Abstract

We would like to thank Anonymous Referees #1 and #3 for their useful and constructive feedback on our work. We additionally thank dr. Andreas Stohl for his comment. In this response letter, we carefully consider the issues that have been raised.

1 Anonymous Referee #1

Comment 1

The manuscript has presented the simulations of surface ozone concentrations over Europe in the regional air quality model (WRF-Chem). Its main focus is to analyse the changes in summertime surface ozone over Europe when replacing the bottom-up NO_x emission inventories with top-down NO_x emission estimates derived from the latest OMI NO₂ product. The results show that OMI-constrained European NO_x emissions are 56% higher than the bottom-up estimates, and that the increases can be largely attributed to large underestimates of agricultural soil emissions in the model. Model results with the top-down emissions significantly improve the comparison with surface in-situ NO₂ measurements and moderately improve the comparison with surface ozone measurements as well.

Overall the manuscript is well organised and written, the methodology is sound. I recommend publish on ACP after the following comments been addressed.

Response

We thank the Anonymous Referee #1 for her/his positive comments about our work and manuscript. We particularly thank the referee for the suggestion to include a discussion of time series and diurnal cycles, which we believe strengthens our message. Below, we address every comment carefully and explain the corresponding changes in the manuscript.

Comment 2

Page 1, Line 20 in the abstract: What does "-48%" mean? Reduced by or to this value? Please clarify.

Response

This should be: reduced by 48%. The sentence has been modified as follows (new text shown in blue):

With respect to the initial simulation, MDA8 O₃ has an improved spatial distribution, expressed by an increase in r^2 from 0.40 to 0.53, and a decrease of the mean bias by 7.4 $\mu\text{g m}^{-3}$ (48%).

Comment 3

Page 4, Line 17: The study assumes 97% of NO_x is emitted as NO and 3% as NO₂. Can the model simulation of NO₂ column be sensitive to this partitioning? Please discuss.

Response

Our NO_x emission partitioning was motivated by the recommendation in the TNO-MACC-III anthropogenic emission dataset that 97% of NO_x be emitted as NO, and the remaining 3% as NO₂. Indeed, the NO₂/NO_x ratio in vehicle emissions, the largest NO_x source in

Europe (Kuenen et al., 2014), is on the order of 10% to 20% (Carslaw, 2005). Surface concentrations can be sensitive to this emission ratio, as is seen at road-side air quality monitoring stations that are close to vehicle emission sources (Grange et al., 2017). Road-side observations sample air that has likely not reached photo-chemical equilibrium, so the NO_x emission partitioning could be a potential source of error when comparing model output to observations from road-side stations. This motivates our choice to use only background air quality observations for our model comparison to in situ data.

However, the NO_2 column represents a vertically integrated amount of NO_2 , composed of NO_x emitted at the surface that has been transported horizontally and vertically, as well as NO_x from adjacent model cells. We can assume that a photo-chemical equilibrium has been reached on the spatial scale of a $20 \times 20 \text{ km}^2$ model pixel, especially in the model levels away from the lowermost level (but still in the boundary layer). Therefore, we do not think that the model-simulated NO_2 column is strongly sensitive to the NO_x emission partitioning.

Comment 4

Page 4, Line 31: Here "+/-40%" should be "40%".

Response

Noted, the \pm sign has been removed.

Comment 5

Page 10, Line 17-20: The sentence is confusing. Why the model underestimates of NO_2 column would reflect emissions from power plants being too strong? Please clarify.

Response

We agree with the referee that this statement can be perceived as confusing. We therefore added extra context to further clarify this issue:

For example, the simulated NO_2 column over northwestern Spain is underestimated by $2 \times 10^{15} \text{ molec. cm}^{-2}$ compared to OMI. The enhanced NO_2 columns in this region mainly reflect the contribution to atmospheric NO_x by power plant emissions. Although emissions from power plants should have decreased in recent years in this region (Zhou et al., 2012), these emissions seem to be underestimated in WRF-Chem. However, since these results are only representative or July 2015, a more dedicated analysis is needed to further corroborate this hypothesis.

Comment 6

Page 10, Line 25-28: This statement did not explain why there was a larger model underestimate of surface NO_2 concentration than that of NO_2 column. Can you explain further? Would it reflect biases in model vertical transport or any measurement bias?

Response

Figure 9a in the main text indeed shows a lower model relative bias of surface NO_2 concentrations than of the tropospheric NO_2 column. We believe that missing surface NO_x sources are responsible for the stronger underestimation at the surface. The surface model level, which is used for the comparison to surface stations, is more sensitive to missing NO_x sources than the tropospheric NO_2 column.

We have investigated this while preparing the manuscript. We calculated the β -values (see Eqn. 3 in the main text) in two different ways: based on changes in the tropospheric NO_2 column, and based on changes in surface NO_2 concentrations (See Fig. 1). Column-based β -values are consistently higher, implying that the emission increase needed to match column observations is larger than for in situ observations at the surface. This conclusion is supported by a study currently under discussion for ACP (Li and Wang, 2019) that also finds a stronger sensitivity for surface NO_x emission changes at the surface compared to the tropospheric column.

Figure 1: Scatter plot of column β -values (β_{column}) versus surface β -values (β_{surface}), calculated by using a perturbation simulation with +20% surface emissions (see Sect. 3, Eq. 3). β_{surface} is calculated in the same manner as β_{column} , using the surface NO_2 mixing ratio as the response variable.

We have modified the statement in the main text:

There is a relatively larger model underestimation of surface NO_2 than of the NO_2 VCD in regions with comparatively low emissions. Given that the surface NO_2 mixing ratios are more sensitive to surface emissions than the NO_2 VCD (Li and Wang, 2019), this suggests that emissions are generally too low in WRF-Chem, but especially that emissions in rural background regions are underesti-

lated.

Comment 7

Page 12, Line 20-22: The sentence stated that model "underestimates the highest monthly averaged NO₂ observations", but Figure 9 showed the opposite. Model results appeared to be slightly biased high for over high NO_x emission regions. And should be 0.86 be 0.89?

Response

Firstly, thank you for noticing this typo, the slope should indeed be 0.89 instead of 0.86.

Figure 8 shows that, on average, WRF-Chem with top-down NO_x emissions still slightly underestimates surface NO₂. However, Figure 9 shows that the model indeed overestimates the NO₂ column and surface NO₂ in regions with high NO_x emissions (though there are only a limited number of AirBase background stations in these high-emission regions).

