Size-resolved Composition and Morphology of Particulate Matter During the Southwest Monsoon in Metro Manila, Philippines

Melliza Templonuevo Cruz, Paola Angela Bañaga, Grace Betito, Rachel A. Braun, Connor Stahl, Mojtaba Azadi Aghdam, Maria Obiminda Cambaliza, Hossein Dadashazar, Miguel Ricardo Hilario, Genevieve Rose Lorenzo, Lin Ma, Alexander B. MacDonald, Preciosa Corazon Pabroa, John Robin Yee, James Bernard Simpas, Armin Sorooshian

Reviewer #1 Report:

1. The authors have generally addressed most of the concerns raised in the review. They have moderated their speculation on the representativeness of the single BC measurement adequately. The only remaining comment I have is regarding their discussion of the updated aged aerosol factor.

Section 3.3.1 and the conclusion in section 4 have been updated to re-characterize the first PMF factor as "Aged Aerosol" with less emphasis on transport from distant regions. The intent was to indicate some contributions from distant sources are still discernible among the larger influence due to local or regional sources. While not critical, I had one suggestion to improve clarity in the description in section 3.3.1. The second paragraph now states:

"This PMF source factor is referred to as Aged Aerosol owing to its characteristic species being linked to secondary particle formation from emissions of local and regional sources. Examples include MSA and DMA being secondarily produced from ocean-derived gaseous emissions (e.g., Sorooshian et al., 2009), and K stemming from biomass burning emissions from upwind regions such as Sumatra and Borneo (Xian et al., 2013)."

The first sentence implies local and regional sources are the main characteristic of the factor. The second sentence then states example include ... MSA, DMA, and K... These are examples of distant transport, not local and regional sources. The authors may wish to add an additional clarification that in addition to these primary components of the factor, some species from more distant sources were detectable, such as ... the examples.

Response: The authors revised this section and now reads as follows:

This PMF source factor is referred to as Aged Aerosol owing to its characteristic species being linked to secondary particle formation from emissions of regional and distant sources. The presence of NH_4^+ and SO_4^{2-} could be attributed to precursors from various local and regional combustion sources, while MSA and DMA are secondarily produced from ocean-derived gaseous emissions (e.g., Sorooshian et al., 2009). Biomass burning emissions from distant upwind regions such as Sumatra and Borneo (Xian et al., 2013) are likely sources of K.

2. In addition, in the conclusion in section 4 they retain two findings:

"The dominant contribution of Aged aerosols to water-soluble mass contradicts two expectations: (i) locally-produced sources in polluted cities should drown out the signal of transported aerosols, and (ii) the signal of transported aerosols should be significantly reduced due to scavenging processes upwind of the measurement site."

The first finding follows more or less from the discussion in 3.3.1, but the second does not. The discussion did not treat the extent to which distant sources were or were not reduced during transport, just that they were detectable as part of the aged PMF factor. I would also echo the comments of reviewer 2's comment here that the authors only really correlate with rainfall at the receptor, not actual meteorology along the transport route. Perhaps the idea behind (ii) should instead be stated as a question for future work in the subsequent paragraphs rather than a finding here.

Response: This part has been edited to:

The dominant contribution of Aged Aerosol to water-soluble mass contradicts the expectation that locally-produced sources in polluted cities should drown out the signal of transported aerosol from distant upwind areas.

As suggested by the reviewer, the comment on the reduction of the signal of transported aerosols has been added to the ideas for future work and the last sentence of the paper now reads as follows:

As the current MOUDI sampling campaign at the Manila Observatory is expected to extend for a full year, future work will focus on changes in aerosol characteristics and sources on a seasonal basis as well as scavenging processes upwind of the measurement site.

3. One last additional specific suggestion:

Section 2.1:

"Trajectory calculations were started at 00, 06, 12, and 18 hours in MO at the height of the MOUDI inlet (~ 12 m above ground level) using meteorological files from the NCEP/NCAR Reanalysis dataset."

While not critical, I typically directly state the HYSPLIT receptor height used to run the model (e.g. HYSPLIT backtrajectories used model run heights of 100 m AGL... or something similar) as actual ground level and ground level in HYSPLIT model datasets often do not agree, so giving the receptor height used is often useful for the purposes of repeatability or comparison by others.

Response: This part has been edited to:

Trajectory calculations were started at 00, 06, 12, and 18 hours in MO using a model run height of 12 m above ground level and meteorological files from the NCEP/NCAR Reanalysis dataset.

4. Lastly, I believe Fig 9 still has a reference to "Aged/Transported Aerosol" rather than "Aged Aerosol"

Response: Figure 9 has been correctly labeled as “Aged Aerosol.”

Reviewer #1:

The authors of this manuscript present a set of size-resolved aerosol measurements made in an urban location in Metro Manila, Philippines during the southwestern monsoon (SWM). Samples were analyzed using a variety of methods to produce average values for both gravimetric and speciated concentrations of particulate matter in twelve, roughly two-day time periods. Results are first compared with general meteorological conditions and transport pathways using a local weather station and the HYSPLIT backtrajectory model. The results were then classified into identified source types influencing the results using PMF.

The study represents a valuable addition to classification of aerosol type and sources impacting Metro Manila during the SWM, in particular through the addition of size-resolved results. The authors' methodology was generally sound and produced findings that are generally consistent with reports of similar studies in other major urban areas. However, several of their primary findings and discussion were not fully supported by the results as presented. In addition, a more thorough description of certain aspects of their experimental setup and analysis are needed to fully understand their work. As a result, I recommend publishing of the manuscript after consideration of several major comments.

Major Comments:

1. The authors present a single short duration period with one measurement of size resolved black carbon aerosol in their dataset. While this is an interesting and useful finding, they over emphasize the extent to which they can claim general representativeness of this result on the wider Manila urban aerosol environment during the SWM. If there is a different interpretation of their results, this needs to be clarified, as it is not apparent in their results as presented. Future work with additional such measurements would be worthwhile and support the current findings, but they should take additional care to not attribute the current BC results to wider claims or conclusions.

Response: To address this comment, the authors have emphasized in many parts of the paper and whenever results of the BC measurements were discussed, that the observations were based on a single MOUDI set only. Nevertheless, visual inspection of all the MOUDI sample sets collected always show black deposits in the supermicrometer range and the filters from Stage 9 (0.18-0.32 μm) were always the blackest. This gives the authors confidence that even though BC was not quantified in all the sample sets, the trends observed in Set 13 may be representative of all the samples collected during the southwest monsoon season. We also agree with the referee comment that additional BC measurements would be important and BC observations in subsequent work will be based on a number of sample sets.

2. The authors conclude that the most common source type identified by PMF analysis, classified as “Aged/Transported aerosol,” is evidence of the influence of a major non-local source. In the conclusions they further state that “the significant presence of Aged/Transported aerosols in Metro Manila indicates that PM in the region has the ability to travel long distances during the SWM season, despite the typical assumption that wet scavenging effectively removes most of the particles.” Non-local sources dominating the Manila aerosol for considerable periods of time (the authors state this factor constituted 48% of PMF classified sources by mass) would indeed constitute a considerable change in the understanding of the sources of particulate matter in Manila, but this conclusion is not supported by the analysis presented here.

Given the results as presented, it would seem this identified PMF type could just as easily be attributed to aged aerosol that includes mixing from various local and regional sources. At the very least the authors need to consider other possible interpretations of this PMF source. Is it possible this source is merely the result of mixing from local and regional sources in circumstances where the aerosol has not been impacted by recent precipitation, and therefore has aged more than other sources?

Response: The authors revisited the “Aged/Transported” aerosol factor from PMF and concluded that indeed, regional and local sources could have influenced this factor and we have changed the name of this factor to just “Aged Aerosol.”

Several open questions need to be answered before this PMF type can be attributed to a non-local source.

- What constitutes a “transported” or non-local aerosol? Smoke transported from biomass burning regions in Borneo or Sumatra that have been transported thousands of kilometers would constitute a considerably different source from an anthropogenic source hundreds of km away in other parts of the Philippines, or from regional sources in cities neighboring Metro Manila.

- Address if markers for various sources constitute actual evidence of such sources dominating the PMF type and observed aerosol, or if they merely constitute mixing of various sources with local aerosol. Do the sources associated with ocean emissions (the authors note MSA and DMA), biomass burning (K is noted), or oxalate production in fact dominate this PMF type? That would not appear to be the case in the mass loadings from Figure 8. Further, NH_4^+ and SO_4^{2-} are observed in other urban areas, why should they constitute evidence of non-local transport here?

- Link the source with precipitation, transport pathways, and aging times. Could precipitation scrubbing or the lack thereof account for the differences between this source and others? The authors note that the source may require aging for production of various measured species, but do not account for what amount of time might be required or if that could be accounted for by local or regional sources, complex meteorology and transport pathways in the region, or differences in precipitation scrubbing of the air mass.

- Account for the high overall mass loading being transported from a non-local source. A consistent non-local accumulation mode aerosol plume with sufficient mass loading to account for the measured mass concentrations should be noted in other measurements (e.g. AOD).

- Validate that the aerosol is not merely aged and associated with complex mixing of local and regional sources already expected to be major sources of aerosol in the region (as correctly noted by the authors).

Response: The authors initially added “Transported” to this PMF factor to account for the presence of markers for ocean emissions and biomass burning. However, as the reviewer has pointed out, the markers for these sources (MSA, DMA, and K) do not dominate this PMF factor. The dominant species for this factor are NH_4^+ and SO_4^{2-} , which are products of secondary particle formation from precursors and could come from local and regional sources.

Classifying this aerosol type as aged aerosol would seem justified by the analysis in section 3.3.1, but it does not necessarily follow that it is therefore a non-local or nonregional source. As this is implied to be a major finding of this work, the authors may wish to revisit this analysis and potentially reframe this source as an aged aerosol with some evidence of mixing with non-local sources.

Response: We thank the reviewer for pointing this out and we have changed this factor from “Aged/Transported” to “Aged Aerosol.” The discussion in Section 3.3.1 has been edited and now reads as follows:

3.3.1 Aged Aerosol

Although not due to one individual source, there was a distinct PMF factor that included species commonly produced via gas-to-particle conversion processes (NH_4^+ , SO_4^{2-} , MSA, oxalate). Correlation analysis (Table 4) also pointed to a large cluster of species significantly related to each other, including the aforementioned ions and a suite of other organic acids (phthalate, succinate, adipate), MSA, and DMA. The latter three inorganic and organic acid ions exhibited significant correlations with each other ($r \geq 0.68$), but also with several elements ($r \geq 0.36$: K, V, Rb, Cs, Sn), which were likely co-emitted with the precursor vapors of the secondarily produced ions. Although BC concentrations were quantified from set MO13 only, the results showed that BC was significantly correlated (r : 0.61-0.92) with 15 species, including those mentioned above (owing to co-emission) and also a few elements that were found via PMF to be stronger contributors to the Combustion source discussed in Section 3.3.3 (Ni, Cu, As, Se, Cd, Tl, Pb).

This PMF source factor is referred to as Aged Aerosol owing to its characteristic species being linked to secondary particle formation from emissions of local and regional sources. Examples include MSA and DMA being secondarily produced from ocean-derived gaseous emissions (e.g., Sorooshian et al., 2009), and K stemming from biomass burning emissions from upwind regions such as Sumatra and Borneo (Xian et al., 2013). Previous studies (Reid et al., 2012; Wang et al., 2013) have shown that phenomena such as SWM and El-Nino events not only influence biomass burning activities in the Malay Peninsula but also impact the transport and distribution of emissions in the study region. For instance, Reid et al. (2016b) showed that enhancement in monsoonal flow facilitates the advection of biomass burning and anthropogenic emissions to the Philippines from Sumatra and Borneo. Subsequent work will investigate more deeply the impact of biomass burning from those upwind regions on the sample site during the SWM.

While NH_4^+ and SO_4^{2-} require time for production owing to being secondarily-produced from precursor vapors (i.e., SO_2 , NH_3), oxalate is the smallest dicarboxylic acid and requires

lengthier chemistry pathways for its production and thus is more likely produced in instances of aerosol transport and aging (e.g., Wonaschuetz et al., 2012; Ervens et al., 2018). The various elements associated with this cluster are co-emitted with the precursors to the aforementioned ions and are linked to a variety of sources: metallurgical processes (Anderson et al., 1988; Csavina et al., 2011; Youn et al., 2016), fuel combustion (Nriagu, 1989; Allen et al., 2001; Shafer et al., 2012; Rocha and Correa, 2018), residual oil combustion (Watson et al., 2004), biomass burning (Maudlin et al., 2015), marine and terrestrial biogenic emissions (Sorooshian et al., 2015), and plastics processing (Fraser et al., 2003). In addition, there is extensive ship traffic in the general study region, which is a major source of species in this cluster of species, particularly V and SO_4^{2-} (e.g., Murphy et al., 2009; Coggon et al., 2012).

PMF analysis suggested that the Aged Aerosol factor contributed 48.0% to the total water-soluble mass budget during the study period. Most of the contribution resided in the submicrometer range (68.9%) unlike the supermicrometer range (18.6%), which is consistent with the overall mass size distribution of total PM peaking in the submicrometer range (Figure 2). The reconstructed mass size distribution for this PMF source factor shows the dominance of the mass in the submicrometer range with a peak between 0.32–0.56 μm (Figure 9). The correlation matrices for the sub- and supermicrometer size ranges also show that the correlations between the species most prominent in the Aged Aerosol category are stronger for the former size range (Tables S2-S3). The contribution of this PMF factor to the supermicrometer range is likely associated with species secondarily produced on coarse aerosol such as dust and sea salt. This is evident in the individual species mass size distributions where there is a dominant submicrometer mode but also non-negligible mass above 1 μm .

Even though the PM in a heavily populated urban region, such as Metro Manila, is typically thought to be dominated by local sources of aerosols, the current PMF results show that contribution from long range transport is still discernible. This finding is contrary to the expectation that the signal of transported aerosols would be lost in the noise of locally-produced aerosols.

The section of the Conclusions, which discussed the “Aged/Transported” aerosol factor, has been revised to read as follows:

- PMF analysis suggested that there were five factors influencing the water-soluble fraction of PM collected at the sampling site. These factors, their contribution to total water-soluble mass, and the main species that permit them to be linked to a physical source are as follows: Aged Aerosol (48.0%; NH_4^+ , SO_4^{2-} , MSA, oxalate), Sea Salt (22.5%; Cl⁻, NO_3^- , Ca^{2+} , Na^+ , Mg^{2+} , Ba, Sr), Combustion (18.7%; Ni, As, Co, P, Mo, Cr), Vehicular/Resuspended Dust (5.6%; Al, Ti, Fe), and Waste Processing (5.1%; Zn, Cd, Pb, Mn, Cu). The dominant contribution of Aged aerosols to water-soluble mass contradicts two expectations: (i) locally-produced sources in polluted cities should drown out the signal of transported aerosols, and (ii) the signal of transported aerosols should be significantly reduced due to scavenging processes upwind of the measurement site. Although the current study focuses exclusively on the SWM season in Metro Manila, results of this study are applicable to the study of aerosol impacts on Southeast Asia and other regions. First, the detection of Aged aerosols not only from local but also from regional sources confirms previous studies that PM in the region has the ability to travel long distances during the SWM season. Characterization of aerosols in Metro Manila is therefore important for better understanding the impacts that local emissions will have on locations downwind of Metro Manila,

including other populated cities in Southeast and East Asia. Transport of pollution and decreased wet scavenging during the SWM season may become increasingly important as studies have shown a decrease in SWM rainfall and increase in the number of no-rain days during the SWM season in the western Philippines in recent decades (e.g., Cruz et al., 2013).

