2018), where the highest levels occurred in winter and the lowest levels
226 occurred in autumn, but these variations are different from those in Hongkong (Xu et
227 al., 2015) where the highest and lowest values of HONO appeared in autumn and
228 spring, respectively. The important point is that the seasonality of HONO coincides
229 with that of NO_x (or NO_2), which is believed to be the main precursor of HONO in
230 current studies.

231

232 The HONO to NO_x ratio or the HONO to NO_2 ratio has been used extensively in
233 previous researches to characterize the HONO levels and to indicate the extent of
234 heterogeneous conversion of NO_2 to HONO, since it is less influenced by convection
235 or transport processes than the individual concentration (Lammel and Cape,
236 1996; Stutz et al., 2002). When a large proportion of HONO comes from direct
237 emissions, the value of HONO/NO_2 usually becomes larger, falsely implying the
238 strong formation of HONO from NO_2 . However, the freshly emitted air masses

239 generally have the lowest HONO/NO_x ratio, meaning that HONO/NO_x behaves better
240 than HONO/NO₂ in a way. As shown in Fig. 1(b), the low value of HONO/NO_x in
241 winter is attributed to heavy emissions because we see high mixing ratios of NO
242 during this cold season (Fig. 1c), the reasons for two peaks of HONO/NO_x in spring
243 and summer will be discussed in sections 3.3, 3.4 and 4.

244

245 All daily changes of HONO concentration in different seasons closely resemble a
246 cycle where HONO peaks in the early morning, and then decreases to the minimum in
247 the late afternoon, following the diurnal trend of NO_x (Fig. 2). The daily variations of
248 HONO in Nanjing are like those seen in other urban areas (Villena et al., 2011a; Wang
249 et al., 2013; Michoud et al., 2014; Lee et al., 2016), but differ from observations on the
250 roadside (Rappenglück et al., 2013; Xu et al., 2015). At night, the mixing ratio of
251 HONO increases rapidly in the first few hours and then stabilizes (in spring and
252 summer) or gradually climbs to its peak in the morning rush hour (in winter and
253 autumn). The accumulation during nighttime hours suggests a significant production
254 of HONO exceeding the dry deposition of HONO. As the sun rises, the HONO sink
255 will be strengthened by photolysis and the vertical mixing processes, resulting that the
256 peak times of the diurnal patterns of HONO concentration varies in different seasons.
257 During the daytime, the rate of HONO abatement is rapid before noon and then
258 becomes progressively until HONO concentration falling to the minimum. Given that
259 the photolytic lifetime of HONO is about 10-20min at the midday (Stutz et al., 2000),
260 the considerable HONO concentration during daytime indicates the existence of
261 strong production of HONO.

262

263 From the daily variations of the HONO to NO_x ratio, we can further understand the
264 behavior of HONO in the atmosphere. the HONO/NO_x ratio is regularly enhanced
265 quickly before midnight then reaches a maximum during the latter half of the night.
266 According to Stutz et al. (2002), the highest HONO/NO_x (or HONO/NO₂) is defined
267 by the balance between production and loss of HONO at each night, the conditions
268 affecting the highest achievable ratio at nighttime will be discussed in section 3.3.

269 What's interesting here is the peak of the HONO/NO_x ratio in the midday sun in
270 spring, summer and autumn, and even in winter, the ratio doesn't decline but remains
271 stationary before and at noon. If the HONO sources during the daytime are consistent
272 with those at night, the minimum HONO/NO_x ratio should occur at noon due to the
273 intense photochemical loss of HONO. Therefore, there must be additional sources of
274 HONO during daytime (e.g. R3). The increase of HONO/NO_x with solar radiation
275 (e.g., UVB) is found in both diurnal and seasonal variations, indicating that these
276 daytime sources have a relationship with the intensity of solar radiation. We will
277 further discuss the potential daytime sources of HONO in section 3.4.

278

279 The elevated mixing ratio of HONO presents an efficient source of OH radicals
280 during daytime in Nanjing. We calculate the OH production rate from HONO, i.e.
281 P_{OH}(HONO), using Eq. (3). As discussed in Su et al. (2008b) and Li et al. (2014),
282 HONO produced by the reaction of NO with OH (R3) is actually a temporary
283 reservoir of OH radicals. The photolysis of HONO from this pathway only
284 regenerates OH radicals, cannot contribute to the concentrations of OH radicals. So it
285 is inappropriate to estimate the primary OH production from HONO based on
286 P_{OH}(HONO) derived from Eq. (3). For comparison, the OH production rate from
287 ozone photolysis, P_{OH}(O₃), is derived from Eq. (4). Only part of the O(¹D) atoms,
288 formed by the photolysis of O₃ at wavelengths below 320 nm (R7), can produce OH
289 radicals by reacting with water (R8) in the atmosphere, so we use the absolute water
290 concentration, which can be derived from relative humidity and temperature, to
291 calculate the branching ratio of O(¹D)(φ_{OH}) between R8 and R9. The reaction rate of
292 O(¹D) with O₂ is 4.0×10⁻¹¹ cm³ molecules⁻¹ s⁻¹ and the reaction rate of O(¹D) with N₂
293 is 3.1×10⁻¹¹ cm³ molecules⁻¹ s⁻¹ (Seinfeld and Pandis, 2016). In addition to the two
294 mechanisms mentioned above, there are other pathways to generate primary OH
295 radicals: the photolysis of aldehydes, mainly HCHO, can form HO₂ radicals, and then
296 converting to OH radicals by reacting with NO; the reactions of ozone with alkenes
297 produce OH radicals directly (Finlayson-Pitts and Pitts, 2000; Seinfeld and Pandis,

298 2016).

299

$$300 \quad P_{\text{OH}}(\text{HONO}) = J(\text{HONO})[\text{HONO}] \quad (3)$$

$$301 \quad P_{\text{OH}}(\text{O}_3) = 2J(\text{O}^1\text{D})[\text{O}_3]\phi_{\text{OH}} \quad (4)$$
$$\phi_{\text{OH}} = k_8[\text{H}_2\text{O}] / (k_8[\text{H}_2\text{O}] + k_9[\text{M}])$$

305

306 Fig. 3 shows that the diurnal peak of OH production rate from HONO is usually found
307 in the late morning, caused by the combined effects of HONO concentration and its
308 photolysis frequency, and the seasonal peak of $P_{\text{OH}}(\text{HONO})$ occurs in spring for the
309 same reason. $P_{\text{OH}}(\text{O}_3)$, coinciding with the trend of $J(\text{O}^1\text{D})$, is highest around noon at
310 daily time scale and is highest in summer at seasonal time scale, respectively.
311 Significantly, the photolysis of HONO produce more OH than that of ozone
312 throughout the daytime in winter, spring, and autumn. In summer, the contribution of
313 HONO to OH is greater in the early morning, and although the photolysis of ozone
314 contributes more OH at noon, the role of HONO is considerable. Overall, the average
315 $P_{\text{OH}}(\text{HONO})$ during 8:00-16:00 LT is 1.16 ppb/h, and the mean value of $P_{\text{OH}}(\text{O}_3)$ is
316 0.41 ppb/h. The impressive role of HONO in the atmospheric oxidizing capacity
317 should benefit photochemical ozone production (Ding et al., 2013; Xu et al., 2017; Xu
318 et al., 2018), new particle formation (Qi et al., 2015) and secondary aerosol formation
319 (Xie et al., 2015; Sun et al., 2018) in Nanjing, the western YRD region.