The results in Figure 8 are not in disagreement with those in Figure 9, because WRF-Chem overestimates the monthly-averaged surface NO₂ concentration at several stations. At those stations, WRF-Chem also shows a positive relative bias compared to AirBase in Figure 9. The improved slope between model and independent in situ observations indicates that our endeavour to derive satellite-based emissions has removed much of the systematic bias in simulated surface NO₂, but now leads to an overestimation in the simulated NO₂ concentrations at some stations. The scatter around the 1:1-line leads to low correlation values for NO₂ (also observed by e.g. Tuccella et al., 2012; Mar et al., 2016), and is likely caused by differences in spatial representativeness between a 20×20 km² model cell and in situ observations.

We have modified the sentence as follows, in order to ensure that the apparent contradiction between the results in Figures 8 and 9 is removed:

The modified model set-up still slightly underestimates the **highest** monthly-averaged NO₂ observations, as indicated by a slope of **0.89**.

Comment 8

Page 14, Line 1: Should 0.40 be 0.41 as seen from Table 1?

Response

That is correct, this typo has been changed in the manuscript.

Comment 9

Page 13, Section 6.2: The improvement on surface ozone simulation with the top-down NO_x emissions appears to be small. Can you also comment on some other metrics, such as time series of ozone levels at representative sites, or their diurnal cycles?

Response

We agree with Anonymous Referee #1 that the remaining model-observation mismatch is substantial. However, we actually believe a domain-average increase of the simulated monthly mean mid-day surface O₃ concentration of 6 µg m⁻³ (in some regions reaching over 15 µg m⁻³) after application of satellite-derived NO_x is remarkable and agrees well with previously reported ozone sensitivities to NO_x emissions (e.g. Mallet and Sportisse, 2005; Li et al., 2019).

Nonetheless, we have taken up the suggestion by Anonymous Referee #1 to include an analysis of monthly diurnal cycles and time series of O₃ in six representative regions in Europe. This analysis supports our point that the afternoon ozone peak depends on NO_x emissions. Therefore, the main text now contains a discussion of O₃ diurnal cycles, whereas the complete time series are included in the supplement.

The six representative regions span several degrees in latitude/longitude and contain 18-59 stations for a time series comparison (Figs. 2 and 3, and Table 1). Two have high NO_x emissions (BeNeLux + Ruhr, Po Valley), with contrasting ozone production efficiency due to temperature and radiation differences. Two sites are situated in low-NO_x rural background areas (Central France and Central Spain), while two other regions show a considerable NO_x emission increase that apparently results in a strong response in O₃ (Southern Germany, Poland).

The following section has been added to the main text:

We additionally analyzed changes in the temporal evolution of ozone concentrations resulting from NO_x emission changes (Fig. 10). Daytime median O₃ concentrations are better captured in the Po Valley, Central Spain and Poland. The NO_x emission changes lead to a model overestimation of surface O₃ concentrations for Central France and South Germany, while concentrations change only slightly in the BeNeLux and Ruhr areas. In those regions, the mean bias error increases, while the hourly correlation coefficient and RMSE values improve for all regions (Supplementary Table 4). In all areas, changes in NO_x emissions lead to increased ozone concentrations particularly during daytime. Enhancements in simulated night-time concentrations are only observed in Central Spain. In other areas, night-time O₃ concentrations are overestimated in both simulations. Peak daytime O₃ concentrations are better captured in all areas, as evidenced by the increase of the 75th percentile of simulated O₃ concentrations with top-down emissions. However, peak O₃ concentrations remain underestimated in the Po Valley, Central Spain and South Germany. Additionally, nighttime O₃ concentration overestimations remain, likely due to issues related to model resolution and vertical mixing. Overall, the NO_x emission changes most effectively increase O₃ concentrations during periods with elevated ozone (Fig. S3), which coincide with high solar radiation and temperatures and thus have a strongly NO_x-dependent O₃ formation.

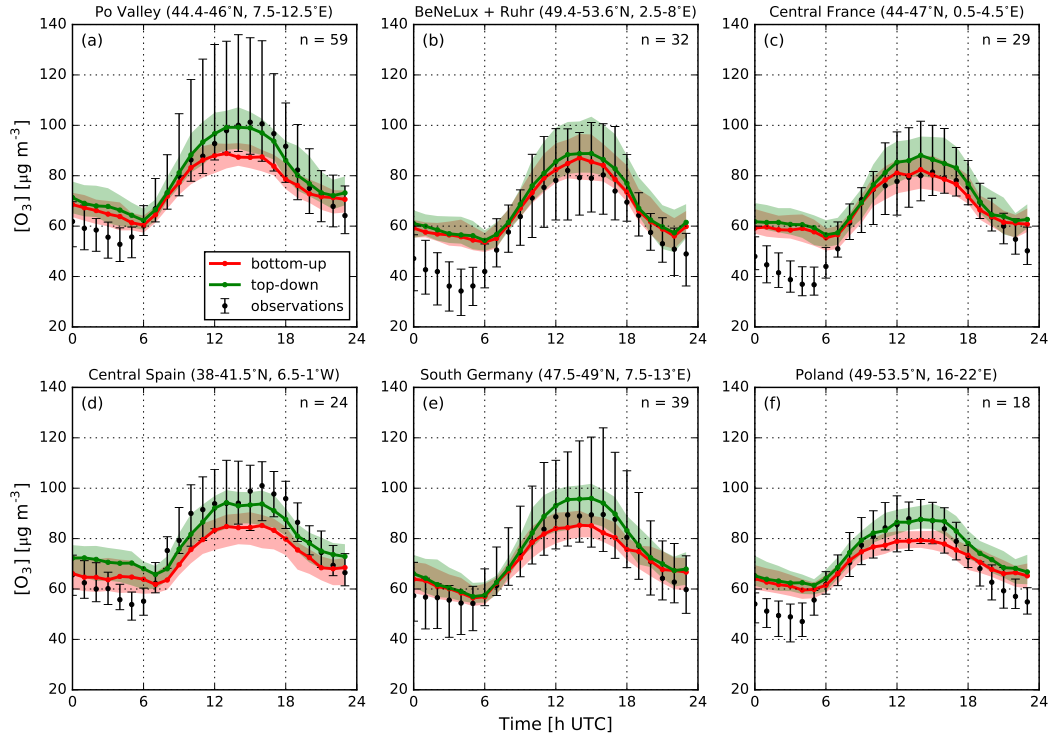

Figure 2: July 2015 monthly median diurnal ozone concentrations for six representative regions in Europe, as simulated by WRF-Chem with a priori NO_x emissions (green line) and a posteriori NO_x emissions (red line), and as observed at AirBase stations in these regions. Shaded areas and whiskers indicate the inter-quartile range. Results represent the median over all model-observation comparisons per region. The sample size for the comparison is displayed on the top right of each subplot.