Minor Comments:

1. Experimental setup and site information. Additional information is needed regarding the setup of the measurement system and weather station. In particular, the location and description of the sample inlet and any initial processing of the sample that occurred. The height of the weather station above ground level in addition to the sea level reference, and its location is needed as well (e.g. Is the third floor near the top of the building? Was the station located on the roof? Were any potential sources of bias considered such as wind steering around buildings considered?) From Figure 1 it appears the sampling location is some distance from the nearest major roadway. Has previous work using this sampling location indicated it is generally representative of the local aerosol?

Response: More details about the study site, the location of the MOUDIs and their inlets, and the location of the weather station have been added to Section 2.1. Since the MOUDI inlet was located outside a window on the southern side of the MO Administration building, the authors have considered the potential bias this could pose but we do not expect it to have a significant effect on our results especially since local wind directions (as determined by the weather station located just above the inlet) mostly came from the east and southeast directions. In terms of the local representativeness of the sampling site, source apportionment results at the Manila Observatory by Cohen et al. (2009) are in agreement with that of Kim Oanh et al. (2013), which presented the source apportionment results of data from six different sites in Metro Manila. This indicates that the aerosol collected at the Manila Observatory is representative of Metro Manila aerosol. To address the comments above, Section 2.1, has been edited as follows:

Sampling was performed at MO in Quezon City, Philippines (14.64° N, 121.08° E). Two MOUDIs were placed inside an unoccupied room on the 3rd floor of the MO administration building (~85 m above sea level). The inlet, located just outside the window, consists of a 2 m long stainless steel tube and a reducer that is connected directly to the MOUDI inlet. Figure 1 visually shows the sampling location and potential surrounding aerosol sources. Past work focused on PM_{2.5} suggested that the study location is impacted locally mostly by traffic, various forms of industrial activity, meat cooking from local eateries, and, based on the season, biomass burning (Cohen et al., 2009). This is consistent with another source apportionment study which reported that potential sources in six sites across Metro Manila include traffic, secondary particles, and biomass burning (Kim Oanh et al., 2013).

Meteorological data were collected using a Davis Vantage Pro 2 Plus weather station located on the roof (~90 m above sea level, ~15 m above ground level) above where the MOUDIs were located. Except for precipitation, which is reported here as accumulated rainfall, reported values for each meteorological parameter represent averages for the sampling duration of each aerosol measurement. The mean temperature during the periods of MOUDI sample collection ranged from 24.9 to 28.1° C, with accumulated rainfall ranging widely from no rain to up to 78.4 mm. To

identify sources impacting PM via long-range transport to the Metro Manila region, Figure 1a summarizes the five-day back-trajectories for air masses arriving at MO on the days when samples were being collected, calculated using the NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPPLIT) model (Stein et al., 2015; Rolph, 2016). Trajectory calculations were started at 00, 06, 12, and 18 hours in MO at the height of the MOUDI inlet (~ 12 m above ground level) using meteorological files from the NCEP/NCAR Reanalysis dataset. Trajectory cluster analysis was conducted using TrajStat (Wang et al., 2009). The back-trajectories in Figure 1a show that indeed 66% of the wind came from the southwest during the sampling periods.

2. Usage of HYSPLIT. Were there any other HYSPLIT receptor heights considered. Vertical wind shear can be considerable in the maritime continent, and can alter transport pathways considerably. Table 1 indicates primarily easterly winds. Was there any comparison between backtrajectories and local wind measurements? Were expected transport pathways or HYSPLIT trajectories related in any way to sample results? Local measurements of wind direction, which are more indicative of local transport pathways, were correlated to mass concentrations, but not backtrajectories that are more indicative of long range transport pathways. Does this relate in any way to expected source type or location?

Response: Aside from simulations at the height of the MOUDI inlet, HYSPLIT runs at 500, 1000, and 1500 m above ground level were also performed. Results of these runs consistently showed that 5-day backward trajectories were in general coming from the southwest (~70%), contrary to local wind measurements that show winds coming mostly from the east. It was only during one occasion (Set 13/14 collected on Oct 6-8) that HYSPLIT and local measurements showed the same wind direction. This suggests that contribution from local sources are significant and this was confirmed by the source apportionment results.

3. Description of data collection and usage in various analyses. The experimental methods section 2 would benefit from more clarity regarding how many data points were utilized in the various analyses, and which measurements they came from. It appears that there were 12 sampling periods during which data was collected for PMF analysis, which each consisted of 11 size bins. How was the data prepared for use in the PMF analysis?

Response: The Methods section has been edited for clarity and the comments above have been considered particularly in Sections 2.3 and 2.5.

Section 2.3:

Twelve sample sets, composed of 11 samples each, were analyzed for water-soluble ions and elements (Table 2). In order to preserve samples for additional analysis, each Teflon substrate was cut in half. A half of each substrate was extracted in 8 mL of Milli-Q water (18.2 MΩ-cm) through sonication for 30 min in a sealed polypropylene vial. A blank substrate was processed in the same method to serve as a background control sample. Subsequent chemical analysis of the water-soluble components in the aqueous extracts were performed using ion chromatography (IC; Thermo Scientific Dionex ICS - 2100 system) for the following species: cations = Na⁺, NH₄⁺, Mg²⁺, Ca²⁺, dimethylamine (DMA), trimethylamine (TMA), diethylamine (DEA); anions =, methanesulfonate (MSA), pyruvate, adipate, succinate, maleate, oxalate, phthalate, Cl⁻, NO₃⁻, SO₄²⁻. Owing to co-elution of TMA and DEA in the IC system, a cumulative sum of the two is

reported here, which represents an underestimate of their total mass concentration owing to overlap in parts of their peaks. Limits of detection (LOD) were calculated for each species based on their respective calibration curve (Table S1), with LOD being three times the standard deviation of the residuals (predicted signal minus measured signal) divided by the slope of the calibration curve (Miller and Miller, 2018).

The aqueous extracts were simultaneously characterized for elemental composition using triple quadrupole inductively coupled plasma mass spectrometry (ICP-QQQ; Agilent 8800 Series) for the following species: K, Al, Fe, Mn, Ti, Ba, Zn, Cu, V, Ni, P, Cr, Co, As, Se, Rb, Sr, Y, Zr, Nb, Mo, Ag, Cd, Sn, Cs, Hf, Tl, Pb. Limits of detection of the examined elements were calculated automatically by the ICP-QQQ instrument and were in the ppt range (Table S1). The sample concentrations represent an average of three separate measurements with a standard deviation of 3% or less.

Note that some species were detected by both IC and ICP-QQQ (i.e., Na^+ , K^+ , Mg^{2+} , Ca^{2+}), and that the IC concentrations are used here for all repeated species with the exception of K^+ owing to better data quality from ICP-QQQ. All IC and ICP-QQQ species concentrations for samples have been corrected by subtracting concentrations from background control samples. For more examples of the application of these methods used for substrate collection and IC/ICP analysis, the reader is referred to other recent work (Braun et al., 2017; Ma et al., 2019; Schlosser et al., 2017).

Section 2.5:

This study reports basic descriptive statistics for chemical concentrations and correlations between different variables. Statistical significance hereafter corresponds to 95% significance based on a two-tailed Student's t-test. To complement correlative analysis for identifying sources of species, positive matrix factorization (PMF) modeling was carried out using the United States Environmental Protection Agency's (US EPA) PMF version 5. A total of 132 samples from the 12 sets analyzed for water-soluble ions and elements were used in the PMF analysis. Species concentrations were examined before being inputted to PMF. Species considered as "strong" based on high signal-to-noise ratios ($\text{S/N} > 1$) and those with at least 50% of the concentrations above the LOD were used in the PMF modeling (Norris et al., 2014). This resulted in a $132 (\text{samples}) \times 30 (\text{species})$ data matrix that was inputted to PMF. Data points with concentrations exceeding the LOD had uncertainty quantified as

$$\sigma_{ij} = 0.05 \cdot X_{ij} + \text{LOD}_{ij}, \quad (\text{Equation 1})$$

where σ_{ij} , X_{ij} , and LOD_{ij} are the uncertainty, concentration, and LOD, respectively, of the j th species in the i th sample (Reff et al., 2007). When concentration data were not available for a particular stage of a MOUDI set for a species, the geometric mean of the concentrations for that MOUDI stage and species was applied with uncertainty counted as four times the geometric mean value (Polissar et al., 1998; Huang et al., 1999). A 25% extra modeling uncertainty was applied to account for other sources of errors, such as changes in the source profiles and chemical transformations (Dumanoglu et al., 2014; Norris et al., 2014). The model was run 20 times with a randomly chosen starting point for each run.

Specific comments and technical corrections:

26. Need to specify that particle size is defined on a diameter basis. Also would help to briefly describe the complete range of sizes measurements were made across before describing results in specific size ranges.

Response: The first part of the abstract has been edited to:

This paper presents novel results from size-resolved particulate matter (PM) mass, composition, and morphology measurements conducted during the 2018 Southwest Monsoon (SWM) season in Metro Manila, Philippines. Micro-Orifice Uniform Deposit Impactors (MOUDIs) were used to collect PM sample sets composed of size-resolved measurements at the following aerodynamic cutpoint diameters (D_p): 18, 10, 5.6, 3.2, 1.8, 1.0, 0.56, 0.32, 0.18, 0.10, 0.056 μm . Each sample set was analyzed for mass, morphology, black carbon (BC), and composition of the water-soluble fraction.

28. The authors need to clarify that the Greenfield gap term is in reference to the reduced efficiency of precipitation scavenging of accumulation mode aerosol particles as compared to particles of other sizes. The wording of this sentence seems to imply that either accumulation mode particles exist because of the lack of precipitation scavenging, or that the Greenfield gap describes accumulation mode particles. At the very least “(the so-called Greenfield gap)” should be moved to the end of the sentence.

Response: This section of the abstract has been edited to:

The bulk of the PM mass was between 0.18–1.0 μm with a dominant mode between 0.32–0.56 μm . Similarly, most of the black carbon (BC) mass was found between 0.10–1.0 μm , peaking between 0.18–0.32 μm . These peaks are located in the Greenfield Gap or the size range between 0.10–1.0 μm , where wet scavenging by rain is relatively inefficient.

105/113: Manila Observatory is defined after the first use of MO as an acronym.

Response: This section has been edited to:

Metro Manila has been drawing growing interest for PM research owing to the significant levels of black carbon (BC). A large fraction of PM in Metro Manila can be attributed to BC (e.g., ~50% of $\text{PM}_{2.5}$; Kim Oanh et al., 2006), with previously measured average values of BC at the Manila Observatory (MO) reaching ~10 $\mu\text{g m}^{-3}$ for $\text{PM}_{2.5}$ (Simpas et al., 2014). The impacts of the high levels of BC present on human health have also received attention (Kecorius et al., 2019). Identified major sources of BC include vehicular, industrial, and cooking emissions (Bautista et al., 2014; Kecorius et al., 2017). Vehicular emissions, especially along roadways where personal cars and motorcycles, commercial trucks, and motorized public transportation, including powered tricycles and jeepneys, are plentiful. For instance, measurements of $\text{PM}_{2.5}$ at the National Printing Office (NPO) located alongside the major thoroughfare Epifanio de los Santos Avenue (EDSA)

were on average $72 \mu\text{g m}^{-3}$; this value is twice the average concentration at MO, an urban mixed site located approximately 5 km from NPO (Simpas et al., 2014).

150: Additional detail about the typical duration and strategy for collection of sample sets would be helpful in this paragraph.

Response: Details about the sampling duration and scheduling have been added in Section 2.2. This section has been edited to:

Sampling was performed at MO in Quezon City, Philippines (14.64° N, 121.08° E). Two MOUDIs were placed inside an unoccupied room on the 3rd floor of the MO administration building (~85 m above sea level). The inlet, located just outside the window, consists of a 2 m long stainless steel tube and a reducer that is connected directly to the MOUDI inlet. Figure 1 visually shows the sampling location and potential surrounding sources. Past work focused on $\text{PM}_{2.5}$ suggested that the study location is impacted locally mostly by traffic, various forms of industrial activity, meat cooking from local eateries, and, based on the season, biomass burning (Cohen et al., 2009).

156: State the specific height of the HYSPLIT backtrajectory receptor.

Response: This section has been edited to:

The mean temperature during the periods of MOUDI sample collection ranged from 24.9 to 28.1° C, with accumulated rainfall ranging widely from no rain to up to 78.4 mm. To identify sources impacting PM via long-range transport to the Metro Manila region, Figure 1a summarizes the five-day back-trajectories for air masses arriving at MO on the days when samples were being collected, calculated using the NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Stein et al., 2015; Rolph, 2016). Trajectory calculations were started at 00, 06, 12, and 18 hours in MO at the height of the MOUDI inlet (~ 12 m above ground level) using meteorological files from the NCEP/NCAR Reanalysis dataset.

Section 2.2: Again, information about the inlet and sample collection strategy is needed. Is there a general methodology that was followed for collection of the aerosol that has been reported elsewhere? If so, this should be cited. If not, more information is needed (e.g. was rotation utilized, was sample RH monitored or expected to affect samples, were there any other expected sources of potential bias in the measurements)? More information or methodology references are also needed to fully describe methodologies for the gravimetric and optical absorption analyses.

Response: Additional details about the location of the sampling equipment, length of inlet, sampling schedule, and gravimetric analysis have been added to Section 2.2. This section now reads as:

PM was collected on Teflon substrates (PTFE membrane, 2 μm pore, 46.2 mm, Whatman) in Micro-Orifice Uniform Deposit Impactors (MOUDI, MSP Corporation, Marple et al., 2014). Size-resolved measurements were taken at the following aerodynamic cutpoint diameters (D_p): 18, 10, 5.6, 3.2, 1.8, 1.0, 0.56, 0.32, 0.18, 0.10, 0.056 μm . Fourteen sample sets were collected during the

SWM season (July-October 2018), with details about the operational and meteorological conditions during each sample set shown in Table 1. To determine the optimum sampling time that will collect enough sample for subsequent analyses, collection time for the first four samples ranged from 24 to 119 hours. Subsequent sampling were then fixed to 48 hours with one sample set collected every week. The sampling collection was designed to include samples from each day of the week so the collection cycled between Monday – Wednesday, Tuesday – Thursday, Wednesday – Friday, and Saturday – Monday, starting at 1400 (local time) for the weekday samples and 0500 for the weekend samples. The Teflon substrates were pretreated by washing with deionized water and air drying in a covered box. Substrates were placed and retrieved from the cascade impactor inside the laboratory in an adjacent building and transported to and from the sampling site using an impactor holder (Csavina et al., 2011). Samples are immediately placed in the freezer upon retrieval.

On two occasions, two pairs of MOUDI sets (Sets MO3/MO4 and MO13/MO14) were collected simultaneously such that one set in each pair could undergo different types of analyses. Sets 3 and 13 underwent gravimetric analysis using a Sartorius ME5-F microbalance. Substrates were conditioned for at least 24 h at a mean temperature of 20-23 °C and a mean relative humidity of 30-40% before pre- and post-weighing (U.S. Environmental Protection Agency, 2016). MOUDI set 13 was additionally examined with a Multi-wavelength Absorption Black Carbon Instrument (MABI; Australian Nuclear Science and Technology Organisation). This optically-based instrument quantifies absorption and mass concentrations at seven wavelengths between 405 and 1050 nm; however, results are reported only for 870 nm to be consistent with other studies as BC is the predominant absorber at that wavelength (e.g., Ramachandran and Rajesh, 2007; Ran et al., 2016). One additional sample set for microscopy analysis was collected for one hour on August 1 using aluminum substrates.