320

321 **3.2. Direct emissions of HONO from Combustion**

322

323 As mentioned above, the good correlation of HONO with NO_x (Fig. 4a) and the
324 similar patterns of HONO and NO_x , particularly sharply increasing together in the
325 fresh plumes, in which the NO/NO_x ratios are usually very high (Fig. S2), indicate the
326 presence of direct combustion emission of HONO, which need to be deducted when

327 analyzing the secondary formation of HONO. The SORPES station is influenced by
328 air masses from both industries and vehicles (Ding et al., 2016), so the traffic
329 emission factor investigated in other experiments cannot be used straightly. We derive
330 the emitted HONO/NO_x ratio according the method of Xu et al. (2015), and the
331 following criteria are adopted to select fresh plumes: (a) [NO_x] > 40 ppbv; (b)
332 $\Delta\text{NO}/\Delta\text{NO}_x > 0.85$; (c) good correlation between HONO and NO_x ($r > 0.9$); (d)
333 short duration of plumes (≤ 2 h); and (e) [UVB] ≤ 0.01 W/m². Then, the slopes of
334 HONO to NO_x in selected plumes were considered as the emission ratios in our study.

335

336 Within the one-year dataset, we select 55 freshly emitted plumes satisfying the criteria
337 above (Table S2), of which 20 air masses were found in the morning and evening rush
338 hours; the derived $\Delta\text{HONO}/\Delta\text{NO}_x$ ratios vary from 0.26% to 1.91% with a mean
339 value of $0.79\% \pm 0.36\%$. Many factors, such as the amount of excess oxygen; the types
340 of fuel used (gasoline, diesel, coal); if engines are catalyst-equipped, and if engines
341 are well-maintained, could result in variances in these ratios. Additionally, the rapid
342 heterogeneous reduction of NO₂ on synchronously emitted BC can also raise the value
343 of $\Delta\text{HONO}/\Delta\text{NO}_x$ (Xu et al., 2015). For our study, an average emission factor of
344 0.79% is deployed to evaluate the emission contribution of HONO (Eq. 5), which is
345 abbreviated as HONO_{emis}.

346

$$347 \quad \text{HONO}_{\text{emis}} = \text{NO}_x \times 0.0079 \quad (5)$$

$$348 \quad \text{HONO}_{\text{corr}} = \text{HONO} - \text{HONO}_{\text{emis}} \quad (6)$$

349

350 Combustion emissions contribute an average of 23% of total measured HONO
351 concentrations at night (Fig. 4b), with a maximum HONO_{emis}/HONO value of 32% in
352 winter and a minimum HONO_{emis}/HONO value of 18% in summer. We then get the
353 corrected observed HONO (HONO_{corr}) by Eq.(6) for further analysis. The slope of the
354 fitted line for HONO and NO_x is 1.62%, higher than emission ratio 0.79% (Fig. 4a),
355 and almost 80% of HONO is from HONO_{corr} that is not affected by emissions (Fig.
356 4b). These imply significant secondary formation of HONO in the atmosphere.

357

358 **3.3. Heterogeneous conversion of NO₂ to HONO during at nighttime**

359

360 **3.3.1. The NO₂-to-HONO conversion rate (C_{HONO})**

361

362 In addition to emissions, heterogeneous reaction of NO₂ on surfaces (R4, R5) is
363 believed to be the major formation pathways of nocturnal HONO. Thus, the
364 NO₂-to-HONO conversion rate is calculated from Eq. (5) (Alicke et al., 2002; Alicke,
365 2003; Wentzell et al., 2010), where NO₂ is adopted to scale HONO to reduce the
366 dilution influence according to Su et al. (2008a). Similar to HONO/NO_x (Fig. 2), the
367 nighttime HONO_{corr}/NO₂ ratio rises from the lowest value and then reaches a
368 quasi-stable state, meaning that C_{HONO} can actually be used to assess how quickly
369 HONO_{corr}/NO₂ can increase to its equilibrium.

370

$$371 \quad C_{\text{HONO}} = \frac{\frac{[\text{HONO}_{\text{corr}}]_{(t_2)} - [\text{HONO}_{\text{corr}}]_{(t_1)}}{[\text{NO}_2]_{(t_2)} - [\text{NO}_2]_{(t_1)}}}{t_2 - t_1} \quad (7)$$

372

373 Following the method of Xu et al. (2015) and Li et al. (2018), 137 cases in which
374 HONO_{corr}/NO₂ increased almost linearly from 18:00 to 24:00 each night are selected,
375 and the slope fitted by the least linear regression for HONO_{corr}/NO₂ against time is
376 just the conversion frequency of NO₂ to HONO. The derived C_{HONO} vary from
377 0.0043±0.0017 h⁻¹ in winter to 0.0066±0.0040 h⁻¹ in summer, with an average value
378 of 0.0055±0.0032 h⁻¹, which is in the range (0.004-0.014 h⁻¹) shown by other studies
379 in urban and suburban sites (Fig. 5). Noting that C_{HONO} assumes all the increase of
380 HONO_{corr}/NO₂ is caused by the conversion of NO₂, excluding other possible sources
381 of HONO (e.g. soil nitrite); and the computed C_{HONO} is the net NO₂-to-HONO
382 conversion rate since the measured HONO_{corr} has already taken the sinks of HONO
383 (mainly deposition) into account. Considering the uncertainties of C_{HONO}, utilizing
384 C_{HONO} directly to analyze the mechanism of HONO formation thoroughly may not be
385 appropriate, but it could be attemptable to facilitate the parameterizations for HONO
386 production in air quality models by C_{HONO} when the chemical mechanisms are not

387 clear yet.

388

389 **3.3.2. RH dependence of HONO chemistry**

390

391 It appears that NO₂ hydrolysis on humid surfaces (R4), having a first order
392 dependence on NO₂ (Jenkin et al., 1988; Ackermann, 2000; Finlayson-Pitts et al., 2003),
393 is influenced by the surface absorbed water (Kleffmann et al., 1998; Finlayson-Pitts et
394 al., 2003), although the exact mechanisms are still unknown. In the studies of Stutz et
395 al. (2002) and Stutz et al. (2004), the pseudo steady state of HONO/NO₂, where this
396 ratio is at a maximum at nighttime, is presumed to be a balance between the
397 production of HONO from NO₂ and the loss of HONO on surfaces, and the highest
398 HONO/NO₂ value is determined by the ratio of the reactive uptake coefficients for
399 each process. Scatter plot of HONO_{corr}/NO₂ against relative humidity in our study are
400 illustrated in Fig. 6. To eliminate as much influence of other factors as possible, the
401 average of the 6 highest HONO_{corr}/NO₂ values in each 5% RH interval is calculated,
402 according to Stutz et al. (2004). The phenomenon that HONO_{corr}/NO₂ first increases
403 and then decreases with an increasing RH in Fig. 6(a) was also observed by other
404 studies (Hao et al., 2006; Yu et al., 2009; Li et al., 2012; Wang et al., 2013). The
405 dependencies of HONO_{corr}/NO₂ on RH and the possible reasons or mechanisms are
406 discussed as follows. Even at the lowest measured RH of 18%, the absolute moisture
407 content in the atmosphere is still greater than 10³ ppm in our study, which is quite
408 abundant to react with NO₂, but the HONO_{corr}/NO₂ ratio is quite small and remains
409 unchanged when RH is below 45%, indicating that the NO₂ to HONO conversion
410 efficiency should be determined by water covering the surfaces, rather than by the
411 amount of water in the air.