Table 1: Model performance statistics for surface ozone concentration time series of the WRF-Chem simulation with bottom-up and top-down emissions for six European regions.

	Po Valley	BeNeLux + Ruhr	Central France	Central Spain	South Germany	Poland
n (stations)	59	32	29	24	39	18
Bottom-up						
MBE	-20.14	16.82	3.35	-22.40	-11.15	1.74
RMSE	68.07	71.48	59.92	45.39	68.68	43.64
r	0.80	0.78	0.76	0.81	0.74	0.77
Top-down						
MBE	-1.58	25.94	17.29	-1.33	5.02	16.10
RMSE	55.08	68.57	56.48	36.44	58.13	41.81
r	0.85	0.81	0.79	0.83	0.81	0.80

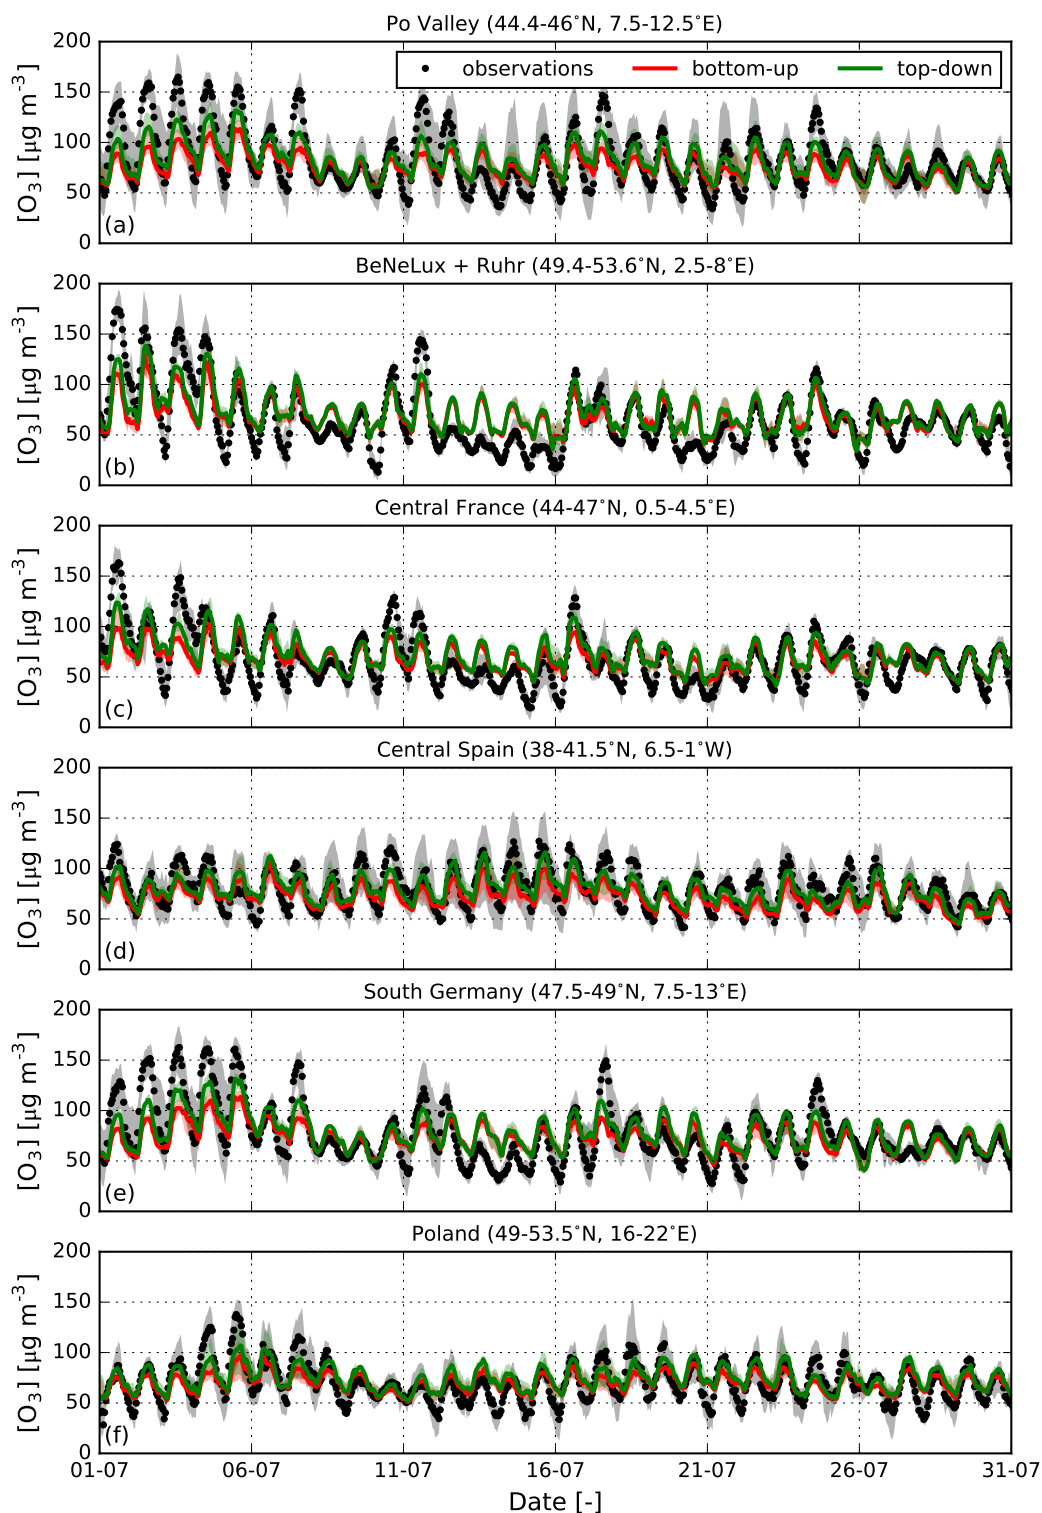

Figure 3: July 2015 time series of the median O_3 concentrations as observed at AirBase stations (black dots), and as simulated by WRF-chem with bottom-up (red) and top-down emissions (green). Medians are calculated by including all stations (resp. co-sampled simulations) in the latitude/longitude range specified in the subplot titles. Shaded areas show the inter-quartile range.