Sections 2.3 and 2.4: Methodologies described in these section are somewhat lacking in references. The authors may want to consider including additional references with more description of both the methods and any caveats to their use for interested readers.

Response: References of the IC and ICP-QQQ analyses have been added and this section now reads:

Note that some species were detected by both IC and ICP-QQQ (i.e., Na^+ , K^+ , Mg^{2+} , Ca^{2+}), and that the IC concentrations are used here for all repeated species with the exception of K^+ owing to better data quality from ICP-QQQ. All IC and ICP-QQQ species concentrations for samples have been corrected by subtracting concentrations from background control samples. For more examples of the application of these methods used for substrate collection and IC/ICP analysis, the reader is referred to other recent work (Braun et al., 2017; Ma et al., 2019; Schlosser et al., 2017).

Section 2.5: Which measurements specifically were included in the PMF and correlation analyses, and how was the size distribution of various species included in these analyses? Also specify how many data points were used for these analyses.

Response: The data from all the collected samples that were analysed for water-soluble ions and elements were collectively used as one input data matrix for PMF. The size was only factored in when substitution for missing concentration data was needed. For example, if a Vanadium concentration datapoint was missing for a sample with cutpoint diameter of 18 μm but V was detected in more than 50% of the samples (66 samples of different cutpoint diameters) and $V\ S/N > 1$, the geometric mean used to substitute for this missing concentration data was taken from the geometric mean of the concentrations of V for samples with cutpoint diameter of 18 μm only. Correlation analyses were done between species analysed by IC (12 sets = 132 samples), ICP-QQQ (12 sets = 132 samples), and BC from Set 13.

Section 2.5 that describes the PMF methodology has been edited to:

This study reports basic descriptive statistics for chemical concentrations and correlations between different variables. Statistical significance hereafter corresponds to 95% significance based on a two-tailed Student's t-test. To complement correlative analysis for identifying sources of species, positive matrix factorization (PMF) modeling was carried out using the United States Environmental Protection Agency's (US EPA) PMF version 5. A total of 132 samples from the 12 sets analyzed for water-soluble ions and elements were used in the PMF analysis. Species concentrations were examined before being inputted to PMF. Species considered as "strong" based on high signal-to-noise ratios ($S/N > 1$) and those with at least 50% of the concentrations above the LOD were used in the PMF modeling (Norris et al., 2014). This resulted in a $132\ (\text{samples}) \times 30\ (\text{species})$ data matrix that was inputted to PMF.

334: May be useful to remind readers that jeepneys are local vehicles in common usage in Manila.

Response: The sentence now reads:

Kecorius et al. (2017) projected that 94% of total roadside refractory PM with number concentration modes at 20 and 80 nm was linked to jeepneys, the most popular and inexpensive mode of public transport in Metro Manila.

349: Need to consider the relatively few BC measurements in this study and moderate speculation about the representativeness of this single measurement unless otherwise justified.

Response: The Abstract and parts of Section 3 have been edited to emphasize that BC observations were based on Set 13 only and that the authors' hypothesis about the effect of inefficient scavenging on the observed size distribution is just one of the many possible explanation for the observation.

354: The authors seem to be claiming that most BC was measured in the accumulation mode primarily as a result of the lack of precipitation scrubbing in the Greenfield gap ("95% of the BC mass is concentrated in the Greenfield gap, and thus the removal of BC due to precipitation is inefficient"). While the claim that BC is not being efficiently removed by precipitation makes conceptual sense, the emphasis on this arising due to precipitation

processes is not supported by the arguments presented here. Precipitation scavenging is not the only process that affects the size distribution of particles. Coagulation, growth, and aging tend to move particles from nucleation and Aitken modes into the accumulation mode, while smaller particles typically already have minimal contributions to mass distributions. Further, there were not enough measurements of BC size distributions (only one it would seem, sample MO13) to compare relative differences between distributions in periods of more and less precipitation. In this sentence specifically, and section 3.2.1 more generally, the authors make a number of claims about the size distribution of BC that appears to be based on only one sample. While the authors may comment on the nature of the BC mass distribution data point, they should refrain from undue speculation on its cause in this case, unless it is merely to mention potential relevant processes.

Response: This section has been changed to:

A possible explanation for the large contribution of BC to PM, and the persistence of PM after rain events (Kim Oanh et al., 2006), is that the BC is not efficiently scavenged by precipitating rain drops. Small particles enter rain drops via diffusion whereas large particles enter via impaction. However, particles with a diameter in the range of 0.1–1 μm (known as the Greenfield gap) are too large to diffuse efficiently and too small to impact, and are therefore not efficiently scavenged (Seinfeld and Pandis, 2016). Absorption spectroscopy of set MO13 (Figure 2b) reveals that 95% of the BC mass is concentrated in the Greenfield gap, and thus the removal of BC due to precipitation is inefficient. The Greenfield gap contains $62 \pm 11\%$ of the total mass (calculated for MO3/MO13) and $65 \pm 10\%$ of the water-soluble mass (calculated for the other 12 MO sets). As noted earlier, BC observations discussed in this paper were based only on a single MOUDI set and the effect of inefficient scavenging in the Greenfield Gap could just be one of the many potential processes affecting BC size distribution. Subsequent work that will include BC measurements in the dry season will further investigate this hypothesis.

445: The sentence beginning on this line is not completely clear, and the authors may wish to reword to better clarify their intent. Additional explanation of why they consider the PMF solution valid may be helpful.

Response: The sentence now reads:

The PMF solution with five factors (Figure 8) was chosen because it passed the criteria of physical meaningfulness and it had a calculated ratio of $Q_{\text{true}}/Q_{\text{expected}}$ (1.2) that was very close to the theoretical value of 1.0.

447: I assume the authors meant to refer to the coefficient of determination (i.e. r^2) rather than the coefficient of variation (i.e. σ/μ) here.

Response: The sentence has been corrected to:

There was a high coefficient of determination between measured and predicted mass concentration when summing up all species for each MOUDI stage ($r^2 = 0.79$; sample size, $n = 132$), which added confidence in relying on the PMF model for source apportionment of PM.

467: I do not understand how the authors came to this conclusion based on one measured BC data point. What is the interrelationship with water soluble ions that justifies concluding they necessarily vary in concert with each other? How do you correlate BC to 15 other species? Is this just based on correlation of the size distribution? Many species exhibit a similar distribution in the accumulation mode, so that alone would not seem to justify this statement.

Response: Correlation was done on BC concentrations from 11 samples from Set 13 and each of the species consisting of 132 samples from 12 MOUDI sets. This section has been edited to:

Although BC concentrations were quantified from set MO13 only, the results showed that BC was significantly correlated (r : 0.61-0.92) with 15 species, including those mentioned above (owing to co-emission) and also a few elements that were found via PMF to be stronger contributors to the Combustion source discussed in Section 3.3.3 (Ni, Cu, As, Se, Cd, Tl, Pb).

508: In this paragraph the authors state they expect PM in Metro Manila to be dominated by local sources of aerosol, and that the “Aged/Transported” pollution PMF type is in fact the largest source. Is it not reasonable to associate this source with precisely what was expected for a typical background aerosol in Manila that features complex mixing between local, regional, and distant sources that have experienced some aging before being either advected to other areas or impacted by precipitation? If mixing with distant sources is in fact detectable, that does not necessarily imply that local sources are not still the dominant source.

Response: The authors agree with this comment and have edited this part to read as follows:

Even though the PM in a heavily populated urban region, such as Metro Manila, is typically thought to be dominated by local sources of aerosols, the current PMF results show that contribution from long range transport is still discernible. This finding is contrary to the expectation that the signal of transported aerosols would be lost in the noise of locally-produced aerosols.

560: How are BC correlations being conducted? Following on the earlier comment regarding valid data points for various analyses, how many data points and of what type are used in this correlation? Is this intended to highlight BC found in the same size bins as As and Ni?

Response: The BC concentrations from Set 13 (11 samples) were correlated with the As and Ni concentrations from 12 sample sets (132 samples of different cutpoint diameters) that were analysed by IC and ICP-QQQ. The authors merely want to highlight the significant correlation of BC to the two species that significantly make up the combustion source.

Reviewer #2:

This manuscript describes size-resolved aerosol particle composition information from the urban Manila center of the Philippines during a relatively time-limited observing campaign.

The information presented represents a very useful summary of the observations and links to local and regional source production. The broad Southeast Asian archipelago is subject to significant air quality hazards and regional aerosol transport, making the region a hotbed for chemical and particulate aerosol study. The topic and manuscript are thus worthy of consideration by ACP. I found the paper to be relatively strong technically and the figures very clear and legible (my technical notes are attached).

My recommendation is that the paper be published after minor revisions.

My primary points of concern are:

1) The paper really lacks a hypothesis. As such, it reads more as a technical report, which is ultimately fine. I suspect that the impact of this paper will be found as a strong reference set of measurements to characterize a major urban center on the eastern side of the South China Sea. But, authors would be wise to reconsider motivation and establish some binding question that makes these measurements wholly unique. To that end, and as I'll point out again below, regional transport is something that the Taiwanese groups have been looking at for decades now. Perhaps this isn't technically SE Asia. But, there is a large body of work (start with N. C. Lin) showing transport from the mainland over the ocean, chemical morphology, size information, and vertical/radiative properties.

Response: We agree with the reviewer's comment that the results of this paper will serve as a strong reference measurement of PM characterization in the region. The size-resolved PM measurements, though initially done during the southwest monsoon season only, are envisioned to shed light on why total PM_{2.5} levels in the study site are comparable during the dry and the wet seasons, in contrast to observations in other cities in the region. Moreover, to the authors' knowledge, the initial size-resolved BC measurements have not been done before in the study area and the results provide a valuable insight on why BC levels are very high. In addition, the PMF results also provide valuable insights on the sources of aerosol in Metro Manila. Recognizing that this work is not the first to report on long range transport of aerosol in the region, the paragraph in the Conclusions related to transport has been edited to:

Although the current study focuses exclusively on the SWM season in Metro Manila, results of this study are applicable to the study of aerosol impacts on Southeast Asia and other regions. First, the detection of Aged aerosols not only from local but also from regional sources confirms previous studies that PM in the region has the ability to travel long distances during the SWM season. Characterization of aerosols in Metro Manila is therefore important for better understanding the impacts that local emissions will have on locations downwind of Metro Manila, including other populated cities in Southeast and East Asia. Transport of pollution and decreased wet scavenging during the SWM season may become increasingly important as studies have shown a decrease in SWM rainfall and increase in the number of no-rain days during the SWM season in the western Philippines in recent decades (e.g., Cruz et al., 2013).

2) I found the discussion in P18/19 to be really clumsy. This simple premise that precipitation is enough to scavenge significant portions of the regional aerosol mass is very coarse. Sure, aerosol transport correlates most strongly with dry air mass movement. But, in SE Asia,

particularly seasonally, the pall is immense and omnipresent. This discussion needs to be reconsidered complete. And, again, some consideration of Taiwanese experiments looking at transport from the mainland is surely relevant context to what is being seen in the Philippines.

Response: The authors recognize that previous Taiwanese studies have shown the transport of aerosols from the mainland and from the Indochinese peninsula. Thus, this section has been edited to:

Even though the PM in a heavily populated urban region, such as Metro Manila, is typically thought to be dominated by local sources of aerosols, the current PMF results show that contribution from long range transport is still discernible. This finding is contrary to the expectation that the signal of transported aerosols would be lost in the noise of locally-produced aerosols.

3) Redefine your acronyms in the Conclusions, in the event that your reader only reads those summary points and nothing else.

Response: The authors have redefined all acronyms on the Conclusions.

I found the paper to be very well written, otherwise. Good luck.

Please also note the supplement to this comment:

<https://www.atmos-chem-phys-discuss.net/acp-2019-270/acp-2019-270-RC2-supplement.pdf>

Response: The authors have addressed the comments in the supplement by shortening the abstract and redefining all acronyms in the Conclusions. Grammar, punctuation, and style corrections suggested by the reviewer have also been made.

Please find, below, the marked-up version of the manuscript.

Size-resolved Composition and Morphology of Particulate Matter During the Southwest Monsoon in Metro Manila, Philippines

Abstract

This paper presents novel results from size-resolved particulate matter (PM) mass, composition, and morphology measurements conducted during the 2018 Southwest Monsoon (SWM) season in Metro Manila, Philippines. Micro-Orifice Uniform Deposit Impactors (MOUDIs) were used to collect PM sample sets composed of size-resolved measurements at the following aerodynamic cutpoint diameters (D_p): 18, 10, 5.6, 3.2, 1.8, 1.0, 0.56, 0.32, 0.18, 0.10, 0.056 μm . ~~that were~~ Each sample set was analyzed for ~~mass, morphology, black carbon (BC), and~~ composition of the water-soluble fraction. Analysis for mass were done on two sample sets while black carbon (BC) and morphology analysis were done on a single sample set. The bulk of the PM mass was between 0.18–1.0 μm with a dominant mode between 0.32–0.56 μm . Similarly, most of the black carbon (BC) mass was found between 0.10–1.0 μm , peaking between 0.18–0.32 μm . These peaks are located in the Greenfield Gap or the size range between 0.10–1.0 μm , where wet scavenging by rain is relatively inefficient. ~~Similarly, most of the black carbon (BC) mass was found between 0.10–1.0 μm (the so-called Greenfield gap), peaking between 0.18–0.32 μm , where wet scavenging by rain is inefficient.~~ In the range of 0.10 – 0.18 μm , BC constituted 78.1% of the measured mass. Comparable contributions of BC (26.9%) and the water-soluble fraction (31.3%) to total PM were observed and most of the unresolved mass, which in total amounted to 41.8%, was for diameters exceeding 0.32 μm . The water-soluble ions and elements exhibited an average combined concentration of 8.53 $\mu\text{g m}^{-3}$, with SO_4^{2-} , NH_4^+ , NO_3^- , Na^+ , and Cl^- as the major contributors. Positive Matrix Factorization (PMF) was applied to identify the possible aerosol sources and estimate their contribution to the water-soluble fraction of collected PM. The factor with the highest contribution was attributed to “Aged/~~Transported~~” ~~a~~ Aerosol” (48.0%) while “Sea Salt” (22.5%) and “Combustion” emissions (18.7%) had comparable contributions. “Vehicular/Resuspended Dust” (5.6%) as well as “Waste Processing” emissions (5.1%) were also identified. Microscopy analysis highlighted the ubiquity of non-spherical particles regardless of size, which is significant when considering calculations of parameters such as single scattering albedo, asymmetry parameter, and extinction efficiency.