412

413 It has been reported that surfaced absorbed water depends on RH values, and the
414 dependences vary for different material surfaces of the ground, but generally follow
415 the shape of a BET isotherm (Lammel, 1999; Saliba et al., 2001; Sumner et al., 2004).
416 The number of mono-layers of water increases slowly from zero to 2-4, accompanied
417 by RH from zero to a turning point, and the water coverage grows dramatically (up to

418 10-100 mono-layers) once RH exceeds the turning point (Finlayson-Pitts et al., 2003).
419 Fig. 6(a) shows the case where the surface for NO₂ converting to HONO is dominated
420 by the ground, the HONO_{corr}/NO₂ increases along with RH when RH is less than 75%,
421 which can be explained by the reaction of NO₂ to generate HONO on wet surfaces.
422 However, a negative correlation between HONO_{corr}/NO₂ and RH is found when RH is
423 over 75%, presumably because that the rapidly growing aqueous layers of the ground
424 surface lead to efficient uptake of HONO and make the surface less accessible or less
425 reactive for NO₂. Hence, the RH turning point for absorbed water on ground surfaces
426 is perhaps around 75% for our observation, within the range of results from
427 experiments on various surfaces (70-80% RH) (Lammel, 1999;Saliba et al.,
428 2001;Sumner et al., 2004). Once RH exceeds 95%, the reaction surface is
429 asymptotically approaching the state of water droplet, where the quite limited
430 formation of HONO and the extremely impactful loss of HONO will result in a
431 dramatic decline of the HONO_{corr}/NO₂ ratio (Fig. 6(a) and Fig. 6(b)).

432

433 Notably, the constant HONO_{corr}/NO₂ value at RH between 75-95% under the
434 condition of high PM_{2.5} mass loading (Fig. 6(b)), compared to the downward trend of
435 HONO_{corr}/NO₂ within the same humidity range in low PM_{2.5} mass concentration (Fig.
436 6(a)), implies a contribution of aerosol surfaces to the NO₂-HONO conversion. Since
437 both HONO_{corr}/NO₂ in Fig. 6(a) and Fig. 6(b) are affected by the ground surfaces, we
438 can use the difference of HONO_{corr}/NO₂ between the two figures to represent the
439 influence of aerosol. As the area of shadow showed in Fig. 6(b), the aerosol-affected
440 HONO_{corr}/NO₂ is positively related to RH before RH reaches 95%. With the increase
441 of RH, the hygroscopic growth of aerosol particles should provide larger surface area.
442 When RH is higher than 75%, which has exceeded the mutual deliquescence relative
443 humidity of inorganic salts (Fountoukis and Nenes, 2007), aerosols will transfer to
444 aqueous phase gradually, and then promoting multiphase or heterogeneous chemistry
445 processes (Herrmann et al., 2015). For example, the oxidation of SO₂ by NO₂ on
446 aqueous aerosol surface may produce NO₂⁻/HONO efficiently under polluted
447 condition (Xie et al., 2015;Wang et al., 2016). In addition, the enhancement NO₂

448 uptake on micro-droplets by anions has been reported in experiments (Yabushita et al.,
449 2009)

450

451 *3.3.3. Impact of aerosols on HONO formation*

452

453 To further understand the heterogeneous formation of HONO on aerosol, we carry out
454 a correlation analysis when $\text{HONO}_{\text{corr}}/\text{NO}_2$ reaches the pseudo steady state at each
455 night (3:00-6:00 LT). The convergence or diffusion processes of gases and particles
456 caused by the decrease or increase of the boundary layer height can also lead to a
457 consistent trend of $\text{HONO}_{\text{corr}}$ and $\text{PM}_{2.5}$ (Fig. 7a), while the ratio of $\text{HONO}_{\text{corr}}$ and
458 NO_2 can not only reduce this physical effect but also represent the conversion degree
459 of NO_2 to HONO, so a moderate positive correlation between $\text{HONO}_{\text{corr}}/\text{NO}_2$ and
460 $\text{PM}_{2.5}$ ($r=0.35$, $p=0.01$) throughout the observation period could be more convincing
461 (Fig. 7b). As shown by larger triangles with gray borders in Fig. 7(b), $\text{HONO}_{\text{corr}}/\text{NO}_2$
462 is better correlated with $\text{PM}_{2.5}$ in the months when the mass concentrations of $\text{PM}_{2.5}$
463 are higher during this 1-year measurement, generally occurring from November to
464 May (Fig. 1d). This finding can be explained with a law that greater contributions of
465 NO_2 heterogeneously reacting on aerosol surface to HONO cause better correlations
466 between $\text{HONO}_{\text{corr}}/\text{NO}_2$ and $\text{PM}_{2.5}$. Interestingly, this relationship can also be divided
467 approximately into two groups by NH_3/CO ; the correlation is good when the value of
468 NH_3/CO is lower than 2‰, but when NH_3/CO is higher than 2‰, a poor correlation is
469 found. We will discuss this phenomenon further in section 4. The evidence of HONO
470 formation on aerosol were also found in other observations (Reisinger, 2000; Wang,
471 2003; Li et al., 2012; Nie et al., 2015; Hou et al., 2016; Cui et al., 2018).

472

473 As is known, producing HONO is not the dominant sink of NO_2 at night, but it seems
474 that more NO_2 can be converted to HONO under conditions of heavy pollution (Fig.
475 7b). We discuss whether heterogeneous reactions of NO_2 on aerosols are able to
476 provide comparable HONO with our measurement by Eq. (8), only considering
477 HONO formation on particle surfaces and assuming that HONO principally settles on

478 the ground surface, neglecting HONO loss on aerosol. c_{NO_2} is the mean molecular
 479 velocity of NO_2 (370m/s); $[\frac{S}{V}]_{\text{aer}}$ is the surface area to volume ratio (m^{-1}) of aerosol;
 480 v_{HONO} is the deposition velocity of HONO, which is considered to be close to the
 481 deposition velocity of NO_2 at night (Stutz et al., 2002;Su et al., 2008a); and a
 482 approximate value of 0.1cm/s is used based on the measurements from Coe and
 483 Gallagher (1992) and Stutz et al. (2002); H is the boundary layer mixing depth, and a
 484 value of 100m is assumed for nighttime (Su et al., 2008a).