Comment 10

Page 28, Figure 10: The right panel of Figure 10 is misleading by showing all values including negative values in red. Can you change the color table, e.g., use red for positive values, white for near-zero values, and blue for negative values?

Response We agree that a diverging colormap is more appropriate here. The colormap has been updated in the figure.

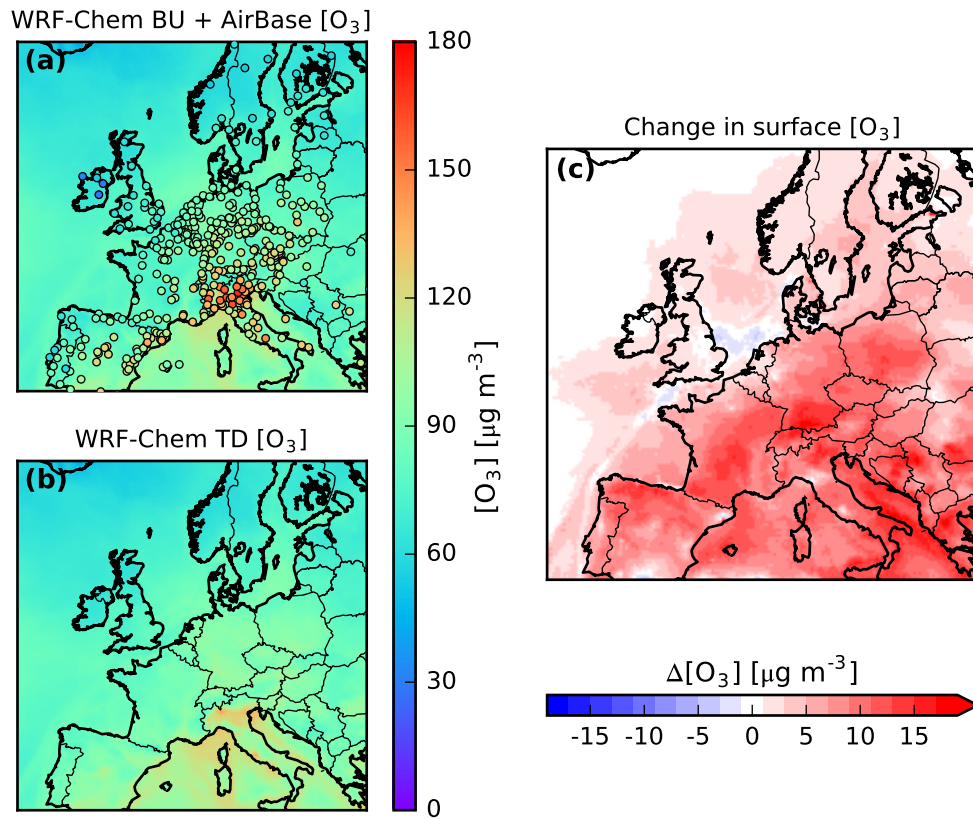

Figure 4: Monthly-averaged 12:00 h UTC surface O₃ concentration with bottom-up (BU, panel a) and top-down (TD, panel b) NO_x emissions. Panel c shows the difference between the two monthly averages (TD - BU).

2 Anonymous Referee #3

Comment 1

I found the manuscript very well written and clear. All details of the methods seem to be explained in order to assure reproducibility and the results are logically and clearly illustrated. I think the manuscript is basically ready for publication, but I have only two comments/suggestions that the authors may evaluate for a minor revision:

Response

We thank Anonymous Referee #3 for her/his positive evaluation of our study. The suggestions for further analysis are interesting, and we address them below.

Comment 2

Attribution to soil NO_x emissions: the authors make a first-order estimate of the contribution of soil NO_x emissions to increased total NO_x emissions, after ingestion of satellite NO₂ column data, using "anthropogenic" grid cells to estimate the contribution to NO_x emissions from sources other than soils. This sounds to be reasonable, also considering the diffuse nature of the NO_x emission change. A further relatively simple test to confirm the hypothesis would be to run an additional simulation with increased bottom-up soil NO_x emissions only by an x%, and see if the changes are consistent with the simulations using top-down emissions, both in terms of spatial distribution and magnitude.

Response

Indeed, a strong and uniform increase in soil NO_x emissions would lead to increases in simulated peak ozone concentrations, and would therefore reduce model bias in rural areas: a recent study found an increase in the monthly-averaged daily maximum ozone mixing ratio of 6 ppb after increasing a priori emissions from soils by 500% (Li et al., 2019). A sensitivity test that we performed while preparing the manuscript, in which soil NO_x emissions were uniformly scaled up by 86%, points in the same direction. We are however hesitant to include a sensitivity study with a uniform scaling factor for soil NO_x emissions in the paper, since this goes against our point that a strong contribution by fertilizer application (Ganzeveld et al., 2010) is likely missing in the a priori soil NO_x emission budget, leading to a wrong spatial distribution of soil NO_x emissions. The contribution of fertilizer-induced NO_x emissions in Europe varies strongly per country (e.g. Butterbach-Bahl et al., 2009). The sensitivity of (peak) ozone concentrations to soil NO_x emissions is further reflected by studies introducing improvements in the process-based representation of soil NO_x emissions in the CMAQ CTM, which found strong increases of MDA8 O₃ and a reduced mean ozone concentration bias over agricultural areas (Rasool et al., 2016, 2019).

The study by Li et al. (2019), which exactly describes the experiment that Anonymous Referee #3 requests, albeit for a different study area, was not yet published at the time of submission. We have therefore added the following content to our discussion:

Several studies previously investigated the relation between soil NO_x emissions and O₃ formation. For example, one study estimated that European soil NO_x emissions contribute 4 ppb to the daily maximum concentration (Stohl et al., 1996). A sensitivity study by Li et al. (2019) indicates that a strong up-scaling of soil NO_x emissions by a factor 5 indeed leads to a better representation of the peak ozone concentration. It has further been shown that an improved process-based representation of soil NO_x emissions leads to MDA8 O₃ changes by up to 6 ppb (Rasool et al., 2016), and a reduced mean bias for ozone concentrations, particularly in agricultural areas (Rasool et al., 2019). Together, these findings provide support for the hypothesis that underestimated soil NO_x emissions, in particular those from agricultural areas, contribute to underestimated peak ozone concentrations.