~~Results of this work have implications for aerosol impacts on public health, visibility, and regional climate as each of these depend on physicochemical properties of particles as a function of size.~~

The significant influence from Aged/~~Transported~~ aerosol to Metro Manila during the SWM season indicates that local sources in this megacity do not fully govern this coastal area’s aerosol

properties ~~and that PM in Southeast Asia can travel long distances regardless of the significant precipitation and potential wet scavenging that could occur.~~ That the majority of the regional aerosol mass burden is accounted for by BC and other insoluble components has important downstream effects on the aerosol hygroscopic properties, which depend on composition. The results are relevant for understanding the impacts of monsoonal features on size-resolved aerosol properties, notably aqueous processing and wet scavenging. Finally, the results of this work provide contextual data for future sampling campaigns in Southeast Asia such as the airborne component of the Cloud, Aerosol, and Monsoon Processes Philippines Experiment (CAMP²Ex) planned for the SWM season in 2019. ~~Aerosol characterization via remote sensing is notoriously difficult in Southeast Asia, which elevates the importance of datasets such as the one presented here.~~

1. Introduction

Ambient atmospheric aerosol particles impact human health, visibility, climate, and the hydrological cycle. Major factors governing these behaviors, such as deposition fraction in the respiratory system and activation into cloud condensation nuclei (CCN), include size and chemical composition. Therefore, size-resolved measurements of ambient aerosol particles can lend additional insights to the behaviors and implications of particulate matter (PM) in the atmosphere. One region of interest for characterization of ~~aerosols~~-PM is Southeast Asia due to increasing urbanization and the exposure of the population to a variety of aerosol sources, both natural and anthropogenic (Hopke et al., 2008). However, use of space-borne remote-sensing instrumentation presents a challenge for characterization of aerosol in this region, due to issues such as varying terrain and cloud cover (Reid et al., 2013).

The Philippines represents a country in Southeast Asia with a developing economy, rapid urbanization, old vehicular technology, and less stringent air quality regulations (e.g., Alas et al., 2017). It is also highly sensitive to the effects of climate change including prolonged dry periods and reductions in southwest monsoon (SWM) rainfall in recent decades (e.g., Cruz et al., 2013). Metro Manila is the country's capital and center of political and economic activities. Also referred to as the National Capital Region, Metro Manila is composed of 16 cities and a municipality that collectively occupy a land area of $\sim 619 \text{ km}^2$. As of 2015, Metro Manila had a population of approximately 12.88 million (Philippine Statistics Authority, 2015). Of the cities comprising the Metro Manila area, the one that is the focus of this study, Quezon City, is the most populated (2.94 million people) with a population density of $\sim 17,000 \text{ km}^{-2}$ as of 2015 (Philippine Statistics Authority, 2015).

The rainfall pattern in Southeast Asia is governed by topographic effects and the prevailing surface winds brought by the monsoons. Mountain ranges in the Philippines are generally oriented north to south in the eastern and western coasts. As such, northeasterly winds during the East Asian winter monsoon that starts in November brings wetness (dryness) on the eastern (western) coasts of the country. In contrast, the rainy season starts in May when the Western North Pacific subtropical high moves northeast and the Asian summer monsoon enables the propagation of southwesterly wind through the Philippines (Villafuerte et al., 2014). Metro Manila, located on the western side of the Philippines, therefore experiences wet (May-October) and dry (November-April) seasons. The large seasonal shift in prevailing wind directions can cause changes in the

source locations of aerosol transported to the Philippines and the subsequent direction in which emissions from the Philippines are transported, such as to the northwest (e.g., Chuang et al., 2013) or southwest (e.g., Farren et al., 2019). However, one interesting feature of Metro Manila is the consistency of $PM_{2.5}/PM_{10}$ mass concentrations during both the dry ($44/54 \mu g m^{-3}$) and wet seasons ($43/55 \mu g m^{-3}$) (Kim Oanh et al., 2006), which stands in contrast to typical assumptions that increased wet scavenging during rainy seasons would lead to decreases in measured PM (e.g., Liao et al., 2006). While similar results are observed in Chennai, India, this behavior is different than other cities in Asia, including Bandung City (Indonesia), Bangkok (Thailand), Beijing (China), and Hanoi City (Vietnam), ~~that-which~~ exhibit reduced $PM_{2.5}$ levels during the wet season as compared to the dry season (Kim Oanh et al., 2006). While the total PM levels may stay constant across the wet and dry seasons, seasonally-resolved analyses will provide additional insights into how the composition, morphology, and sources (transported vs. local emissions) change on a seasonal basis.

Metro Manila has been drawing growing interest for PM research owing to the significant levels of black carbon (BC). A large fraction of PM in Metro Manila can be attributed to BC (e.g., ~50% of $PM_{2.5}$; Kim Oanh et al., 2006), with previously measured average values of BC at the Manila Observatory (MO) reaching $\sim 10 \mu g m^{-3}$ for $PM_{2.5}$ (Simpas et al., 2014). The impacts of the high levels of BC present on human health have also received attention (Kecorius et al., 2019). Identified major sources of BC include vehicular, industrial, and cooking emissions (Bautista et al., 2014; Kecorius et al., 2017). Vehicular emissions, especially along roadways where personal cars and motorcycles, commercial trucks, and motorized public transportation, including powered tricycles and *jeepneys*, are plentiful. For instance, measurements of $PM_{2.5}$ at the National Printing Office (NPO) located alongside the major thoroughfare Epifanio de los Santos Avenue (EDSA) were on average $72 \mu g m^{-3}$; this value is twice the average concentration at ~~the Manila Observatory (MO)~~, an urban mixed site located approximately 5 km from NPO (Simpas et al., 2014). In addition to local emissions, long-range transport of pollution, such as biomass burning, can also impact the study region (e.g., Xian et al., 2013; Reid et al., 2016a/b). However, most past work referenced above has focused on either total $PM_{2.5}$ or PM_{10} composition, and therefore, detailed size-resolved composition information has been lacking in this region. Like other monsoonal regions (Crosbie et al., 2015; Qu et al., 2015), it is of interest for instance to know if products of aqueous processing (e.g., sulfate, organic acids) during the monsoonal period, promoted by the

high humidity, become more prominent in certain size ranges to ultimately enhance hygroscopicity, which is otherwise suppressed with higher BC influence.

A year-long sampling campaign (Cloud, Aerosol, and Monsoon Processes Philippines Experiment (CAMP²Ex) weathER and CompoSition Monitoring (CHECSM) study) was established in July 2018 to collect size-resolved aerosol measurements in Metro Manila. The aim of this study is to report size-resolved PM measurements taken over the course of the SWM (July-October) of 2018 in Quezon City, Metro Manila, Philippines as part of CHECSM. The results of this study are important for the following reasons: (i) they provide size-resolved analysis of BC in an area previously characterized as having one of the highest BC mass percentages in the whole world; (ii) they provide a basis for better understanding the unusual phenomenon of having similar PM levels during a wet and dry season; (iii) they provide contextual data for contrasting with both other coastal megacities and also other monsoonal regions; and (iv) they can lend insights into the characteristics of aerosol transported both into and out of Metro Manila and how important local sources are in Metro Manila relative to transported pollution.

Outcomes of this study include (i) the first size-resolved characterization of both aerosol composition and morphology in Metro Manila for the SWM, with implications in terms of PM effects on climate, visibility, the hydrological cycle, and public health owing to the dependence of these impacts on particle size; (ii) archival data that contributes to the timeline of aerosol research in Metro Manila, and more broadly Southeast Asia, where there is considerable concern over air pollution; and (iii) baseline data for aerosol composition to be used to inform and assist research to be conducted during future field campaigns in Southeast Asia including the same seasonal period (i.e., SWM) in 2019 as part of CAMP²Ex, which will involve both surface and airborne measurements.

2. Experimental Methods

2.1 Sample Site

Sampling was performed at MO in Quezon City, Philippines (14.64° N, 121.08° E). ~~The sampling instrumentation was located~~Two MOUDIs were placed ~~inside an unoccupied room~~ on the 3rd floor of the MO ~~office-administration~~ building (~~~85-87~~ m above sea level). ~~The inlet, located just outside the window, consists of a 2 m long stainless steel tube and a reducer and a reducer that is connected directly to the MOUDI inlet.~~ Figure 1 visually shows the sampling

location and potential surrounding aerosol sources. Past work focused on $PM_{2.5}$ suggested that the study location is impacted locally mostly by traffic, various forms of industrial activity, meat cooking from local eateries, and, based on the season, biomass burning (Cohen et al., 2009). This is consistent with another source apportionment study which reported that potential sources in six sites across Metro Manila include traffic, secondary particles, and biomass burning (Kim Oanh et al., 2013). Fourteen sample sets were collected during the SWM season (July–October 2018), with details about the operational and meteorological conditions during each sample set shown in Table 4.

Meteorological data were collected using a Davis Vantage Pro 2 Plus weather station ~~co-~~ located with the aerosol measurements at located on the roof (~90 m above sea level, ~15 m above ground level) above where the MOUDIs were located–MO. Except for precipitation, which is reported here as accumulated rainfall, reported values for each meteorological parameter represent averages for the sampling duration of each aerosol measurement.

—The mean temperature during the periods of MOUDI sample collection ranged from 24.9 to 28.1° C, with accumulated rainfall ranging widely from no rain to up to 78.4 mm. To identify sources impacting PM via long-range transport to the Metro Manila region, Figure 1a summarizes the five-day back-trajectories for air masses arriving at MO on the days when samples were being collected, calculated using the NOAA Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPPLIT) model (Stein et al., 2015; Rolph, 2016). Trajectory calculations were started at 00, 06, 12, and 18 hours in MO using a model run height of at the height of the MOUDI inlet 12 m above ground level using and meteorological files from the NCEP/NCAR Reanalysis dataset. Trajectory cluster analysis was conducted using TrajStat (Wang et al., 2009). The back-trajectories in Figure 1a show that indeed 66% of the wind came from the southwest during the sampling periods.

2.2 MOUDI Sample Sets

~~Particulate matter~~PM was collected on Teflon substrates (PTFE membrane, 2 μ m pore, 46.2 mm, Whatman) in Micro-Orifice Uniform Deposit Impactors (MOUDI, MSP Corporation, Marple et al., 2014). Size-resolved measurements were taken at the following aerodynamic cutpoint diameters (D_p): 18, 10, 5.6, 3.2, 1.8, 1.0, 0.56, 0.32, 0.18, 0.10, 0.056 μ m. Fourteen sample sets were collected during the SWM season (July–October 2018), with details about the

operational and meteorological conditions during each sample set shown in Table 1. To determine the optimum sampling time that will collect enough sample for subsequent analyses, collection time for the first four samples ranged from 24 to 119 hours. Subsequent sampling were then fixed to 48 hours with one sample set collected every week. The sampling collection was designed to include samples from each day of the week so the collection cycled between Monday – Wednesday, Tuesday – Thursday, Wednesday – Friday, and Saturday – Monday, starting at 1400 (local time) for the weekday samples and 0500 for the weekend samples. The Teflon substrates were pretreated by washing with deionized water and air drying in a covered box. Substrates were placed and retrieved from the cascade impactor inside the laboratory in an adjacent building and transported to and from the sampling site using an impactor holder (Csavina et al., 2011). Samples are immediately placed in the freezer upon retrieval.

For a subset of the sampling periodsOn two occasions, two pairs of MOUDI sets (Sets MO3/MO4 and MO13/MO14) were collected simultaneously such that ~~both sets~~one set in each pair could undergo different types of analyses. Sets 3 and 13 ~~One set in each pair~~ underwent gravimetric analysis using a Sartorius ME5-F microbalance. Substrates were conditioned for at least 24 h at a mean temperature of 20-23 °C and a mean relative humidity of 30-40% before pre- and post-weighing (U.S. Environmental Protection Agency, 2016). MOUDI set 13 was additionally examined with a Multi-wavelength Absorption Black Carbon Instrument (MABI; Australian Nuclear Science and Technology Organisation). This optically-based instrument quantifies absorption and mass concentrations at seven wavelengths between 405 and 1050 nm; however, results are reported only for 870 nm to be consistent with other studies, as BC is the predominant absorber at that wavelength (e.g., Ramachandran and Rajesh, 2007; Ran et al., 2016). One additional sample set for microscopy analysis was collected for one hour on August 1 using aluminum substrates.

2.3 Chemical Composition Analysis

Twelve sample sets, composed of 11 samples each, were analyzed for water-soluble ions and elements (Table 2). In order to preserve samples for additional analysis, each Teflon substrate was cut in half. A half of each substrate was extracted in 8 mL of Milli-Q water (18.2 MΩ-cm) through sonication for 30 min in a sealed polypropylene vial. A blank substrate was processed in the same method to serve as a background control sample. Subsequent chemical analysis of the

water-soluble components in the aqueous extracts were performed using ion chromatography (IC; Thermo Scientific Dionex ICS - 2100 system) for the following species: cations = Na^+ , NH_4^+ , Mg^{2+} , Ca^{2+} , dimethylamine (DMA), trimethylamine (TMA), diethylamine (DEA); anions =, methanesulfonate (MSA), pyruvate, adipate, succinate, maleate, oxalate, phthalate, Cl^- , NO_3^- , SO_4^{2-} . Owing to co-elution of TMA and DEA in the IC system, a cumulative sum of the two is reported here, which represents an underestimate of their total mass concentration owing to overlap in parts of their peaks. Limits of detection (LOD) were calculated for each species based on their respective calibration curve (Table S1), with LOD being three times the standard deviation of the residuals (predicted signal minus measured signal) divided by the slope of the calibration curve (Miller and Miller, 2018).

The aqueous extracts were simultaneously characterized for elemental composition using triple quadrupole inductively coupled plasma mass spectrometry (ICP-QQQ; Agilent 8800 Series) for the following species: K, Al, Fe, Mn, Ti, Ba, Zn, Cu, V, Ni, P, Cr, Co, As, Se, Rb, Sr, Y, Zr, Nb, Mo, Ag, Cd, Sn, Cs, Hf, Tl, Pb. Limits of detection of the examined elements were calculated automatically by the ICP-QQQ instrument and were in the ppt range (Table S1). The sample concentrations represent an average of three separate measurements with a standard deviation of 3% or less.

Note that some species were detected by both IC and ICP-QQQ (i.e., Na^+ , K^+ , Mg^{2+} , Ca^{2+}), and that the IC concentrations are used here for all repeated species with the exception of K^+ owing to better data quality from ICP-QQQ. All IC and ICP-QQQ species concentrations for samples have been corrected by subtracting concentrations from background control samples. [For more examples of the application of these methods used for substrate collection and IC/ICP analysis, the reader is referred to other recent work \(Braun et al., 2017; Ma et al., 2019; Schlosser et al., 2017\).](#)

2.4 Microscopy Analysis

As already noted, one MOUDI set on August 1 was devoted to microscopy analysis. Morphology and additional elemental composition analysis was carried out on this set of aluminum substrates using scanning electron microscopy equipped with energy dispersive X-ray spectroscopy (SEM-EDX) in the Kuiper Imaging cores at the University of Arizona. Secondary electron (SE) imaging and EDX elemental analysis were performed using a Hitachi S-4800 high

resolution SEM coupled to a Noran system Six X-ray Microanalysis System by Thermo Fisher Scientific. EDX analysis on individual particles was performed with 30 kV accelerating voltage to obtain weight percentages of individual elements. SEM-EDX results showed that the background control aluminum substrate was dominated by Al (88.27%), with minor contributions from Ag (5.34%), C (4.87%), O (0.79%), Fe (0.67%), and Co (0.05%). Such contributions were manually subtracted from spectra of individual particles on sample substrates, with the remaining elements scaled up to hundred percent. Image processing was conducted with Image J software to measure particle dimensions and adjust the contrast and brightness of images to provide better visualization.