485

$$486 \quad C_{\text{HONO}} = \frac{1}{4} \gamma_{\text{NO}_2 \rightarrow \text{HONO}} c_{\text{NO}_2} [\frac{S}{V}]_{\text{aer}} - \frac{v_{\text{HONO}}}{H} \frac{[\text{HONO}]}{[\text{NO}_2]} \quad (8)$$

487

488 Considering at nighttime period with severe haze, the aerosol surface density
 489 calculated from the particle number size distributions between 6 nm and 800 nm is
 490 about $1.2 \times 10^{-3} \text{ m}^{-1}$, matched by $200 \mu\text{g}/\text{m}^3$ of $\text{PM}_{2.5}$ from our observations, and the
 491 averaged mixing ratios of HONO and NO_2 are 1.15 ppb and 28.4 ppb, respectively
 492 (Table 2). For 30%-100% of the measured mean C_{HONO} (0.0043 h^{-1}) in winter, the
 493 uptake coefficient of NO_2 -to-HONO ($\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$) calculated from Eq. (8) is in the range
 494 of 6.9×10^{-6} to 1.44×10^{-5} , consistent with the results from many laboratory studies
 495 which demonstrate that the uptake coefficients of NO_2 (γ_{NO_2}) on multiple aerosol
 496 surfaces or wet surfaces are mainly distributed around 10^{-5} with the HONO yield
 497 varying from 0.1 to 0.9 (Grassian, 2002;Aubin and Abbatt, 2007;Khalizov et al.,
 498 2010;Han et al., 2017). It is necessary to elaborate that: (1) the ambient particles were
 499 dried with silica gel before measuring their number size distributions, and the mass
 500 concentrations of $\text{PM}_{2.5}$ were also measured under a system where the temperature
 501 was maintained at 30°C , usually above ambient temperature; (2) the aerosol surface
 502 was calculated by assuming that all particles are spherically shaped, but the particles
 503 could in fact have irregular bodies and porous structure; (3) the particle size of both

504 PM_{2.5} and derived $[\frac{S}{V}]_{\text{aer}}$ is just a part of the total suspended particulate matter. As
 505 described, the aerosol surface in the atmosphere is actually underestimated in our
 506 study, thus the $\gamma_{\text{NO}_2 \rightarrow \text{HONO}}$ we derived could be the upper limit of the uptake coefficient
 507 for NO₂ conversion to HONO on aerosol. In addition to particles surfaces, other
 508 aerosol parameters such as surface water content, chemical composition, pH value,
 509 and phase state of surfaces may also influence the heterogeneous formation of
 510 HONO.

511

512 *3.4. Missing daytime HONO source*

513

514 After discussing the nocturnal formation mechanism of HONO, we now focus on
 515 the chemistry of daytime HONO whose concentrations are still about 0.25-0.6 ppb at
 516 noon with a lifetime of only 10-20 min (Fig. 2). We are not certain if the observed
 517 HONO can be provided by known mechanisms (gas phase reaction (R4) and
 518 emissions) to date, so a budget equation of daytime HONO (Eq. 9) is utilized to
 519 analyze its source and sinks (Su et al., 2008b;Sörgel et al., 2011). Here, dHONO/dt is
 520 the change rate of the observed HONO. The sources rates of HONO contain the
 521 homogeneous formation rate ($P_{\text{NO}+\text{OH}}$, R3); the combustion emission rate (P_{emis}); and
 522 the unknown HONO daytime source (P_{unknown}). The sink rates of HONO consist of the
 523 photolysis rate (L_{phot} , R1); the reaction rate of HONO with OH ($L_{\text{HONO}+\text{OH}}$, R2); and
 524 the dry deposition rate (L_{dep}). T_v and T_h represent the vertical (T_v) and horizontal (T_h)
 525 transport processes of HONO, which are thought to be negligible for intense radiation
 526 and relatively homogeneous atmospheres with generally calm winds (Dillon, 2002;Su
 527 et al., 2008b;Sörgel et al., 2011).

528

$$529 \quad \frac{d\text{HONO}}{dt} = (P_{\text{NO}+\text{OH}} + P_{\text{emis}} + P_{\text{unknown}}) - (L_{\text{phot}} + L_{\text{HONO}+\text{OH}} + L_{\text{dep}}) + T_v + T_h \quad (9)$$

530

531 Therefore, the undiscovered daytime source of HONO (P_{unknown}) can be derived by Eq.
 532 (10), which is a deformation of Eq. (9) without minor terms (T_v and T_h) and where

533 $d\text{HONO}/dt$ is substituted by $\Delta\text{HONO}/\Delta t$ that is counted as difference between
 534 observed HONO at two time points. The reaction rate constants of reaction 2
 535 ($k_{\text{HONO}+\text{OH}}$) and reaction 3 ($k_{\text{NO}+\text{OH}}$) are $6.0 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ and 9.8×10^{-12}
 536 $\text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$, respectively (Atkinson et al., 2004). The emission ratio of
 537 HONO and NO_x ($\text{HONO}/\text{NO}_x=0.79\%$) obtained in section 3.2, is used to estimate
 538 P_{emis} . For L_{dep} , the dry deposition velocity of diurnal HONO (v_{HONO}) is measured as
 539 2 cm/s in the work of Harrison et al. (1996), and a practical mixing height of 200 m is
 540 adopted, considering that most of the HONO cannot rise above this altitude due to
 541 rapid photolysis (Alicke et al., 2002). Although we did not observe OH radicals
 542 directly, the uncertainty of P_{unknown} caused by the calculated OH radicals from Eq. (2)
 543 can be reduced substantially in the case of low concentration of NO and high value of
 544 $J(\text{O}^1\text{D})$ (Fig. S1(d)).

545

$$\begin{aligned}
 P_{\text{unknown}} = & J(\text{HONO})[\text{HONO}] + k_{\text{HONO}+\text{OH}}[\text{HONO}][\text{OH}] + \frac{v_{\text{HONO}}}{H}[\text{HONO}] \\
 & + \frac{\Delta\text{HONO}}{\Delta t} - k_{\text{NO}+\text{OH}}[\text{NO}][\text{OH}] - \frac{0.79\% \times \Delta\text{NO}_x}{\Delta t}
 \end{aligned} \quad (10)$$

547

548 Fig. 8 shows the average daytime HONO budget from 8:00 LT to 16:00 LT during
 549 different seasons. The major loss route of HONO is photodecomposition (L_{phot}) with
 550 an average value of 1.50 ppb/h around noontime (10:00-14:00 LT) during this
 551 observation period, next to dry deposition (L_{dep}) whose mean value at the same time is
 552 0.21 ppb/h , and by $L_{\text{HONO}+\text{OH}}$ which is less than 5% of that of L_{phot} . For the sources of
 553 HONO around noon, the average homogeneous reaction rate between NO and OH
 554 ($P_{\text{NO}+\text{OH}}$) is 0.63 ppb/h and P_{emis} just gives a tiny part of HONO at a rate of 0.02 ppb/h ,
 555 meaning that most of HONO comes from an unknown source whose average rate
 556 (P_{unknown}) is 1.04 ppb/h , contributing about 61% of the production of HONO.
 557 Comparing summer data, the mean unknown daytime source strength of HONO in
 558 Nanjing is almost at the upper-middle level of those reported in the existing literature:
 559 0.22 ppb/h at a rural site of New York state, USA (Zhou et al., 2002); 0.5 ppb/h in a
 560 forest near Jülich, Germany (Kleffmann, 2005); 0.77 ppb/h in a polluted rural area of

561 the Pearl River Delta, China (Li et al., 2012); 0.98 ppb/h at an urban site in Xi'an,
562 China (Huang et al., 2017); 1.7 ppb/h in an urban area of Santiago, Chile (Elshorbany
563 et al., 2009); 2.95 ppb/h in the urban atmosphere of Jinan, China (Li et al., 2018). In
564 our study, the OH production rate from the missing HONO accounts for about 53% of
565 total $P_{OH}(HONO)$ (Fig. S2), suggesting that the unconventional source of HONO is of
566 significance to atmospheric oxidation.