Comment 3

One interesting area is the Po Valley, which is the one showing the highest NO₂ and O₃ levels in the observations. The top-down correction of NO_x emissions, however, does not seem to be effective enough in this area to fill the gap with observations. This point is sparsely discussed in the manuscript, but it would be useful to have some slightly further comment. For example, Figure 1 in the supplement shows that low values of beta (proportional to NO₂ lifetime, from my understanding) are calculated upon main urban settlements (e.g. Milan), but the gamma factor (accounting for changes in the "shape" of the NO₂ profile after update of emissions) is the lowest in Europe and pretty flat over the valley. Why is that and could this be a cause for the persistent underestimation of NO_x emissions and O₃ levels in the area? One rough idea is that the model possibly simulates a quite uniform PBL (thus a low gamma, from my understanding), even if this could be quite vertically inhomogeneous, due to recirculation of air in the valley (see e.g. Zhang and Rao (1999), J. Appl. Meteorol., 38, 1674-1691, doi:10.1175/1520-0450(1999)038<1674:TROVMI>2.0.CO;2; Ordonez et al. (2006) J. Geophys. Res., 111, D05310, doi:10.1029/2005JD006305; Curci et al. (2015) Atmos. Chem. Phys., 15, 2629-2649, <https://doi.org/10.5194/acp-15-2629-2015>). A further inspection in the vertical profiles over Po Valley, perhaps compared to other polluted regions such as Benelux would be instructive.

Response

Firstly, we do not agree with Anonymous Referee #3 that NO_x emissions and O₃ concentrations are underestimated in the Po Valley in the simulation with top-down emissions. Our approach to re-calculate NO_x emissions based on OMI data leads to an almost 1:1 agreement with OMI (the dependent variable, indicating that biases are effectively removed using our approach) at an r^2 of 0.84, and a better agreement with surface NO₂ observations. Additionally, in Fig. 2 (Fig. 10 in the revised manuscript) we show that median ozone levels in the Po Valley in the simulation with top-down NO_x emissions agree well with observations, although peak ozone concentrations remain underestimated.

However, we thank Anonymous Referee #3 for raising this interesting point regarding the effect of γ on NO_x emissions. It is correct that γ expresses the sensitivity of the AMF to a change in the NO₂ profile shape resulting from NO_x emission changes (Vinken et al., 2014).

In simple terms, the air mass factor (AMF) can be understood as the convolution of the averaging kernel, expressing the decreasing vertical sensitivity of the instrument (Esques and Boersma, 2003) towards the surface (in cloud-free conditions), and the vertical NO₂ profile. The relative change in the profile shape is lower for high-emission areas compared to low-emission areas, since high-emission regions already have a strongly peaked NO₂ profile at the surface. A +20% perturbation in NO_x emissions, as used to calculate γ , will lead to a relatively lower increase of NO₂ levels in high-NO_x regions compared to low-NO_x areas. The resulting change in the AMF is low in high-emission areas such as the Po Valley, the BeNeLux and the Ruhr area. This explains the low γ values in polluted regions.

Lastly, suppose that vertical re-circulation of NO_x- and O₃-rich air (as can be seen in the references brought forward by Anonymous Referee #3) is indeed underestimated in WRF-Chem. More efficient vertical mixing conditions would then lead to a less strongly peaked monthly-average NO₂ profile at the surface following a +20% emission perturbation. The OMI NO₂ column will display a relatively lower increase following AMF updates compared to a case with lower vertical mixing. Therefore, following Eqn. 4 in the main text, this will lead to *lower* γ -values and thus to a less strong emission update.

3 Dr. Andreas Stohl

Comment 1

This is an interesting study about European NO_x emissions. I was puzzled by the fact that the ozone increase of 6 ug/m³ due to optimized emissions (which is reported to be largely due to increases in soil NO_x emissions) is very similar to what I estimated as the impact of soil NO_x emissions (albeit with even higher soil NO_x emissions) of 4 (1.4-9.6) ppb a long time ago using a very simple all-European box model (Stohl, 1996). Is this just a coincidence, given the very simple set-up in Stohl (1996) and also differences in both soil and other NO_x emissions between the two studies?

Response

We would like to thank Dr. Stohl for his interest, his positive words about our study and his question.

Given the large differences in approach between the current study and Stohl et al. (1996), concerning model complexity and input emission datasets, the similarity in ozone sensitivity to (soil) NO_x emissions could be coincidental. Nonetheless, the study by Stohl et al. (1996) provides support for our hypothesis that mis-representations in soil NO_x emissions, particularly from land management practices, can contribute to biased ozone simulations. The one-dimensional model that is used in the study is likely to generally represent NO_x-limited conditions during daytime, meaning that an addition of NO_x from soils leads to efficient O₃ production.

The annual emission totals reported by Stohl et al. (1996) are indeed higher than ours, but are difficult to compare to our results without accurate knowledge on the seasonal cycle in emissions. However, soil emissions are 21.4% of combustion-related 'pyrogenic' emissions in summer (JJA) 1994 in Stohl et al. (1996), which amounts to 17.6% of total surface emissions (soils + pyrogenic). We derive soil emissions to be 14-22% of total European NO_x emissions in July 2015, suggesting that our top-down estimates are reasonable.

Since the study brought to our attention by Dr. Stohl provides support for our satellite-based soil NO_x emission estimate, we added a reference to Stohl et al. (1996) to Table 2 in the manuscript. We additionally added a reference to Stohl et al. (1996) in a new section in the discussion (see response to Anonymous Referee #3, comment 2), which places our findings regarding the ozone increases and our attribution to soil NO_x in a literature context:

Several studies previously investigated the relation between soil NO_x emissions and O₃ formation. For example, one study estimated that European soil NO_x emissions contribute 4 ppb to the daily maximum concentration (Stohl et al., 1996). A sensitivity study by Li et al. (2019) indicates that a strong up-scaling of soil NO_x emissions by a factor 5 indeed leads to a better representation of the peak ozone concentration. It has further been shown that an improved process-based representation of soil NO_x emissions leads to MDA8 O₃ changes by up to 6 ppb (Rasool et al., 2016), and a reduced mean bias for ozone concentrations, particularly in agricultural areas (Rasool et al., 2019). Together, these findings

provide support for the hypothesis that underestimated soil NO_x emissions contribute to underestimated peak ozone concentrations.