2.5 Computational Analysis

This study reports basic descriptive statistics for chemical concentrations and correlations between different variables. Statistical significance hereafter corresponds to 95% significance based on a two-tailed Student's t-test. To complement correlative analysis for identifying sources of species, positive matrix factorization (PMF) modeling was carried out using the United States Environmental Protection Agency's (US EPA) PMF version 5. A total of 132 samples from the 12 sets analyzed for water-soluble ions and elements were used in the PMF analysis. Species concentrations were examined before being using as inputted to PMF. Species considered as "strong" based on high signal-to-noise ratios ($S/N > 1$) and those with at least 50% of the concentrations above the detection limit LOD were used in the PMF modeling (Norris et al., 2014). This resulted in a 132 (samples) ~~xx~~ 30 (species) data matrix that was used as inputted to PMF. Data points with concentrations exceeding the LOD had uncertainty quantified as ~~follows~~:

$$\sigma_{ij} = 0.05 \cdot X_{ij} + LOD_{ij}, \quad (\text{Equation 1})$$

where σ_{ij} , X_{ij} , and LOD_{ij} are the uncertainty, concentration, and LOD, respectively, of the j^{th} species in the i^{th} sample (Reff et al., 2007). When concentration data were not available for a particular stage of a MOUDI set for a species, the geometric mean of the concentrations for that MOUDI stage and species was applied with uncertainty counted as four times the geometric mean value (Polissar et al., 1998; Huang et al., 1999). A 25% extra modeling uncertainty was applied to account for other sources of errors, such as changes in the source profiles and chemical

transformations (Dumanoglu et al., 2014; Norris et al., 2014). The model was run 20 times with a randomly chosen starting point for each run.

3. Results

3.1 Total Mass Concentrations and Charge Balance

The average total mass concentration (\pm standard deviation) of water-soluble species across all MOUDI stages (Table 1) during the study period was $8.53 \pm 4.48 \mu\text{g m}^{-3}$ (range = 2.7–16.6 $\mu\text{g m}^{-3}$). The species contributing the most to the total water-soluble mass concentration during the SWM included SO_4^{2-} ($44\% \pm 6\%$), NH_4^+ ($18\% \pm 5\%$), NO_3^- ($10 \pm 3\%$), Na^+ ($8 \pm 3\%$), and Cl^- ($6\% \pm 3\%$). The meteorological parameters from Table 1 best correlated to total water-soluble mass concentrations were temperature ($r = 0.64$) and rainfall ($r = -0.49$). The highest total mass concentration (set MO13/14 = 16.6 $\mu\text{g m}^{-3}$) occurred during the period with one of the highest average temperatures (27.8 °C) and second least total rainfall (0.8 mm). Other sampling periods with high mass concentrations (sets MO7, MO8, and MO12) coincided with the highest temperature and lowest rainfall observations. High temperatures, and thus more incident solar radiation, presumably enhanced production of secondary aerosol species via photochemical reactions as has also been observed in other regions for their respective monsoon season (Youn et al., 2013).

Low rainfall is thought to have been coincident with reduced wet scavenging of aerosol at the study site as has been demonstrated for other regions such as North America (Tai et al., 2010) and megacities such as Tehran (Crosbie et al., 2014). However, set MO11 exhibited a very low concentration even with high temperature and lack of rainfall, which may be due to changes in the source and transport of aerosol since this sample set coincided with a significant change in average wind direction (290.2° for MO11 vs. 90.1° – 127.5° for all other MOUDI sets). While the reported rainfall measurements were taken at MO, inhomogeneous rainfall patterns in the regions surrounding the Philippines could also contribute to the wet scavenging of PM, thereby lowering the quantity of transported particles reaching the sample site. Future work will address the influence of spatiotemporal patterns of precipitation on PM loadings in the Philippines as a point measurement at an aerosol observing site may be misleading.

On two occasions, two simultaneous MOUDI sets (Sets MO3/MO4 and MO13/MO14) were collected for the potential to compare different properties that require separate substrates.

The total mass concentrations based on gravimetric analysis of sets MO3 and MO13 were $18.6 \mu\text{g m}^{-3}$ and $53.0 \mu\text{g m}^{-3}$, respectively (Figure 2). Both sets exhibited a dominant concentration mode between $0.32\text{--}0.56 \mu\text{m}$ and the MO3 set was different in that it exhibited bimodal behavior with a second peak between $1.8\text{--}3.2 \mu\text{m}$. The sum of speciated water-soluble species accounted for only 27.8% and 31.3% of the total gravimetric mass of sets MO3 and MO13, respectively, indicative of significant amounts of water-insoluble species undetected by IC and ICP-QQQ. When adding the total mass of BC ($14.3 \mu\text{g m}^{-3}$) to the other resolved species from set MO13 (the one time BC was measured), there was still $22.1 \mu\text{g m}^{-3}$ of unresolved mass (41.8% of total PM). Most of the unaccounted mass was for $D_p > 0.32 \mu\text{m}$.

The observation of BC accounting for 26.9% of total PM ($14.3 \mu\text{g m}^{-3}$) is consistent with past work highlighting the significant fraction of BC in the ambient aerosol of Manila (Kim Oanh et al., 2006; Bautista et al., 2014; Simpas et al., 2014; Kecorius et al., 2017). However, this fraction of BC is very high compared to measurements during the monsoon season in other parts of the world. The mass fraction of BC in total suspended PM (TSPM) was 1.6%/2.2% for the monsoon season in 2013/2014 in Kadapa in southern India, even though the TSPM measured was comparable to that in Manila (64.9 and $49.9 \mu\text{g m}^{-3}$, for 2013 and 2014 in Kadapa, respectively) (Begam et al., 2017). Multiple studies during the monsoon season in a coastal region in southwest India showed BC mass contributions of 1.9 – 5% (Aswini et al., 2019 and references therein). Airborne measurements around North America and in Asian outflow revealed that BC accounted for only ~1-2% of $\text{PM}_{1.0}$ (Shingler et al., 2016) and ~5-15% of accumulation mode aerosol mass (Clarke et al., 2004), respectively.

To investigate further about the missing species, a charge balance was carried out for all MOUDI sets (Table 2) to compare the sum of charges for cations versus anions based on IC analysis including K from ICP-QQQ analysis (species listed in Section 2.3). The slope of the charge balances (cations on y-axis) for the cumulative dataset was 1.33 and ranged from 0.89 to 1.41 for the 12 individual MOUDI sets that had IC and ICP-QQQ analysis conducted on them. Eleven of the 12 sets exhibited slopes above unity indicating that there was a deficit in the amount of anions detected, which presumably included species such as carbonate and various organics. To further determine if there were especially large anion or cation deficits in specific size ranges, slopes are also reported for $0.056\text{--}1 \mu\text{m}$ and $> 1 \mu\text{m}$. There were no obvious differences other than

two MOUDI sets exhibited slopes below 1.0 for the smaller diameter range (0.056–1 μm) while all slopes exceeded unity for $> 1 \mu\text{m}$.

3.2 Mass Size Distributions and Morphology

3.2.1 Black Carbon

The size-resolved nature of BC has not been characterized in Manila and MOUDI set MO13 offered a view into its mass size distribution (Figure 3a). There was a pronounced peak between 0.18–0.32 μm ($5.0 \mu\text{g m}^{-3}$), which is evident visually in the substrate's color when compared to all other stages of that MOUDI set (Figure 3b). This observed peak in the mass size distribution of BC is similar to previous studies of the outflow of East Asian countries (Shiraiwa et al., 2008), biomass burning and urban emissions in Texas (Schwarz et al., 2008), measurements in the Finnish Arctic (Raatikainen et al., 2015), and airborne measurements over Europe (Reddington et al., 2013). In contrast, measurements in Uji, Japan showed a bimodal size distribution for the mass concentration of BC in the submicrometer range (Hitzenberger and Tohno, 2001).

In the present study, there were significant amounts of BC extending to as low as the 0.056–0.1 μm MOUDI stage ($0.28 \mu\text{g m}^{-3}$) and extending up in the supermicrometer range, with up to $0.25 \mu\text{g m}^{-3}$ measured between 1.8–3.2 μm . Remarkably, BC accounted for approximately 78.1% (51.8%) by mass of the total PM in the range of 0.10 – 0.18 μm (0.18 – 0.32 μm). For comparison, the mass percent contribution of BC measured in the megacity of Nanjing, China was 3.3% (1.6%) at 0.12 (0.08) μm (Ma et al., 2017). Based on visual inspection of color on all MOUDI sets, MO13 appears to be representative of the other sets based on the relative intensity of the color black on substrates with different cutpoint diameters (Figure 3b); the 0.18–0.32 μm substrate always was the most black, with varying degrees of blackness extending consistently into the supermicrometer stages.

Microscopy analysis revealed evidence of non-spherical particles in each MOUDI stage below 1 μm (Figure 4), which is significant as the common assumption theoretically is that submicrometer particles are typically spherical (e.g., Mielonen et al., 2011). Errors in this assumption impact numerical modeling results and interpretation of remote sensing data for aerosols particles (e.g., Kahnert et al., 2005), owing to incorrect calculations of parameters such as single scattering albedo, asymmetry parameter, and extinction efficiency (e.g., Mishra et al.,

2015). Some studies have noted that submicrometer particles could be composed of an agglomeration of small spherical particles originally formed through gas-to-particle conversion processes (Almeida et al., 2019), which could potentially explain the appearance for some of the observed particles in Figure 4. Since only single particles were examined that may not be fully representative of all particles on a particular MOUDI substrate, it is noteworthy that all five particles shown between 0.056 – 1 μm were irregularly shaped with signs of both multi-layering and constituents adhered to one another.

The images show that a potentially important source of BC in the area could be soot aggregates, which are formed by a vaporization-condensation process during combustion often associated with vehicular exhaust (e.g., Chen et al., 2006; Chithra and Nagendra, 2013; Wu et al., 2017). Kecorius et al. (2017) projected that 94% of total roadside refractory PM ~~with number concentration modes at 20 and 80 nm in the same study region~~ was linked to *jeepneys*, ~~the most popular and inexpensive mode of public transport in Metro Manila. with number concentration modes at 20 and 80 nm.~~ They associated the larger mode with soot agglomerates, which is consistent with the smallest MOUDI size range examined here (0.056-0.1 μm ; Figure 4b) exhibiting signs of agglomeration.

The total BC mass concentration integrated across all stages of MOUDI set MO13 (14.3 $\mu\text{g m}^{-3}$) was remarkably high in contrast to BC levels measured via either filters, aethalometers, or single particle soot photometers in most other urban regions of the world (Metcalf et al., 2012 and references therein): Los Angeles Basin (airborne: 0.002–0.53 $\mu\text{g m}^{-3}$), Atlanta, Georgia (ground: 0.5–3.0 $\mu\text{g m}^{-3}$), Mexico City (airborne: 0.276–1.1 $\mu\text{g m}^{-3}$), Sapporo, Japan (ground: 2.3–8.0 $\mu\text{g m}^{-3}$), Beijing, China (ground: 6.3–11.1 $\mu\text{g m}^{-3}$), Bangalor, India (ground: 0.4–10.2 $\mu\text{g m}^{-3}$), Paris, France (ground: 7.9 $\mu\text{g m}^{-3}$), Dushanbe, Russia (ground: 4–20 $\mu\text{g m}^{-3}$), Po Valley, Italy (ground: 0.5–1.5 $\mu\text{g m}^{-3}$), Thessaloniki, Greece (ground: 3.3–8.9 $\mu\text{g m}^{-3}$). This is intriguing in light of extensive precipitation, and thus wet scavenging of PM, during the study period, which is offset by enormous anthropogenic emissions in the region, such as by powered vehicles like the *jeepneys* that are notorious for BC exhaust (Kecorius et al., 2017).

A possible explanation for the large contribution of BC to PM, and the persistence of PM after rain events (Kim Oanh et al., 2006), is that the BC is not efficiently scavenged by precipitating rain drops. Small particles enter rain drops via diffusion whereas large particles enter via impaction. However, particles with a diameter in the range of 0.1–1 μm (known as the Greenfield

gap) are too large to diffuse efficiently and too small to impact, and are therefore not efficiently scavenged (Seinfeld and Pandis, 2016). Absorption spectroscopy of set MO13 (Figure 2b) reveals that 95% of the BC mass is concentrated in the Greenfield gap, and thus the removal of BC due to precipitation is inefficient. The Greenfield gap contains $62 \pm 11\%$ of the total mass (calculated for MO3/MO13) and $65 \pm 10\%$ of the water-soluble mass (calculated for the other 12 MO sets). As noted earlier, BC observations discussed in this paper were based only on a single MOUDI set and the effect of inefficient scavenging in the Greenfield Gap could just be one of the many potential processes affecting the BC mass size distribution. Subsequent work that will include BC measurements in the dry season will further investigate this hypothesis.

3.2.2 Water-Soluble Ions

There were two characteristic mass size distribution profiles for the water-soluble ions speciated by IC₂ depending on whether the species were secondarily produced via gas-to-particle conversion or associated with primarily emitted supermicrometer particles. The average IC species mass concentration profile across all MOUDI sets is shown in Figure 5. ~~Secondarily-Secondarily-~~produced species exhibited a mass concentration mode between 0.32–0.56 μm , including common inorganic species (SO_4^{2-} , NH_4^+), MSA, amines (DMA, TMA+DEA), and a suite of organic acids, such as oxalate, phthalate, succinate, and adipate, produced via precursor volatile organic compounds (VOCs). Two organic acids with peaks in other size ranges included maleate (0.56–1 μm) and pyruvate (0.1–0.18 μm). Sources of the inorganics are well documented with SO_4^{2-} and NH_4^+ produced by precursor vapors SO_2 and NH_3 , respectively, with ocean-emitted dimethylsulfide (DMS) as an additional precursor to SO_4^{2-} and the primary precursor to MSA.

Precursors leading to ~~secondarily-secondarily-~~produced alkyl amines such as DMA, TMA, and DEA likely originated from a combination of industrial activity, marine emissions, biomass burning, vehicular activity, sewage treatment, waste incineration, and the food industry (e.g., Facchini et al., 2008; Sorooshian et al., 2009; Ge et al., 2011; VandenBoer et al., 2011); another key source of these species, animal husbandry (Mosier et al., 1973; Schade and Crutzen, 1995; Sorooshian et al., 2008), was ruled out owing to a scarcity of such activity in the study region. ~~Secondarily-Secondarily-~~produced amine salts likely were formed with SO_4^{2-} as the chief anion owing to its much higher concentrations relative to NO_3^- or organic acids.

Dimethylamine was the most abundant amine similar to other marine (Muller et al., 2009) and urban regions (Youn et al., 2015); the average concentration of DMA integrated over all MOUDI stages for all sample sets was 62.2 ng m^{-3} in contrast to 29.8 ng m^{-3} for TMA+DEA. For reference, the other key cation (NH_4^+) participating in salt formation with acids such as H_2SO_4 and HNO_3 was expectedly much more abundant ($1.64 \text{ } \mu\text{g m}^{-3}$). With regard to the competitive uptake of DMA versus NH_3 in particles, the molar ratio of $\text{DMA}:\text{NH}_4^+$ exhibited a unimodal profile between $0.1\text{--}1.8 \text{ } \mu\text{m}$ with a peak of 0.022 between $0.32\text{--}0.56 \text{ } \mu\text{m}$ and the lowest values at the tails (0.004 between $0.1\text{--}0.18$ and $1\text{--}1.8 \text{ } \mu\text{m}$); DMA was not above detection limits for either $D_p < 0.1 \text{ } \mu\text{m}$ or $D_p > 1.8 \text{ } \mu\text{m}$. The molar ratios observed were consistent with values measured in urban air of Tucson, Arizona and coastal air in Marina, California ($0\text{--}0.04$; Youn et al., 2015) and near the lower end of the range measured in rural and urban air masses sampled near Toronto ($0.005\text{--}0.2$; VandenBoer et al., 2011).