567

568 Hence, we perform a correlation analysis to explore the potential unknown daytime
569 mechanisms of HONO (Table 3). $P_{unknown}$ is better correlated with NO_2*UVB than
570 with NO_2 or UVB alone in winter, spring and autumn ($p=0.05$), perhaps associated
571 with the photo-enhanced conversion from NO_2 to HONO (George et al.,
572 2005;Stemmler et al., 2006;Stemmler et al., 2007). The average value of $P_{unknown}$
573 normalized by NO_2 is $0.1 h^{-1}$, over 18 times greater than the nighttime conversion rate
574 ($0.0055 h^{-1}$), also implying that $P_{unknown}$ cannot be explained by the nocturnal
575 mechanism of NO_2 -to-HONO. Assuming that the height of a well-mixed boundary
576 layer around noon remains constant for each day, $UVB*NO_2$ and $UVB*NO_2*PM_{2.5}$
577 could be proxies for photo-induced heterogeneous reactions of NO_2 on ground and
578 aerosol surfaces, respectively. We do not have any solid evidence to identify which
579 surfaces (ground or aerosol) are more important to the photo-heterogeneous reaction
580 of NO_2 based on the present analysis. For the same reason, the photolysis of
581 particulate nitrates (NO_3^-) as a source of HONO (Ye et al., 2016;Ye et al., 2017)
582 cannot be determined whether it is momentous in our study. The comparisons of
583 correlation coefficients showed above follow the method provided by Meng et al.
584 (1992).

585

586 Our study suggest that the missing source of HONO should be considered in the air
587 quality forecasting or regional models to characterize atmospheric oxidizing capacity
588 better, especially in warm seasons (spring and summer). Based on the measurement
589 (Fig. S3), the light-induced heterogeneous conversion of NO_2 to HONO on aerosol
590 surfaces and ground surface can be included in simulation works probably, as what

591 did in Lee et al. (2016).

592

593 *4. Semi-quantitative estimation of the contribution from different sources*

594

595 From this and previous studies, we can conclude that not only the concentration of
596 ambient HONO but also the sources of HONO have temporal and spatial patterns,
597 which is supposed to be considered in model studies. Nocturnal HONO is selected to
598 discuss the monthly variations of HONO sources in detail without the uncertainties of
599 daytime HONO formation, the influences of HONO photolysis, and the mixing effect
600 of boundary layer. The heterogeneous reaction of NO₂ on aerosol produces a
601 considerable portion of HONO in relatively polluted months (Dec.-May), but
602 contributes very little less than nothing in clean months (Jun.-Oct.), as seen in section
603 3.3.3. Coincidentally, direct emissions from burning processes of HONO decrease
604 from their peak values from winter to summer (section 3.2). However, the monthly
605 averaged ratios of HONO and NO_x are highest in summer, which conflicts with the
606 two sources mentioned above.

607

608 As is known, higher NO₂-to-HONO conversion level or other NO_x-independent
609 sources can cause an increase in the HONO/NO_x ratio. For the case of a mostly
610 constant surface with low reactivity due to the prolong exposure to oxidizing gases
611 and radiation, the yield of nighttime HONO from NO₂ reacting on ground surfaces
612 could be imprecisely assumed to be unchanged. Thus, soil nitrite formed through
613 microbial activities, especially nitrification by ammonia-oxidizing bacteria
614 (NH₄⁺→NO₂⁻) (Su et al., 2011;Oswald et al., 2013), is adopted to be an source for
615 atmospheric HONO in this study, considering the nearby presence of some grassland
616 and natural vegetation mosaics. Although we do not directly measure HONO
617 emissions from soil, the observed ammonia can represent its monthly average
618 intensity indirectly, based on the following hypothesis: the dominant source of NH₃ is
619 from soil, especially from fertilizers (NH₄⁺→NH₃) for a good correlation between
620 ammonia and temperature in the site (r=0.63, p=0.01), omitting the contributions of
621 livestock to NH₃ since there is only a small poultry facility within 10 km of this site

622 (Meng et al., 2011;Huang et al., 2012;Behera et al., 2013). Combustion sources
623 (vehicles, industry, biomass burning) should contribute only a fraction of NH_3 seeing
624 that NH_3 is not related to NO_x or CO in our study. Moreover, the release of both
625 HONO and NH_3 depend on the strength of microbial activities, fertilizing amount, and
626 soil properties (e.g., temperature, acidity and water content of soil). Although the
627 processes of HONO and NH_3 emission from soil may not be completely synchronized,
628 the seasonal patterns for each should be consistent.

629

630 Until now, we can separate the sources of HONO into four parts: (1) the combustion
631 emissions from vehicles and industries (HONO_{emi}) with a constant emitted
632 HONO/ NO_x ratio of 0.79%; (2) the conversion of NO_2 to HONO on the ground
633 surfaces (HONO_{grd}) with a constant but unknown yield x_1 ; (3) the conversion of NO_2
634 to HONO on aerosol surfaces (HONO_{aer}) with a $\text{PM}_{2.5}$ -dependent yield
635 ($\text{HONO}_{\text{aer}}/\text{NO}_2$); and (4) emission from soil (HONO_{soi}), expressed by corrected NH_3
636 multiplied by an unknown coefficient x_2 . The corrected NH_3 is obtained by
637 subtracting combustion emission from total observed ammonia. Ammonia from
638 combustion is found to be proportional to simultaneous CO (Meng et al., 2011;Chang
639 et al., 2016), and a proportion of 0.3%, which is in the lower quantile of the
640 NH_3/CO ratios in fresh air masses (for hourly data: $\text{NO}/\text{NO}_x > 0.75$; $\text{UVB} = 0$;
641 $\text{temperature} < 5^\circ\text{C}$) is used from our measurements. Substituting monthly average
642 values of measured HONO, NO_2 , $\text{PM}_{2.5}$, NH_3 , and CO into Eq.(11) by assuming that
643 HONO_{tot} is equal to HONO_{obs} , we can get an overdetermined system of equations,
644 which have 11 equations with 2 unknowns (excluding mean values of related
645 parameters from February), and then we derive an approximate solution ($x_1 = 1.89\%$,
646 $x_2 = 1.62\%$) by the method of ordinary least squares.