Abstract. Ozone (O₃) is a secondary air pollutant that negatively affects human and ecosystem health. Ozone simulations with regional air quality models suffer from unexplained biases over Europe, and uncertainties in the emissions of ozone precursor group nitrogen oxides (NO_x = NO + NO₂) contribute to these biases. The goal of this study is to use NO₂ column observations from the OMI satellite sensor to infer top-down NO_x emissions in the regional meteorology-chemistry model WRF-Chem, and to evaluate the impact on simulated surface O₃ with in situ observations. We first perform a simulation for July 2015 over Europe and evaluate its performance against in situ observations from the AirBase network. The spatial distribution of mean ozone concentrations is reproduced satisfactorily. However, the simulated maximum daily 8-hour ozone concentration (MDA8 O₃) is underestimated (mean bias error (MBE) = -14.2 µg m⁻³), and its spread is too low. We subsequently derive satellite-constrained surface NO_x emissions using a mass balance approach based on the relative difference between OMI and WRF-Chem NO₂ columns. The method accounts for feedbacks through OH, NO₂'s dominant daytime oxidant. Our optimized European NO_x emissions amount to 0.50 Tg N (for July 2015) 0.18 Tg N higher than the bottom-up emissions (which lacked agricultural soil NO_x emissions). Much of the increases occur across Europe, in regions where agricultural soil NO_x emissions dominate. Our best estimate of soil NO_x emissions in July 2015 is 0.1 Tg N, much higher than the bottom-up 0.02 Tg N natural soil NO_x emissions from the MEGAN model. A simulation with satellite-updated NO_x emissions reduces the systematic bias between WRF-Chem and OMI NO₂ (slope = 0.98, r² = 0.84), and reduces the low bias against independent surface NO₂ measurements by 1.1 µg m⁻³ (-56%). Following these NO_x emission changes, daytime ozone is strongly affected, since NO_x emission changes particularly affect daytime ozone formation. Monthly averaged simulated daytime ozone increases by 6.0 µg m⁻³, and increases of >10 µg m⁻³ are seen in regions with large emission increases. With respect to the initial simulation, MDA8 O₃ has an improved spatial distribution, expressed by an increase in r² from 0.40 to 0.53, and a ~~reduced-mean-bias~~ (-7.4 decrease of the mean bias by 7.4 µg m⁻³, -48(48%)). Overall, our results highlight the dependence of surface ozone on its precursor NO_x and demonstrate that simulations of surface ozone benefit from constraining surface NO_x emissions by satellite NO₂ column observations.

1 Introduction

Ozone (O_3) is an air pollutant that affects human and ecosystem health (Lelieveld et al., 2015; Ainsworth et al., 2012). It also affects radiative forcing directly as a greenhouse gas (IPCC, 2013), and indirectly by impacting ecosystem carbon uptake via deposition (Sitch et al., 2007). Despite decreases in ozone concentrations in Europe since 2000 (Chang et al., 2017), peak
5 ozone concentrations still exceed the WHO air quality guideline of $100 \mu g m^{-3}$ and the European long-term objective of $120 \mu g m^{-3}$ (EMEP/CCC, 2016). For example, 87% of European air quality stations did not meet this long-term objective (EEA, 2017) in 2015, and vegetation exposure thresholds were exceeded in large parts of the continent during this year, particularly in Southern and Central Europe (Rouil and Meleux, 2018).

The formation of ozone in the lower troposphere is a photochemical process that depends nonlinearly on concentrations
10 of its precursor species nitrogen oxides ($NO_x = NO + NO_2$) and volatile organic compounds (VOCs) (e.g. Sillman et al., 1990). In NO_x -limited conditions, ozone production increases with NO_x emissions and is less sensitive to VOC emissions. However, ozone production under NO_x -saturated conditions increases with VOC emissions, but decreases with increasing NO_x emissions. European NO_x emissions are dominated by the anthropogenic contribution from fossil fuel combustion for transportation, electricity generation and industry. In summer, there are additional contributions from soils and lightning, which
15 together comprise 40% of the total European NO_x emission budget (Jaeglé et al., 2005). Soil NO_x emissions in turn have an anthropogenic component, since nitrogen-containing fertilizers are partly re-emitted to the atmosphere as NO_x (Steinkamp and Lawrence, 2011).

Anthropogenic emissions in Europe have decreased due to air pollution abatement measures and the economic crisis that started in 2008 (Castellanos and Boersma, 2012). Bottom-up anthropogenic emission inventories suggest a continued reduction
20 of NO_x emissions in more recent years. This is consistent with the ongoing development of European air quality conditions towards the NO_x -limited regime (Jin et al., 2017), which is projected to continue in the future (Beekmann and Vautard, 2010). On the other hand, a decrease in European anthropogenic and natural NO_x emissions is not supported by trend analysis of remote sensing and in situ NO_2 observations (Jiang et al., 2019, submitted), although this potentially reflects a growing relative contribution from natural NO_x emission sources (Silvern et al., 2019). Nevertheless, downward anthropogenic emission trends
25 have been suggested as an important driver of the decreasing trend in peak ozone concentrations in Europe (ETC/ACM, 2016).

Regional air quality (AQ) models are important tools for studying and forecasting ozone pollution. These models simulate processes relevant for ozone pollution at a resolution that can better capture observed spatial gradients compared to coarser global models. Regional AQ models can therefore be applied to simulate polluted conditions in or surrounding urban areas, or for air quality impact assessments. Coupled (or "online") meteorology-chemistry models resolve meteorology, transport,
30 chemical transformation and removal of pollutants at the same spatial and temporal resolution. The coupled treatment of meteorology and chemistry is mandatory, because ozone concentrations depend on feedbacks between meteorological and chemical processes: 1) O_3 sources such as chemical formation depend on radiation, temperature and water vapour (Pusede et al., 2015; Coates et al., 2016), and 2) O_3 sinks, such as dry deposition, also largely depend on meteorological drivers (Clifton et al., 2017; Kavassalis and Murphy, 2017). However, coupled regional air quality models are subject to several

sources of uncertainties. These uncertainties are related to the limited knowledge on ozone precursor emissions (Kuenen et al., 2014; Pouliot et al., 2015), the representation of boundary conditions (Giordano et al., 2015), tropospheric chemistry in the chemical mechanism (Knote et al., 2015), and the land surface and its feedbacks with tropospheric chemistry (Baklanov et al., 2014).