The most abundant organic acid was oxalate ($195 \pm 144 \text{ ng m}^{-3}$), followed by succinate ($21 \pm 41 \text{ ng m}^{-3}$), phthalate ($19 \pm 25 \text{ ng m}^{-3}$), maleate ($17 \pm 15 \text{ ng m}^{-3}$), and adipate ($5 \pm 8 \text{ ng m}^{-3}$). The observation of mass concentrations increasing with decreasing carbon number for dicarboxylic acids (i.e., oxalate > succinate > adipate) is consistent with many past studies for other regions as larger chain acids undergo oxidative decay to eventually form oxalate (e.g., Kawamura and Ikushima, 1993; Kawamura and Sakaguchi, 1999; Sorooshian et al., 2007). Maleate is an unsaturated dicarboxylic acid emitted from gas and diesel engines (Rogge et al., 1993) and a product from the photo-oxidation of benzene (Kawamura and Ikushima, 1993). The aromatic dicarboxylic acid phthalate is a known photo-oxidation product of naphthalene and stems largely from plastic processing and fuel combustion (Fraser et al., 2003; Kautzman et al., 2010; Fu et al., 2012; Kleindienst et al., 2012). The oxidation product (MSA) of ocean-derived DMS exhibited an overall average concentration of $11 \pm 7 \text{ ng m}^{-3}$, which is near the lower end of the range of levels reported in other coastal and marine environments (from undetected up to $\sim 200 \text{ ng m}^{-3}$) (e.g., Saltzman et al., 1983, 1986; Berresheim 1987; Watts et al., 1987; Burgermeister and Georgii, 1991; Sorooshian et al., 2015; Xu and Gao, 2015).

Water-soluble species exhibiting a peak in the supermicrometer range, usually between $1.8\text{--}5.6 \text{ } \mu\text{m}$, include those with known affiliations with sea salt (Na^+ , Cl^- , K^+ , Mg^{2+}) and crustal materials such as dust (Ca^{2+}). Nitrate peaked between $1.8\text{--}3.2 \text{ } \mu\text{m}$, and was best correlated with Na^+ and Mg^{2+} , suggestive of HNO_3 partitioning to sea salt as has been observed in other coastal

regions (e.g., Prabhakar et al., 2014a). There was very little NO_3^- in the submicrometer range ($0.05 \pm 0.04 \mu\text{g m}^{-3}$) in contrast to supermicrometer sizes ($0.78 \pm 0.47 \mu\text{g m}^{-3}$). More submicrometer NO_3^- in the form of NH_4NO_3 would be expected if there was an excess of NH_3 after neutralizing SO_4^{2-} . The mean ammonium-to-sulfate molar ratio for submicrometer sizes was 2.32 ± 0.52 (range: $1.11 - 2.78$), with full neutralization of SO_4^{2-} in 10 of 12 MOUDI sets. Thus, there was a non-negligible excess in NH_3 that presumably participated in salt formation with HNO_3 and organic species. The significant levels of NO_3^- in the same mode as Na^+ and Cl^- contributed to the significant Cl^- depletion observed, as the mean $\text{Cl}^-:\text{Na}^+$ mass ratio between 1-10 μm (i.e., range of peak sea salt influence) was 0.81 ± 0.28 , which is much lower than the ratio for pure sea salt (1.81) (Martens et al., 1973). The subject of Cl^- depletion in this region will be investigated more thoroughly in subsequent work.

Figure 6 shows SEM images of representative single particles in each supermicrometer stage. As would be expected for sea salt and crustal material, most of the particles shown are not spherical. Interestingly, only the particle shown between 1–1.8 μm was close to being spherical. Its composition based on EDX analysis was accounted for mostly by carbon (93.7%) with lower amounts of oxygen (5.8%) and Fe (0.5%). Sea salt particles were found in the next two stages owing to the highest combined weight percentages of Na^+ and Cl^- based on EDX analysis: 1.8–3.2 μm = 36.9%; 3.2–5.6 μm = 46.9%. The salt particles are not necessarily cubical but more rounded with signs of agglomeration. These two particles were the only ones among the 11 MOUDI stages exhibiting an EDX signal for S, with contributions amounting to ~2% in each particle. This may be linked to natural SO_4^{2-} existing in sea salt particles. Also, the particle between 3.2–5.6 μm contained a trace amount of Sc (1%). The largest three particles ($\geq 5.6 \mu\text{m}$) were expectedly irregularly shaped with both sharp and rounded edges, comprised mostly of oxygen, Al, Fe, and Ca based on EDX analysis.

3.2.3 Water-Soluble Elements

Averaged data across all MOUDI sets reveal that ICP-QQQ elements exhibited a variety of mass concentration profiles ranging from a distinct mode in either the sub- or supermicrometer range to having multiple modes below and above 1 μm (averages across all MOUDI sets shown in Figure 7). There were several elements with only one distinct peak, being in one of the two stages between 0.18-1.0 μm , including As, Cd, Co, Cr, Cs, Cu, Hf, Mn, Mo, Ni, Rb, Se, Sn, Tl, V,

Pb, and Zn. In contrast, the following elements exhibited only one distinct peak in the supermicrometer range: Al, Ba, P, Sr, Ti, Y, and Zr. The rest of the elements exhibited more complex behavior with two distinct peaks in the sub- and supermicrometer range (Ag, Fe, Nb). The following section discusses relationships between all of the ions and elements with a view towards identifying characteristic sources.

3.3 Characteristic Sources and Species Relationships

A combination of PMF and correlation analysis helped identify clusters of ~~closely-closely-~~ related species stemming from distinct sources. The ~~final~~ PMF solution ~~with five factors, based on five groups of species~~ (Figure 8); ~~was chosen because it~~ passed ~~the~~ criteria of physical meaningfulness ~~associated with being physically valid and it had a~~ the close proximity of the calculated ratio of $Q_{\text{true}}:Q_{\text{expected}}$ (1.2) ~~that was very close to the theoretical value of~~ 1.0. There was a high coefficient of ~~variation-determination~~ between measured and predicted mass concentration when summing up all species for each MOUDI stage ($r^2 = 0.79$; sample size, $n = 132$), which added confidence in relying on the PMF model for source apportionment of PM. The five distinct clusters were named for their most plausible sources based on the species included in the groupings, with their overall contributions to the total mass based on PMF analysis shown in parenthesis (Table 3): Aged/~~Transported~~ (48.0%), Sea Salt (22.5%), Combustion (18.7%), Vehicular/Resuspended Dust (5.6%), and Waste Processing (5.1%). For reference, a previous study near the northwestern edge of the Philippines identified six source factors for $\text{PM}_{2.5}$ that are fairly similar to those here (Bagtasa et al., 2018): sea salt, resuspended fine dust, local solid waste burning, and long range transport of (i) industrial emissions, (ii) solid waste burning, and (iii) secondary sulfate. Each of our five groupings will be discussed in detail below in decreasing order of contribution to total measured mass concentrations.

3.3.1 Aged/~~Transported~~ Aerosol

Although not due to one individual source, there was a distinct PMF factor that included species commonly produced via gas-to-particle conversion processes (NH_4^+ , SO_4^{2-} , MSA, oxalate). Correlation analysis (Table 4) also pointed to a large cluster of species significantly related to each other, including the aforementioned ions and a suite of other organic acids (phthalate, succinate, adipate), MSA, and DMA. The latter three inorganic and organic acid ions

exhibited significant correlations with each other ($r \geq 0.68$), but also with several elements ($r \geq 0.36$: K, V, Rb, Cs, Sn), which were likely co-emitted with the precursor vapors of the secondarily produced ions. Although BC concentrations were quantified from set MO13 only, their interrelationships with water-soluble ions from simultaneously collected set MO14 are representative for other sets. The results showed that BC was significantly correlated (r : 0.61-0.92) with 15 species, including those mentioned above (owing to co-emission) and also a few elements that were found via PMF to be stronger contributors to the Combustion source discussed in Section 3.3.3 (Ni, Cu, As, Se, Cd, Tl, Pb).

This PMF source factor is referred to as Aged Aerosol/Transported owing to its characteristic species being linked to secondary particle formation from emissions of regional and distant sources ~~sources distant from the sample site.~~ The presence of NH_4^+ and SO_4^{2-} could be attributed to precursors from various local and regional combustion sources. Examples include while MSA and DMA being are secondarily produced from ocean-derived gaseous emissions (e.g., Sorooshian et al., 2009) and K stemming from biomass burning emissions from distant upwind regions such as Sumatra and Borneo (Xian et al., 2013) are likely sources of K. Previous studies (Reid et al., 2012; Wang et al., 2013) have shown that phenomena such as SWM and El-Nino events not only influence biomass burning activities in the Malay Peninsula but also impact the transport and distribution of emissions in the study region. For instance, Reid et al. (2016b) showed that enhancement in monsoonal flow facilitates the advection of biomass burning and anthropogenic emissions to the Philippines from Sumatra and Borneo. Subsequent work will investigate more deeply the impact of biomass burning from those upwind regions on the sample site during the SWM.

While NH_4^+ and SO_4^{2-} require time for production owing to being ~~secondarily~~ secondarily produced from precursor vapors (i.e., SO_2 , NH_3), oxalate is the smallest dicarboxylic acid and requires lengthier chemistry pathways for its production and thus is more likely produced in instances of aerosol transport and aging (e.g., Wonaschuetz et al., 2012; Ervens et al., 2018). The various elements associated with this cluster are co-emitted with the precursors to the aforementioned ions and are linked to a variety of sources: metallurgical processes (Anderson et al., 1988; Csavina et al., 2011; Youn et al., 2016), fuel combustion (Nriagu, 1989; Allen et al., 2001; Shafer et al., 2012; Rocha and Correa, 2018), residual oil combustion (Watson et al., 2004), biomass burning (Maudlin et al., 2015), marine and terrestrial biogenic emissions (Sorooshian et

al., 2015), and plastics processing (Fraser et al., 2003). In addition, there is extensive ship traffic in the general study region, which is a major source of species in this cluster of species, particularly V and SO_4^{2-} (e.g., Murphy et al., 2009; Coggon et al., 2012).

PMF analysis suggested that the Aged ~~Aerosol/Transported~~ factor contributed 48.0% to the total water-soluble mass budget during the study period. Most of the contribution resided in the submicrometer range (68.9%) unlike the supermicrometer range (18.6%), which is consistent with the overall mass size distribution of total PM peaking in the submicrometer range (Figure 2). The reconstructed mass size distribution for this PMF source factor shows the dominance of the mass in the submicrometer range with a peak between 0.32–0.56 μm (Figure 9). The correlation matrices for the sub- and supermicrometer size ranges also show that the correlations between the species most prominent in the Aged ~~Aerosol/Transported~~ category are stronger for the former size range (Tables S2-S3). The contribution of this PMF factor to the supermicrometer range is likely associated with species secondarily produced on coarse aerosol such as dust and sea salt. This is evident in the individual species mass size distributions where there is a dominant submicrometer mode but also non-negligible mass above 1 μm .

Even though the PM in a heavily populated urban region, such as Metro Manila, is typically thought to be dominated by local sources of aerosols, the current PMF results show that ~~the largest contributions to water soluble aerosol mass are from Aged/Transported pollution contribution from long range transport is still discernible.~~ This finding is contrary to the expectation that ~~(a) the signal of transported aerosols would be lost in the noise of locally-produced aerosols, and (b) the removal of aerosols over the ocean surrounding the Philippines by processes such as wet scavenging would significantly reduce the contribution of transported aerosols. Even though other cities may have different pollution signatures, varying in pollutant type and amount, this phenomenon of Aged/Transported pollution forming a significant portion of the water soluble mass may be applicable to other cities, especially those in Southeast Asia.~~

3.3.2 Sea Salt

As the MO sampling site is approximately 13 km from the nearest shoreline (Figure 1a) and downwind of Manila Bay in the SWM season, there was a great potential for marine emissions to impact the samples. There were several species with similar mass size distributions (mode: 1.8–5.6 μm) and highly correlated total mass concentrations ($r \geq 0.51$) that are linked to sea salt: Cl^- ,

Na⁺, Ca²⁺, Mg²⁺, Ba, and Sr. The correlations between these species were stronger when examining just the supermicrometer range as compared to the submicrometer range (Tables S2-S3). The majority of these species was used in PMF analysis and formed a distinct cluster amounting to 22.0% of the total study period's mass budget. This source contributed only 0.6% to the submicrometer mass concentration but 53.5% for the supermicrometer size range. The reconstructed mass size distribution for this source factor is shifted farthest to the larger diameters as compared to the other four sources with a peak between 1.8-3.2 μm (Figure 9).

It is noteworthy that this factor has the highest share of NO₃⁻ among all identified sources. This result is consistent with mass size distributions shown in Figure 5 in which NO₃⁻ peaks in the supermicrometer range similar to sea salt constituents (e.g., Na⁺ and Cl⁻). Although sea salt particles naturally contain NO₃⁻ (Seinfeld and Pandis, 2016) (mass ratio of NO₃⁻:Na⁺ = 9.8×10^{-8} – 6.5×10^{-5}), the extremely high ratio of NO₃⁻:Na⁺ (mass ratio ~1.8) suggests that only a negligible portion of NO₃⁻ in this factor originated from primary sea salt particles. Thus, the majority of NO₃⁻ is most likely due to HNO₃ partitioning to existing sea salt particles (e.g., Fitzgerald, 1991; Allen et al., 1996; Dasgupta et al., 2007; Maudlin et al., 2015). In addition, the Cl⁻:Na⁺ mass ratio in this profile (0.65) is smaller than that in sea salt particles (1.81), indicating high Cl⁻ depletion mainly due to reactions of HNO₃ with NaCl (Ro et al., 2001; Yao et al., 2003; Braun et al., 2017). Moreover, elevated loadings of trace elements (e.g., Ba, Cu, Zn, and Co) could be linked to mixing of marine emissions with urban sources (e.g., vehicle and industrial emissions) during their transport inland to the sampling site (Roth and Okada, 1998). This process of aging is consistent with the observed morphology of the sea salt particles in this study, revealing non-cubical shapes that are rounded owing to the likely addition of acidic species such as HNO₃ (Figure 6).

3.3.3 Combustion

There are numerous sources of combustion in the study region, including a variety of mobile sources (e.g., cars, utility vehicles, trucks, buses, motorcycles) and stationary sources (e.g., power stations, cement works, oil refineries, boiler stations, utility boilers). Consequently, the next highest contributor to total mass during the study period according to PMF (18.7%) was the cluster of species including Ni, As, Co, P, Mo, and Cr, which is defined as the Combustion factor. These species have been reported to be rich in particles emitted from combustion of fossil fuel and residual oil (Linak and Miller, 2000; Allen et al., 2001; Wasson et al., 2005; Mahowald et al.,

2008; Mooibroek et al., 2011; Prabhakar et al., 2014b). Although not included in PMF analysis, other species significantly correlated with the previous ones include maleate and Ag, which also stem from fuel combustion (Kawamura and Kaplan, 1987; Lin et al., 2005; Sorooshian et al., 2007). Ag specifically is an element in waste incinerator fly ash (Buchholz and Landsberger, 1993; Tsakalou et al., 2018) and its strong correlation with Co ($r = 0.85$) and Mo ($r = 0.64$) provides support for this source factor being linked to combustion processes. Maleate is commonly found in engine exhaust (Kawamura and Kaplan, 1987), while Cr is a tracer for power plant emissions (Singh et al., 2002; Behera et al., 2015). Of all species examined in this study, BC was best correlated with As ($r = 0.92$), while its correlation with Ni ($r = 0.85$) was among the highest.