647

648 Fig. 9 shows that an average of 36% of HONO is produced heterogeneously on
649 ground surfaces without perceptible temporal variations, but the contribution of this
650 source is overtaken by NO_2 converting to HONO on aerosols in January
651 (approximately 40% of HONO), and was exceeded by soil emission in July and

652 August (approximately 40% of HONO). The seasonal variations of HONO from
653 different pathways at night indicate that short-term observations may just capture a
654 small part of the total picture when exploring the source mechanisms of HONO. The
655 total HONO concentration (HONO_{tot}) is the sum of derived HONO from the four
656 sources listed above. The good correlation between HONO_{tot} and HONO_{obs} and the
657 low mean normalized error of HONO_{tot} to HONO_{obs} reveal that our assumption on
658 nocturnal HONO sources is reasonable. It should be noted that the slope of the
659 linearly fitted line between $\text{HONO}_{\text{corr}}/\text{NO}_2$ and $\text{PM}_{2.5}$ in spring ($r=0.74$, $\text{slope}=0.68\%$)
660 is much higher than that in winter ($r=0.60$, $\text{slope}=0.20\%$), but we just use a mean
661 slope of 0.26% to evaluate aerosol effects throughout the year, this may be why our
662 method underestimates HONO in March and April and overestimates HONO in
663 January, and indicating that the mass concentration of $\text{PM}_{2.5}$ is not the only factor
664 affecting formation of HONO on aerosols. Besides, lacking considerations of the
665 impact of RH and temperature on NO_2 -to-HONO conversion and of seasonal
666 variations in ground surface properties, uncertainties of NO_2 -to-HONO conversion
667 mechanisms and of combustion HONO emissions, and lacking direct observation for
668 soil emitted HONO, could all result in the bias between HONO_{tot} and HONO_{obs} , so
669 more studies on the detailed mechanism of various HONO sources need to be
670 performed.

671

$$\begin{aligned}
\frac{[\text{HONO}_{\text{grd}}]}{[\text{NO}_2]} &= x_1 \\
\frac{[\text{HONO}_{\text{aer}}]}{[\text{NO}_2]} &= 0.26\% \times [\text{PM}_{2.5}] \\
\frac{[\text{HONO}_{\text{emi}}]}{[\text{NO}_x]} &= 0.79\% \\
\frac{[\text{HONO}_{\text{soi}}]}{[\text{NH}_3] - 0.3\% \times [\text{CO}]} &= x_2 \\
[\text{HONO}_{\text{tot}}] &= [\text{HONO}_{\text{emi}}] + [\text{HONO}_{\text{soi}}] + [\text{HONO}_{\text{grd}}] + [\text{HONO}_{\text{aer}}]
\end{aligned} \tag{11}$$

673

674 **5. Conclusions**

675

676 Continuous field measurement of HONO over 1 year was conducted at the SORPES

677 station in Nanjing in the western YRD of China, from December 2017 to
678 December2018. The observed seasonal average concentrations of HONO are in the
679 range of 0.45-1.04 ppb, which are comparable to those in other urban or suburban
680 regions and appears to be of vital importance to atmospheric oxidation as the OH
681 production rate of HONO is almost 3 times as that of ozone at daytime. HONO and
682 NO_x have coincident monthly variations peaking in December and decreasing to the
683 lowest value in August, and have similar diurnal pattern with the highest value in the
684 early morning and a low point in the late afternoon, both indicating that NO_x is a
685 crucial precursor of HONO.

686

687 Combustion emissions contribute an average of 23% to nocturnal HONO
688 concentrations, with an average emission ratio $\Delta\text{HONO}/\Delta\text{NO}_x$ of 0.79%. During the
689 nighttime, the dominant source of RH-dependent HONO could be the heterogeneous
690 reaction of NO₂ on wet ground or aerosol surfaces with a mean estimated conversion
691 rate of 0.0055 h⁻¹. During the daytime, a missing HONO source with an average
692 strength of 1.04 ppb/h was identified around noon, contributing about 61% of the
693 production of HONO and seeming to be photo-enhanced. HONO released from soil is
694 adopted to discuss the seasonal changes of nocturnal HONO, and can contribute 40%
695 to HONO during summer. Ground formation provides a major part of HONO at a
696 roughly constant proportion of 36%. The uptake of NO₂ on aerosol surface could
697 generate the greatest amount of HONO during heavily polluted periods (e.g. January).
698 Our results draw a complete picture of the sources of HONO during different seasons,
699 and demonstrated the needs of long-term and comprehensive observations to improve
700 the understanding of HONO chemistry.

701

702 *Data availability.* Measurement data at SORPES, including HONO data and relevant
703 trace gases and aerosol data as well as meteorological data, are available upon request
704 from the corresponding author before the SORPES database is open to the public.

705

706 *Author contribution.* W.N. and A.D. designed the study; Y.L. and W.N. wrote the
707 manuscript; Y.L., Z.X. and R.X. collected the HONO data and contributed to the data
708 analysis; T.W., Y.L., L.W. and X.C. collected other related data, e.g. NH₃, NO_x and
709 PM_{2.5}.

710

711 *Competing interests.* The authors declare that they have no conflict of interest.

712

713 *Acknowledgments.* This work was mainly funded by the National Key R&D Program
714 of China (2016YFC0202000 and 2016YFC0200500), the National Natural Science
715 Foundation of China (NSFC) project (D0512/41675145 and D0510/41605098), and
716 Jiangsu Provincial Science Fund (BK20160620). Data analysis was also supported by
717 other NSFC projects (D0512/41875175 and D0510/91644218).

Tables

Table 1. Sources and sinks for nitrous acid (HONO) in the troposphere.

Budget	Occurrence	Pathways	Abbr.
Sinks	Only daytime	$\text{HONO} + h\nu \xrightarrow{320-400\text{nm}} \text{OH} + \text{NO}$	R1
	Mainly daytime	$\text{HONO} + \text{OH} \rightarrow \text{NO}_2 + \text{H}_2\text{O}$	R2
	All day	Deposition/heterogeneous loss on aerosol	/
Sources	Mainly daytime	$\text{NO} + \text{OH} \xrightarrow{\text{M}} \text{HONO}$	R3
	Mainly nighttime	$2\text{NO}_{2(\text{g})} + \text{H}_2\text{O}_{(\text{ads})} \xrightarrow{\text{surf}} \text{HONO}_{(\text{g})} + \text{HNO}_{3(\text{ads})}$	R4
	Mainly daytime	$\text{NO}_{2(\text{g})} + \text{HC}_{\text{red}} \xrightarrow{\text{surf}} \text{HONO}_{(\text{g})} + \text{HC}_{\text{ox}}$	R5
	Only daytime	$\text{HNO}_3 / \text{NO}_3^- + h\nu \xrightarrow{\text{surf}} \text{HONO} / \text{NO}_2^- + \text{O}$	R6
	All day	Release of soil nitrite	/
	All day	Combustion emission(fossil and biomass)	/

Table 2. Overview of the measured HONO and NO_x levels in Nanjing and comparison with other urban or suburban sites.