- 5 Many regional AQ models have been applied to simulate NO_x and O_3 in European summers, for research and forecasting purposes. Models tend to underestimate summertime NO_x compared to rural background in situ observations (Terrenoire et al., 2015; Mar et al., 2016). Comparison against satellite NO_2 column observations also revealed underestimations at regional scales (Huijnen et al., 2010; Aidaoui et al., 2015). Another study found both positive as well as negative biases, which were attributed to the coarse resolution of the emission inventories (Pope et al., 2015). AQ models satisfactorily reproduce the
- 10 spatial distribution in summer O_3 . However, mean O_3 can be under- or overestimated depending on the model and chemical mechanism (Terrenoire et al., 2015; Mar et al., 2016). In addition, many models consistently underestimate peak ozone values that typically occur in the afternoon (Tuccella et al., 2012; Solazzo et al., 2012; Marécal et al., 2015; Im et al., 2015). This is problematic for air pollution impact assessments, since the peak ozone values are important for determining the detrimental effects on human health and ecosystems.
- 15 The sensitivity of O_3 to its precursor NO_x , which is particularly pronounced in summer (e.g. Jin et al., 2017), suggests that there is good potential to improve O_3 simulations by constraining simulated NO_x with observations. The past 20 years have seen the development of methods to estimate NO_x emissions with satellite-based NO_2 columns in a mass balance approach, where biases in the model-simulated and satellite-observed NO_2 columns are used to update NO_x emissions. The technique has been applied in global models (Martin et al., 2003; Lamsal et al., 2008; Vinken et al., 2014a), and more recently also in
- 20 regional models (e.g. Ghude et al., 2013). Applications of the technique include emission trend analysis (e.g. Lamsal et al., 2011) and source-specific constraints on NO_x emissions (e.g. Ghude et al., 2013; Vinken et al., 2014a, b; Verstraeten et al., 2015). Changes in NO_x emissions impact tropospheric chemistry, and therefore changes in O_3 are expected. This was shown by Ghude et al. (2013), who found local changes in surface O_3 mole fractions up to 10 ppb over India after satellite-based NO_x emission scaling. Verstraeten et al. (2015) reported ozone increases up to 8 ppb at 800 hPa (± 1.5 km) in China after scaling
- 25 local NO_x emissions with OMI observations, and found that simulated free-tropospheric ozone between 3-9 km was in better agreement with tropospheric O_3 columns observed by the Tropospheric Emission Sounder. However, ozone changes at the surface after constraining NO_x emissions with satellite observations have thus far not been evaluated with in situ data to our knowledge.

Considering the importance of NO_x for simulations of ozone and the previously reported ozone changes after applying

30 satellite-based NO_x emissions, we here investigate the potential improvement in simulated surface ozone concentrations over Europe due to the application of satellite observations of NO_2 to adjust NO_x emissions. To this end, we use the WRF-Chem meteorology-chemistry model (Grell et al., 2005) to simulate surface ozone in Europe in July 2015, at the approximate peak of the ozone season. We first perform a model evaluation with AirBase in situ NO_2 and O_3 observations (EEA, 2018) and OMI NO_2 column measurements from the recently released QA4ECV dataset (Boersma et al., 2017a). We subsequently derive a

new, OMI-based ("top-down") NO_x emission inventory, and evaluate its effects on WRF-Chem simulations of surface NO_2 and O_3 with the independent AirBase observations.

The structure of the paper is as follows. We describe the model set-up and observations in section 2. Section 3 presents the method to calculate OMI-derived NO_x emissions. In section 4, we evaluate a WRF-Chem set-up with bottom-up emissions in situ and column observations, and in section 5 we describe the derived modified surface NO_x emissions. We evaluate the impacts on surface NO_x and O_3 with independent in situ observations in section 6. We conclude with a discussion (section 7) and summarize our conclusions in section 8.

2 Model and data description

2.1 WRF-Chem

We perform simulations with the coupled meteorology-chemistry model WRF-Chem, version 3.7.1 (Grell et al., 2005). The model domain consists of 170 by 170 cells at $20 \times 20 \text{ km}^2$ horizontal resolution covering Europe, centered at 51.98°N and 5.66°E . Vertically, the domain extends from the Earth's surface up to 50hPa, and consists of 27 layers with 13 layers in the lowermost 1500m. Chemistry simulations of O_3 and its precursor groups NO_x and VOCs are performed with the CBM-Z gas-phase chemical mechanism (Zaveri and Peters, 1999). Simulations of atmospheric chemistry with this mechanism compare well with the European multi-model mean for summer O_3 in a gas-phase mechanism comparison study (Knote et al., 2015). A complete list of parameterization options adopted in our WRF-Chem setup can be found in Table 1 of the Supplement. Our simulations were performed with a time stepping of 180 s for a period of 38 days (24 June - 31 July 2015), allowing a 1-week spin-up to analyze the model output for July. An evaluation of large-scale meteorological performance with ERA-Interim reanalysis fields can be found in Sect. 2 of the Supplement.

We used anthropogenic emissions from the TNO-MACC-III inventory (Kuenen et al., 2014) for 2011, the most recent inventory available when the model experiments were performed. TNO-MACC-III contains anthropogenic emissions for lumped species groups NO_x and VOCs. NO_x emissions were partitioned assuming that 97% is emitted as NO and 3% as NO_2 . VOC emissions were divided over 15 emission categories in CBM-Z, following the VOC speciation by Archer-Nicholls et al. (2014). This speciation procedure is further described in Table 3 of the Supplement. Point source emissions were distributed over the five lowermost model layers following sector-specific emission altitude profiles (Bieser et al., 2011).

Biogenic emissions of VOCs and soil NO_x were calculated online with the MEGAN model implementation within WRF-Chem (Guenther et al., 2006, 2012). The domain-total biogenic isoprene emissions are 1.82 Tg of isoprene, which is slightly lower than the 9-year spread of 2-4.5 Tg isoprene for July, based on an inverse modeling study using OMI HCHO column measurements for 2005-2013 (Bauwens et al., 2016). We simulate lightning NO_x emissions using a parameterization based on cloud-top height (Price and Rind, 1993; Wong et al., 2013), using a flash rate of $80 \text{ mol flash}^{-1}$ based on a recent satellite-based estimate (Pickering et al., 2016). Simulations with higher flash rates of $500 \text{ mol flash}^{-1}$ (Ott et al., 2010) and $310 \text{ mol flash}^{-1}$ (Miyazaki et al., 2014) resulted in overestimated upper-tropospheric contributions to the NO_2 columns relative to OMI.

Anthropogenic emissions are the dominant NO_x source over Europe in July with a total monthly emission strength of 304 Gg N (76%). Minor contributions are associated with lightning (81.4 Gg N; 20%) and soils (15.0 Gg N; 4%). We note that especially soil NO_x emissions are low compared to previous studies, in which soils, including agricultural areas, have been estimated to contribute ~~± 40~~ $\pm 40\%$ to the total European NO_x emission budget (Jaeglé et al., 2005; Ganzeveld et al., 2010).