As the elements in this cluster peaked in concentration in the submicrometer mode, the weight percentage of this factor is more than double below $1\text{ }\mu\text{m}$ (23.9%) as compared to above $1\text{ }\mu\text{m}$ (11.3%). The reconstructed mass size distribution for this source factor peaks between $0.18\text{--}0.32\text{ }\mu\text{m}$, which is smaller than the modal diameter range for the Aged/~~Transported~~ source factor ($0.32\text{--}0.56\text{ }\mu\text{m}$) likely owing to closer sources and thus less time for growth to occur via condensation and coagulation.

3.3.4 Vehicular/Resuspended Dust

The next PMF source factor contains chemical signatures of dust because of high contributions to Al, Ti, Ca, and Fe. These crustal elements are strongly related to resuspension of dust by traffic and construction activities (Singh et al., 2002; Harrison et al., 2011). Other elements that were prominent in this factor included Zr, Y, Mn, Cr, and Ba, which are associated with tire and brake wear (Adachi and Tainosho, 2004; Gietl et al., 2010; Song and Gao, 2011; Harrison et al., 2012; Vossler et al., 2016), although some of them can be linked to ~~the~~ exhaust as well (e.g., Lin et al., 2005; Song and Gao, 2011). This source is named Vehicular/Resuspended Dust and contributed 5.6% to the total study period's mass concentrations.

The weight percentage contribution of this factor was much higher for the supermicrometer range (11.3%) as compared to the submicrometer range (1.5%), which is consistent with the Sea Salt source factor owing to similar mass size distributions of the individual species associated with the two source categories (Figures 5 and 7). Additional species correlated significantly with the crustal species included Hf and Nb, which also exhibited mass peaks between $1.8\text{--}3.2\text{ }\mu\text{m}$. The reconstructed mass size distribution for this source factor is similar to that of Sea Salt in that there

is a peak between 1.8–3.2 μm , but there is less of a unimodal profile owing to what appears to be a secondary mode between 0.56–1.0 μm (Figure 9), which could be linked to some of the non-dust components of vehicular emissions.

3.3.5 Waste Processing

The final PMF source factor, contributing the least overall to total mass (5.1%), featured Zn, Cd, Pb, Mn, and Cu as its main components. These species are linked to waste processing, including especially electronic waste (e-waste) and battery burning and recycling (Gullett et al., 2007; Iijima et al., 2007), which was previously reported for Manila (Pabroa et al., 2011). The latter study reported that although there are a few licensed operations for battery recycling, there are numerous unregulated cottage melters across Manila that regularly melt metal from batteries and discard the waste freely. Fujimori et al. (2012) additionally showed that e-waste recycling led to emissions of the following elements (in agreement with this PMF cluster) around Metro Manila: Ni, Cu, Pb, Zn, Cd, Ag, In, As, Co, Fe, and Mn.

This was the only PMF factor exhibiting comparable weight percentages both below (5.1%) and above 1 μm (5.3%). This is reflected in the mass size distributions of the species included in this cluster being fairly uniformly distributed below and above 1 μm . This is also demonstrated in the reconstructed mass size distribution of this source factor as it clearly exhibits a mode between the other four sources (0.56–1.0 μm) and is the broadest mode (Figure 9). The explanation for this is likely rooted in the diversity of sources contained within this source profile that lead to different sizes of particles. Examples of such sources include processing of different types of waste at varying temperatures and through various processes (e.g., burning, melting, grinding) (Keshtkar and Ashbaugh, 2007),

4. Conclusions

This study used various analytical techniques (gravimetry, ~~IC~~ion chromatography, triple quadrupole inductively coupled plasma mass spectrometry~~ICP-MS~~, black carbon spectroscopy, and microscopy), meteorological data, and a source apportionment model (Positive Matrix Factorization) to characterize the sources, chemical composition, and morphology of size-resolved ambient particulate matter (PM) collected using Micro-Orifice Uniform Deposit Impactors

(MOUDIs) in Metro Manila, Philippines during the southwest monsoon season (SWM) season of 2018. The main results of this study include the following:

- The total mass concentrations were measured on two occasions and were $18.6 \mu\text{g m}^{-3}$ and $53.0 \mu\text{g m}^{-3}$. Water-soluble mass concentrations were measured on 12 occasions and were on average $8.53 \pm 4.48 \mu\text{g m}^{-3}$ (range = $2.7\text{--}16.6 \mu\text{g m}^{-3}$). Simultaneous measurements of total, water-soluble, and black carbon (BC) mass revealed a composition of 26.9% BC, 31.3% water-soluble components, and 41.8% unaccounted mass.
- Size-resolved BC mass concentration was measured on one occasion, with the mass sum of all MOUDI stages reaching $14.3 \mu\text{g m}^{-3}$. Most of the BC mass (95%) was contained in the $0.1\text{--}1 \mu\text{m}$ range (i.e., the Greenfield gap) where wet scavenging by rain is relatively inefficient. The measured BC peaked in the size range of $0.18\text{--}0.32 \mu\text{m}$ and accounted for 51.8% of the measured PM for that stage. In the range of $0.10\text{--}0.18 \mu\text{m}$, the mass percent contribution of BC to the measured PM was 78.1%.
- Most of the total mass resided in the submicrometer mode ($0.32\text{--}0.56 \mu\text{m}$); however, one MOUDI set revealed an additional supermicrometer mode ($1.8\text{--}3.2 \mu\text{m}$). Water-soluble species that peaked in the submicrometer mode were associated with secondarily produced species, including inorganic acids, amines, Methanesulfonate (MSA), and organic acids. Water-soluble species that peaked in the supermicrometer mode were associated with sea salt and crustal material. Most of the unaccounted mass was for $D_p > 0.32 \mu\text{m}$.
- The most abundant water-soluble species was SO_4^{2-} ($44\% \pm 6\%$), followed by NH_4^+ ($18\% \pm 5\%$), NO_3^- ($10 \pm 3\%$), Na^+ ($8 \pm 3\%$), and Cl^- ($6\% \pm 3\%$). Correlation analysis revealed that total water-soluble mass was most correlated with temperature ($r = 0.64$) and rainfall accumulation ($r = -0.49$) among meteorological factors considered, although other factors were likely influential such as wind direction and speed.
- Regardless of particle size, the majority of single particles examined with energy dispersive X-ray spectroscopy (SEM-EDX) were non-spherical with evidence of agglomeration.
- PMF analysis suggested that there were five factors influencing the water-soluble fraction of PM collected at the sampling site. These factors, their contribution to total water-soluble mass, and the main species that permit them to be linked to a physical source are as follows: Aged Aerosol/Transported (48.0% ; NH_4^+ , SO_4^{2-} , MSA, oxalate), Sea Salt (22.5% ; Cl^- , NO_3^- , Ca^{2+} ,

Na⁺, Mg²⁺, Ba, Sr), Combustion (18.7%; Ni, As, Co, P, Mo, Cr), Vehicular/Resuspended Dust (5.6%; Al, Ti, Fe), and Waste Processing (5.1%; Zn, Cd, Pb, Mn, Cu). The dominant contribution of Aged/~~Transported~~ ~~a~~Aerosols to water-soluble mass contradicts ~~two—the~~ expectations: ~~that (i) locally-produced sources in polluted cities should drown out the signal of transported aerosol from distant upwind areas, and (ii) the signal of transported aerosols should be significantly reduced due to scavenging processes upwind of the measurement site.~~

Although the current study focuses exclusively on the SWM season in Metro Manila, results of this study are applicable to the study of aerosol impacts on Southeast Asia and other regions. First, the ~~significant presence detection of Aged/Transported a~~Aerosols not only from regional but also distant sources in Metro Manila indicates confirms previous studies that PM in the region has the ability to travel long distances during the SWM season, ~~despite the typical assumption that wet scavenging effectively removes most of the particles.~~ Characterization of aerosols in Metro Manila is therefore important for better understanding the impacts that local emissions will have on locations downwind of Metro Manila, including other populated cities in Southeast and East Asia. Transport of pollution and decreased wet scavenging during the SWM season may become increasingly important as studies have shown a decrease in SWM rainfall and increase in the number of no-rain days during the SWM season in the western Philippines in recent decades (e.g., Cruz et al., 2013).

Second, Southeast Asia has been named “one of the most hostile environments on the planet for aerosol remote sensing” (Reid et al., 2013) because of high cloud occurrence. Therefore, space-based remote sensing of aerosol characteristics, such as retrievals of aerosol optical depth (AOD), in this region are difficult. In situ measurements are critical for characterization of PM in this region, especially during seasons such as the SWM when clouds are especially prevalent and remote-sensing retrievals dependent on clear-sky conditions are lacking.

Third, this study provides a valuable dataset to compare to other regions impacted by monsoons where the impacts of enhanced moisture and rainfall on size-resolved composition are not well understood. As aqueous processing results in enhanced production of water-soluble species (e.g., sulfate, organic acids), it is noteworthy for this monsoonal region that the water-soluble fraction remains low relative to BC and other insoluble components. This has major implications for the hygroscopicity of the regional PM.

Finally, the results of this study will be used to inform future sampling campaigns in this region, including CAMP²Ex planned for the SWM season of 2019 based in the Philippines. As the current MOUDI sampling campaign at [the Manila Observatory](#) is expected to extend for a full year, future work will focus on changes in aerosol characteristics and sources on a seasonal basis [as well as scavenging processes upwind of the measurement site](#).

Data availability: All data used in this work are available upon request.

Author Contribution: MTC, MOC, JBS, ABM, CS, and AS designed the experiments and all co-authors carried out some aspect of the data collection. MTC, RAB, CS, LM, HD, and AS conducted data analysis and interpretation. MTC and AS prepared the manuscript with contributions from all co-authors.

Competing interests: The authors declare that they have no conflict of interest.

Table 1. Summary of average operating parameters, meteorological conditions, and total resolved water-soluble mass concentration for each MOUDI sample set collected at Manila Observatory (MO) during the 2018 Southwest Monsoon period. On two occasions, simultaneous MOUDI sets were collected for one set to undergo gravimetric analysis (MO3 and MO13) to compare with mass resolved from chemical speciation of the water-soluble fraction (MO4 and MO14). One additional MOUDI set devoted to microscopy analysis was collected using aluminum substrates for one hour on August 1 at 30 LPM.

Sample set name	Dates	Duraton (hrs)	Flow rate (LPM)	Wind speed (m/s)	Wind direction (°)	T (°C)	Rain (mm)	Water-soluble mass ($\mu\text{g m}^{-3}$)
MO1	Jul 19-20	24	30	3.3	90.1	24.9	47	4.6
MO2	Jul 23-25	54	30	1.3	95.8	26.7	7.8	6.5
MO3/4	Jul 25-30	119	28/30	1.2	111.8	26.7	49.6	5.2
MO5	Jul 30-Aug 1	42	29	2.6	98.1	27.5	52.8	9.2
MO6	Aug 6-8	48	27	0.9	127.5	26.1	30.4	5.1
MO7	Aug 14-16	48	28	3.0	107.8	27.8	2.8	13.7
MO8	Aug 22-24	48	29	3.5	108.7	28.1	1	12.8
MO9	Sep 1-3	48	27	0.7	98.6	26.6	51.6	6.2
MO10	Sep 10-12	48	29	1.0	94.7	26.2	78.4	6.4
MO11	Sep 18-20	48	27	0.5	290.2	27.8	0	2.7
MO12	Sep 26-28	48	27	1.2	96.3	27.8	6.8	13.5
MO13/14	Oct 6-8	48	28/26	0.6	108.2	27.8	0.8	16.6

Table 2. Charge balance slopes (cations on y-axis; anions on x-axis) for the MOUDI sets shown including the averages of all sets (All) for three size ranges: submicrometer stages spanning 0.056 – 1.0 μm ; supermicrometer stages (> 1.0 μm); and all stages (> 0.056 μm). The species used in the charge balance analysis include those speciated with the IC (listed in Section 2.3) plus K from ICP-QQQ analysis.

Sample set	0.056 – 1.0 μm	> 1 μm	> 0.056 μm
MO1	0.87	1.37	0.89
MO2	1.46	1.26	1.41
MO4	1.25	1.17	1.21
MO5	1.35	1.43	1.41
MO6	1.29	1.45	1.31
MO7	1.40	1.23	1.36
MO8	1.35	1.33	1.36
MO9	1.28	1.55	1.26
MO10	1.37	1.36	1.35
MO11	0.97	1.60	1.27
MO12	1.37	1.19	1.33
MO14	1.31	1.28	1.29
All	1.35	1.24	1.33

Table 3. Contributions (in weight percentage) of each PMF source factor to the total mass in different diameter ranges.

Diameter Range (µm)	Aged Aerosol/ Transported	Sea Salt	Combustion	Vehicular/ Resuspended Dust	Waste Processing
> 0.056	48.0%	22.5%	18.7%	5.6%	5.1%
0.056 - 1.0	68.9%	0.6%	23.9%	1.5%	5.1%
> 1.0	18.6%	53.5%	11.3%	11.3%	5.3%

Table 4. Correlation matrix (r values) between water-soluble species based on total MOUDI-integrated mass concentrations (> 0.056 μm). Blank cells represent statistically insignificant values. Results for the sub- and supermicrometer ranges are in Tables S2-S3. Panels A-E represent important species from each of the source profiles identified in Section 3.3: A = Aged Aerosol/Transported, B = Sea Salt, C = Combustion, D = Vehicular/Resuspended Dust, E = Waste Processing. DMA – Dimethylamine, MSA – Methanesulfonate, PH – Phthalate, OX – Oxalate, MA – Maleate, SU – Succinate, AD – Adipate.

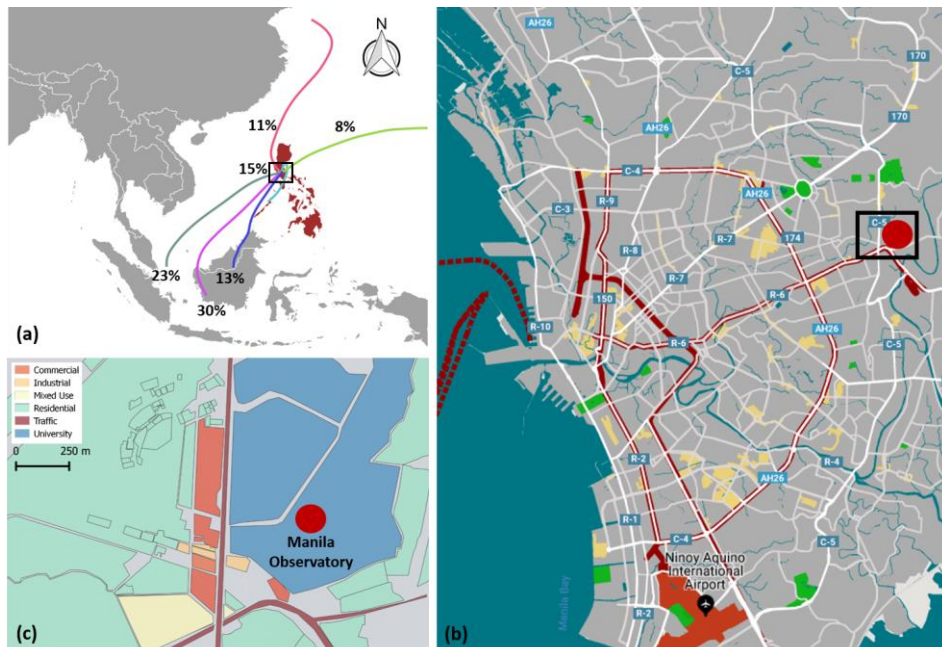

Figure 1. (a) Location of Metro Manila, Philippines relative to Southeast Asia. Also shown are 5-day backward trajectory frequencies during the sampling duration based on HYSPLIT cluster analysis; note that 15% correspond to trajectories within the black square. (b) Close-up view of Metro Manila showing the location of the Manila Observatory sampling site with a black rectangle. The base map shows roads, commercial centers, and major transit lines in the city. (c) Land use classification in the vicinity of the sampling site. (Sources: GADM, Snazzy Maps, OpenStreetMap, NOAA HYSPLIT, & TrajSat)

Figure 2. Mass size distributions of total PM (blue markers) and resolved chemical species (colored bars) for MOUDI sets (a) MO3/4 and (b) MO13/14. Note that set MO13 was the single MOUDI set where BC was quantified. ICP-QQQ = sum of water-soluble elements except K; amines = sum of DMA, TMA, DEA; organic acids = sum of oxalate, succinate, adipate, pyruvate, phthalate, maleate.