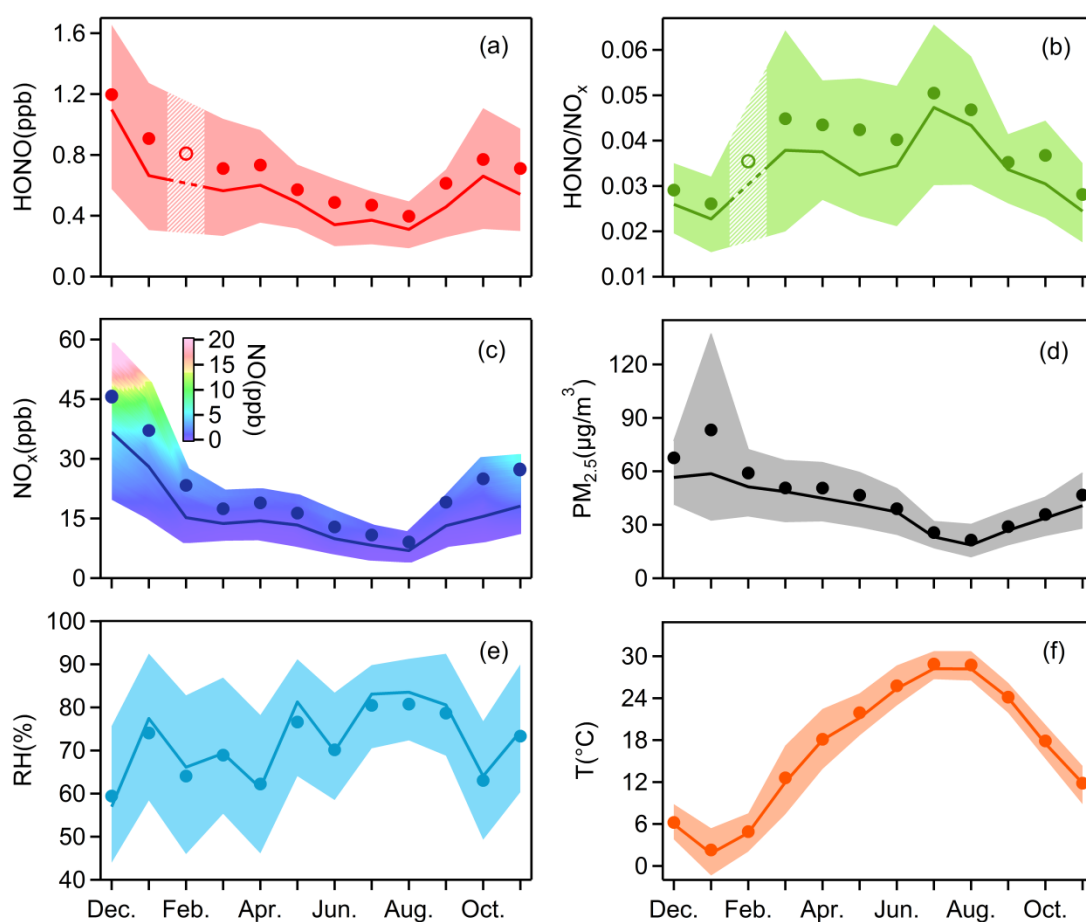

Location	Date	HONO(ppb)		NO ₂ (ppb)		NO _x (ppb)		HONO/NO ₂		HONO/NO _x		Ref

1151
1152 **Fig. 1.** Monthly variations of (a) HONO, (b) HONO/NO_x, (c) NO_x, (d) PM_{2.5}, (e) RH and (f) T.
1153 The solid bold lines are median values, the markers indicate mean values, and the shaded areas
1154 represent percentiles of 75% and 25%. In (a) and (b), values in February are linearly interpolated
1155 based on the data from the months before and after, since there were only few days when HONO
1156 was observed in February. In (c), the shaded area is colored by the 25th to the 75th percentiles of
1157 NO.

Fig. 5. Comparison of observed NO₂ to HONO conversion rates in cities: Nanjing (this study); Mainz (Lammel, 1999); Hongkong (Xu et al., 2015); Jinan (Li et al., 2018); Shanghai (Wang et al., 2013); Beijing (Wang et al., 2017); Milan (Alicke et al., 2002); and Kathmandu (Yu et al., 2009).