Figure 3. (a) Mass size distribution of BC retrieved from the MABI optical measurement at 870 nm for set MO13. Missing values were below detection limits. (b) Photographs of each stage of set MO13 with numbers below each image representing the aerodynamic diameter ranges in units of μm .

Figure 4. SEM image of a (a) blank filter and (b-f) individual particles in different sub-micrometer aerodynamic diameter ranges sampled by the MOUDI: (b) 0.056–0.1 μm , (c) 0.1–0.18 μm , (d) 0.18–0.32 μm , (e) 0.32–0.56 μm , (f) 0.56–1.0 μm .

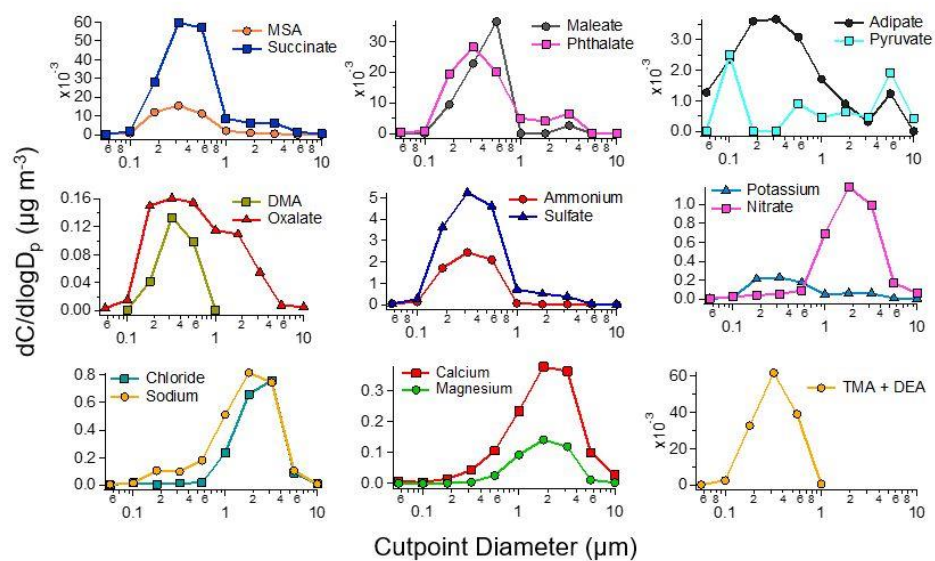

Figure 5. Average mass size distribution of water-soluble ions speciated via IC in addition to potassium from ICP-QQQ analysis.

Figure 6. Same as Figure 4, but for different supermicrometer aerodynamic diameter ranges sampled by the MOUDI: (a) 1.0–1.8 μm , (b) 1.8–3.2 μm ; (c) 3.2–5.6 μm , (d) 5.6–10 μm , (e) 10–18 μm , (f) > 18 μm .

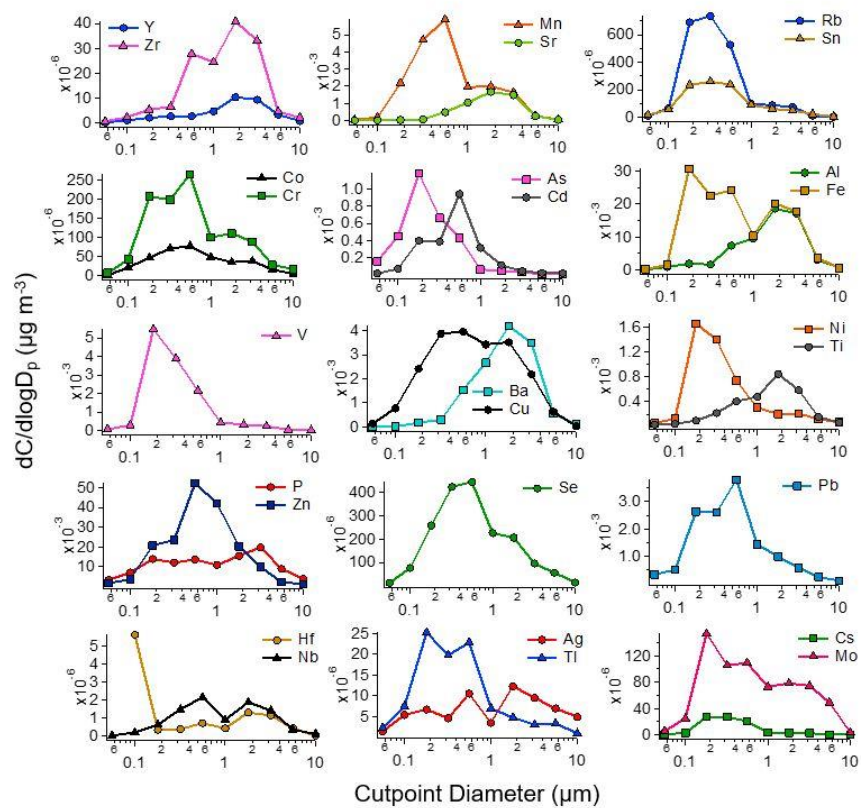

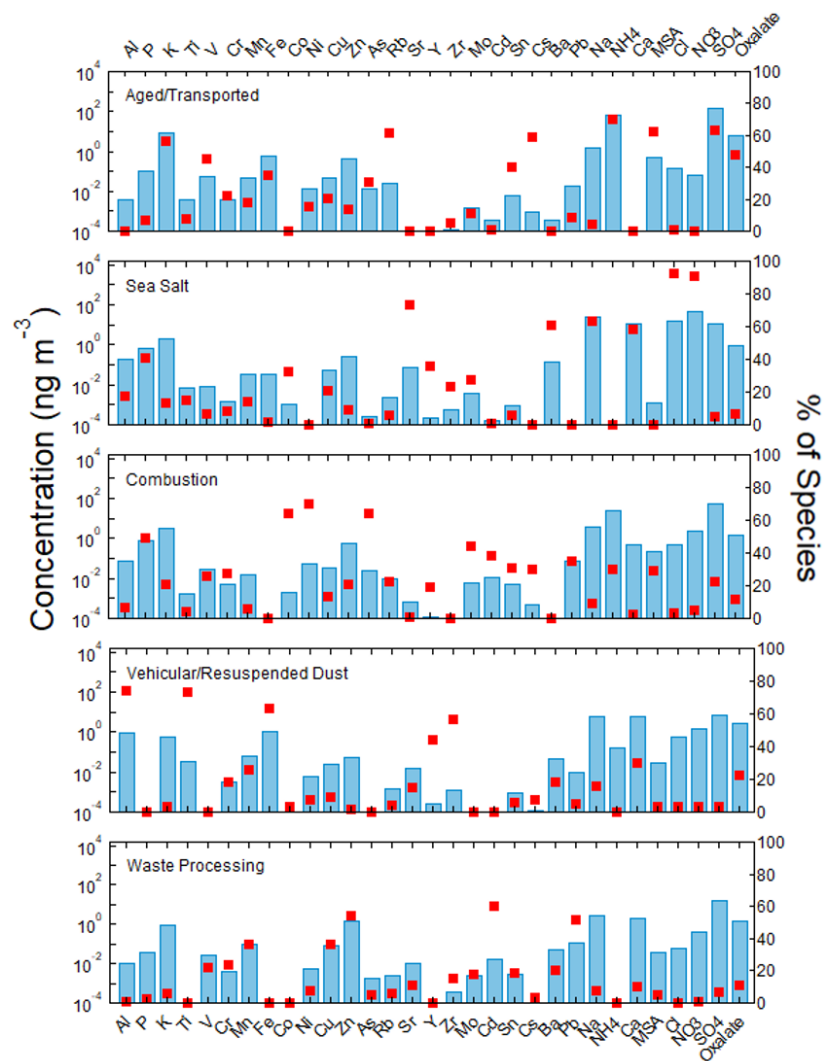

Figure 7. Average mass size distribution of water-soluble elements speciated via ICP-QQQ.

Formatted: Font color: Custom Color(RGB(0,0,10))

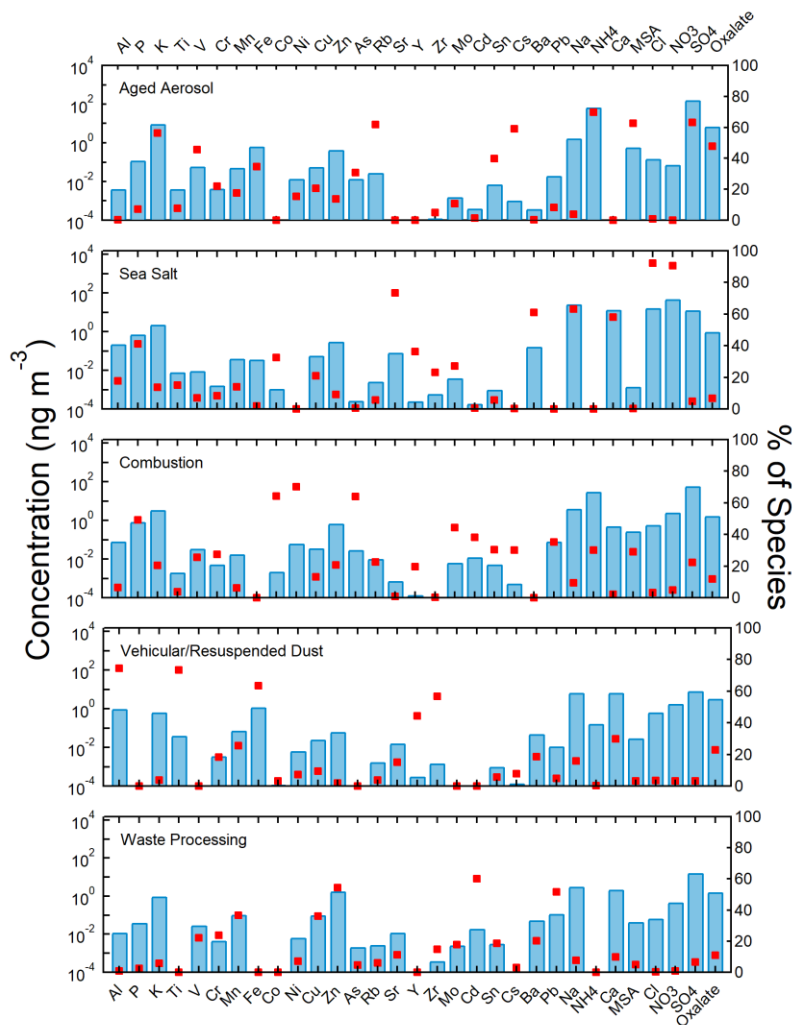

Figure 8. Overview of the PMF five factor solution with blue bars representing mass concentrations and red squares signifying the percentage of mass concentration contributed to constituents by each source factor.

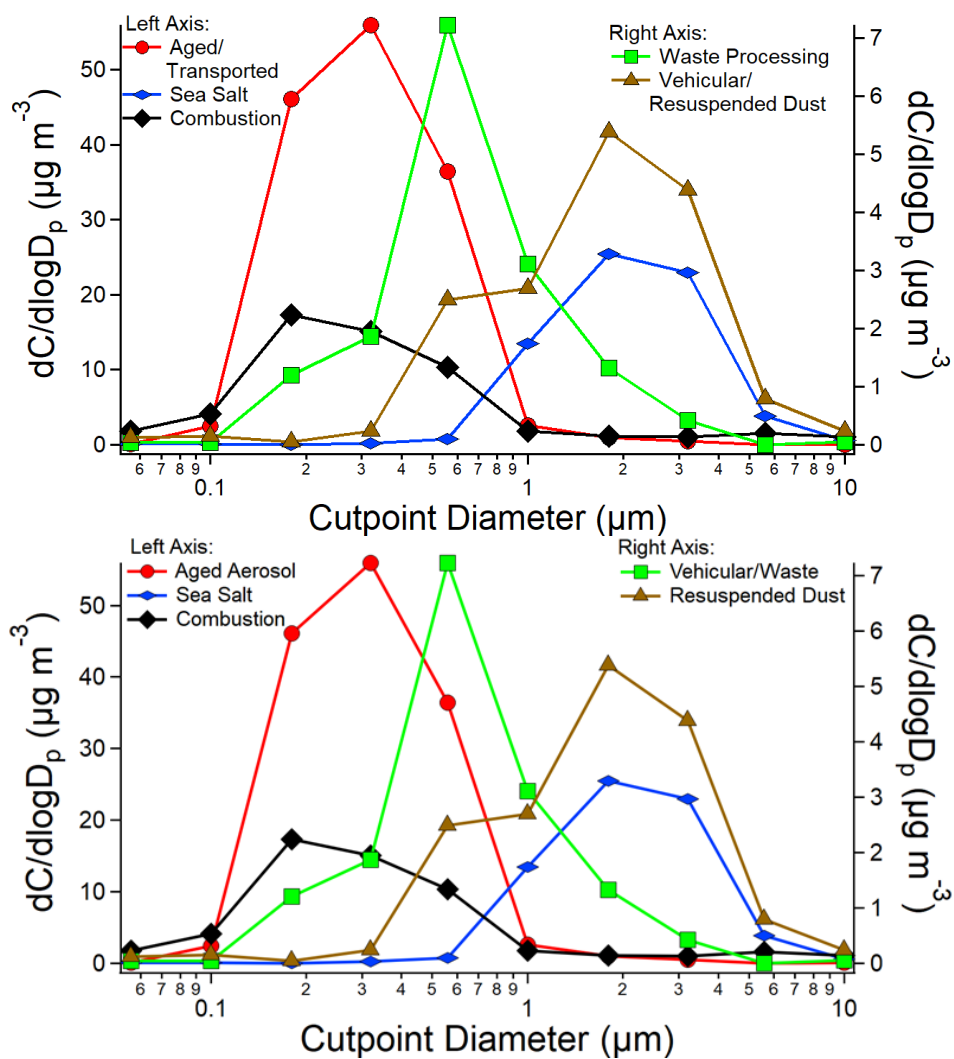

Figure 9. Reconstructed mass size distributions using PMF for the five major source profiles.