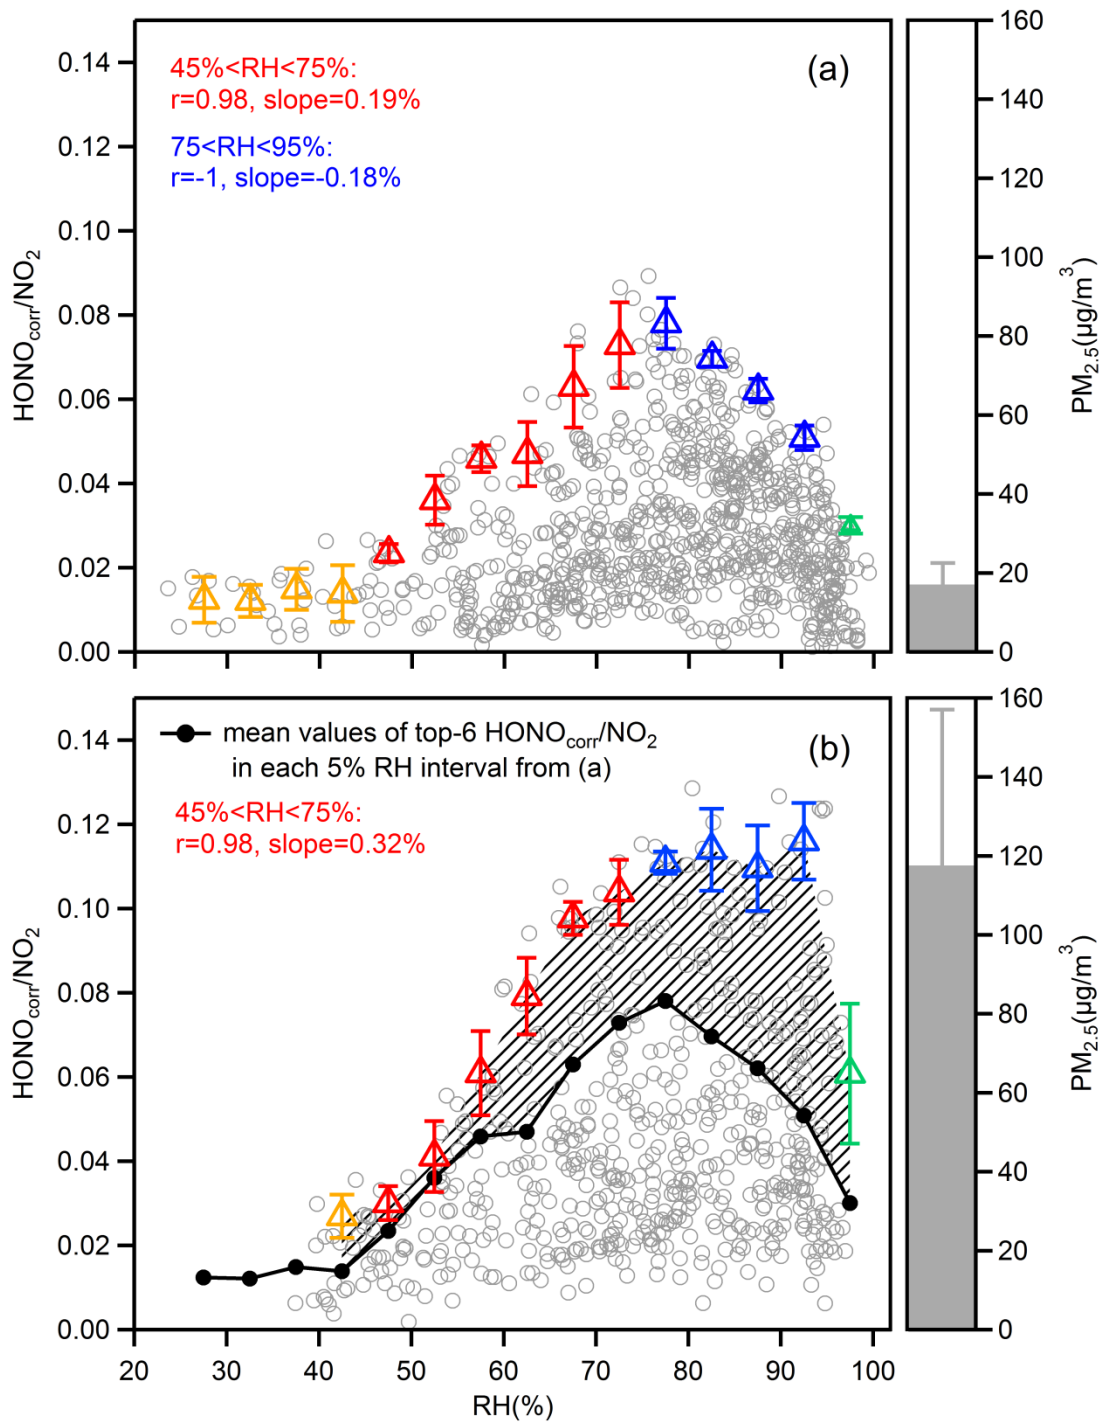

Fig. 6. Scatter plot of the $\text{HONO}_{\text{corr}}/\text{NO}_2$ ratio and RH during nighttime, separating the data into (a) clean hours (hourly mean $\text{PM}_{2.5} < 25 \mu\text{g}/\text{m}^3$) and (b) polluted hours (hourly mean $\text{PM}_{2.5} > 75 \mu\text{g}/\text{m}^3$). Triangles are the averaged top-6 $\text{HONO}_{\text{corr}}/\text{NO}_2$ in each 5% RH interval, and the error bars are the standard deviations. The overall average concentrations of $\text{PM}_{2.5}$ in (a) and (b) are shown to the right of the figures.

Fig. 7. (a) The correlation between $\text{HONO}_{\text{corr}}$ and $\text{PM}_{2.5}$, and (b) the correlation between $\text{HONO}_{\text{corr}}/\text{NO}_2$ and $\text{PM}_{2.5}$, all scatters come from the time (3:00–6:00 LT) when the $\text{HONO}_{\text{corr}}/\text{NO}_2$ ratio reaches the pseudo steady state at each night and are colored by NH_3/CO . In (b), the larger triangles with gray borders, depict the measured data from November to May, and the boxplot in each $30 \mu\text{g}/\text{m}^3$ interval of $\text{PM}_{2.5}$ is illustrated according to the same data, the red box boundaries represent interquartile range, the whiskers represent the 10%–90% percentile range, the horizontal red lines represent median values and the red markers represent mean values. The correlation coefficient and the slope of the linearly fitted line in (b) are derived from the averaged $\text{HONO}_{\text{corr}}/\text{NO}_2$ and averaged $\text{PM}_{2.5}$ in each box.

1184

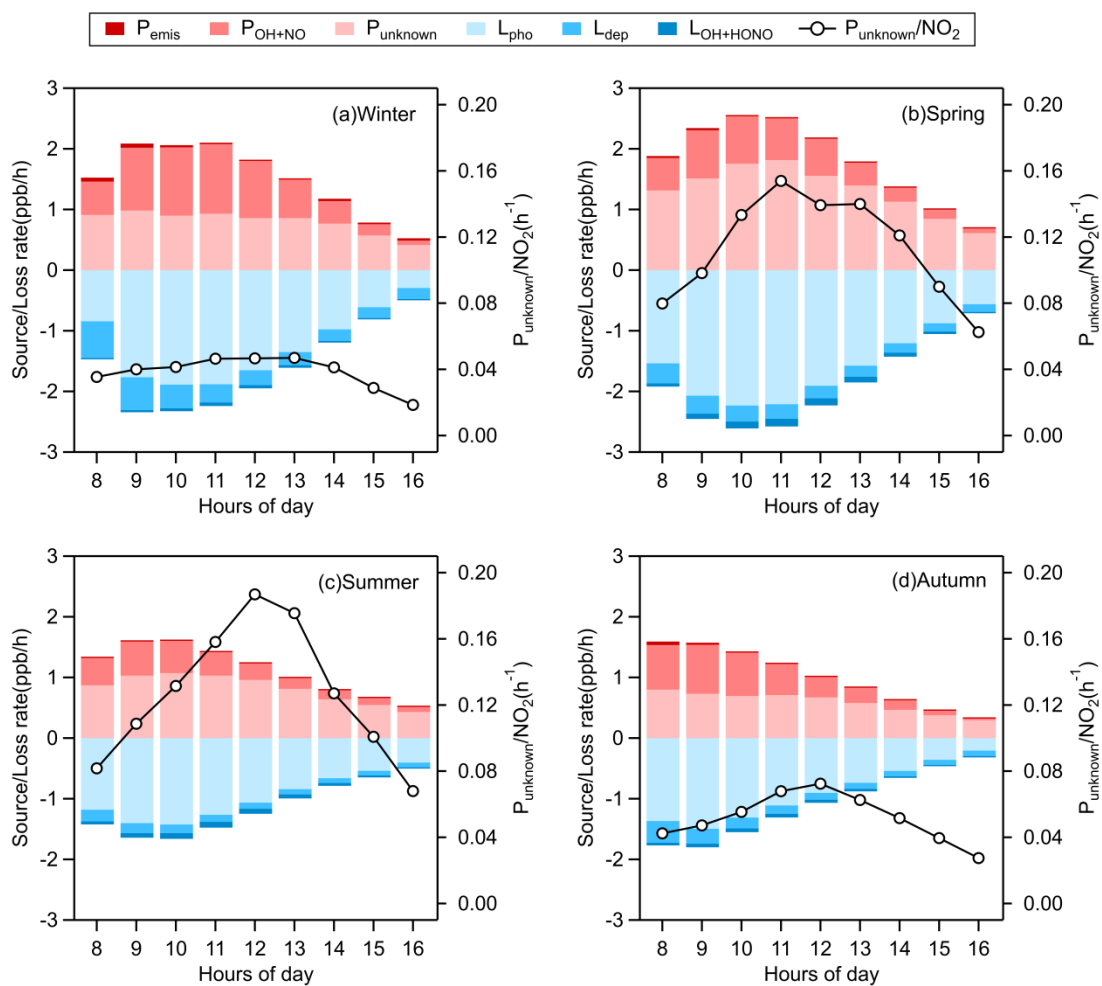

Fig. 8. Averaged daytime HONO budget and the missing source strength (P_{unknown}) normalized by NO_2 in (a) winter, (b) spring, (c) summer, and (d) autumn. The mean values of P_{unknown} around noontime (10:00-14:00 LT) are: 0.91 ppb/h in winter, 1.61 ppb/h in Spring, 0.98 ppb/h in summer, 0.68 ppb/h in autumn.

Fig. 9. Seasonal variations of 4 sources of HONO at night (3:00-6:00 LT). The mean normalized error (MNE) of HONO_{tot} to HONO_{obs} is 6.42%.