5 Meteorological initial and boundary conditions were taken from ERA-Interim reanalysis data (Dee et al., 2011). Chemical boundary conditions for O_3 , NO, NO_2 , CO and peroxyacetyl nitrate (PAN) are taken from the CAMS chemical reanalysis product for Europe (Inness et al., 2015, retrieved at: <http://apps.ecmwf.int/datasets/data/cams-nrealtime/levtype=sfc/>). Upper boundary conditions for ozone were prescribed with climatological values (retrieved at: <https://www2.acom.ucar.edu/wrf-chem/wrf-chem-tools-community>).

10 2.2 AirBase NO_2 and O_3 in situ measurements

Surface measurements are taken from the European Air Quality Data Portal operated by the European Environment Agency, hereafter referred to as AirBase (EEA, 2018). We used all data at rural background stations from the validated E1a data stream. The large availability of the data allows us to make a strict selection on data availability. For monthly averages, we discard stations if data is missing for more than 24 hours. Stations used for the evaluation of monthly averages at 12:00 h
 15 UTC may have a maximum data gap of 1 data point. This resulted in a final selection of 184-397 stations, depending on the performance metric (see Table 1). In our analysis of O_3 and NO_2 we evaluate monthly time series and mid-day (12:00 h UTC) concentrations (denoted as $[\text{O}_3]^{12h}$ and $[\text{NO}_2]^{12h}$, respectively). We additionally calculate the maximum daily 8-hour mean ozone concentration (MDA8 O_3), a widely applied metric for O_3 health impacts.

2.3 OMI NO_2 column measurements

20 We use tropospheric NO_2 columns from the Ozone Monitoring Instrument (OMI) onboard NASA's EOS Aura mission (Levelt et al., 2006). The polar-orbiting instrument detects radiation backscattered from the Earth's atmosphere. Retrieval of tropospheric vertical column densities (VCDs) from space follows a three-step procedure (Boersma et al., 2018). First, total slant columns (SCDs; i.e., columns along the average light path through the atmosphere) are obtained from a spectral fit to the OMI-measured reflectance spectra in the visible wavelength range using the Differential Optical Absorption Spectroscopy (DOAS)
 25 method. Then, the stratospheric contribution component is separated from the total NO_2 column via data assimilation into the TM5 global Chemistry Transport Model (Dirksen et al., 2011). The final step is to obtain tropospheric VCDs by dividing the SCDs by a tropospheric Air Mass Factor (AMF) that describes the vertical sensitivity of the instrument to atmospheric NO_2 (Eskes and Boersma, 2003). This is a function of satellite viewing geometry, surface albedo, terrain height, cloud properties, and a priori NO_2 profile.

30 The recent EU FP7 project Quality Assurance for Essential Climate Variables (QA4ECV) has led to the development of a new OMI NO_2 data product (Boersma et al., 2017a). The underlying consortium retrieval algorithm is based on the NO_2 column retrieval principles described in Boersma et al. (2007), but with improvements in the three aforementioned steps (Boersma et al., 2018). Zara et al. (2018) described how better wavelength calibration, and inclusion of liquid water absorption and an intensity

offset-correction reduced uncertainties in NO₂ SCDs to $0.7 - 0.8 \times 10^{15}$ molec. cm⁻² (up to ± 35 %). Lorente et al. (2017) improved the AMF calculation method via the extension of the AMF look-up table with more reference points, and a correction for the sphericity of the atmosphere. The ancillary data for the AMF calculation has also improved relative to earlier algorithms such as DOMINO v2 (Boersma et al., 2011): surface albedo from the 5-year OMI albedo climatology (Kleipool et al., 2008), cloud information from the improved OMI O₂-O₂ algorithm (Veefkind et al., 2016), and a priori NO₂ profiles from TM5-MP at $1^\circ \times 1^\circ$ (Williams et al., 2017). The study by Lorente et al. (2017) also showed that substantial differences between AMFs arise when different a priori NO₂ profiles (as well as surface albedo and cloud properties) are used in the retrieval. This underlines that a re-calculation of the tropospheric AMFs based on simulated WRF-Chem 20×20 km², replacing the coarse TM5-MP $1^\circ \times 1^\circ$ NO₂ profiles, may help to reduce model-satellite differences (Lamsal et al., 2010; Vinken et al., 2014b), and we will explore this further below.

2.4 AMF re-calculation

We take care to remove inconsistencies in the model-satellite comparison introduced by different assumptions about the vertical NO₂ profile in the satellite product compared to the model. The AMF calculation requires assumptions about the vertical profile of NO₂ to convert slant columns into vertical columns. We replace the a priori TM5-MP NO₂ profiles (at $1^\circ \times 1^\circ$) by WRF-Chem NO₂ profiles at a 20×20 km² resolution. This has two advantages: 1) model-satellite comparisons are no longer affected by differences in model assumptions between WRF-Chem and TM5-MP that lead to different vertical NO₂ profiles, and 2) the higher resolution WRF-Chem setup resolves spatial gradients in the a priori profile that are not appropriately captured in TM5-MP due to the coarser model resolution. Single-orbit results indicate that re-calculation of the AMFs leads to retrieved columns that are 1×10^{15} molec. cm⁻² higher in densely populated areas, and lower or unaffected in surrounding non-urban regions. This effect has been seen before in earlier studies (Huijnen et al., 2010; Heckel et al., 2011; Russell et al., 2011; Maasakkers, 2013; Vinken et al., 2014b).

We apply the method described by Lamsal et al. (2010) and Boersma et al. (2016) to replace the TM5-MP vertical NO₂ profile by the WRF-Chem profile in the calculation of the air mass factor (AMF):

$$M_{trop,WRF-Chem} = M_{trop,TM5} \times \frac{\sum_{l=1}^L A_{trop,l} x_{l,WRF-Chem}}{\sum_{l=1}^L x_{l,WRF-Chem}} \quad (1)$$

where M_{trop} is the tropospheric AMF based on an assumed profile from WRF-Chem or TM5, $A_{trop,l}$ is the tropospheric averaging kernel element for layer l , $x_{l,WRF-Chem}$ is the NO₂ column density in model layer l , and L is the uppermost TM5-MP layer in the troposphere. The tropospheric averaging kernel in Eq. 1 is defined as follows (Boersma et al., 2017b): $A_{trop} = A \times \frac{M}{M_{trop}}$, where M and M_{trop} refer to the AMF and the tropospheric AMF, respectively. Note that the WRF-Chem vertical NO₂ profile has been sampled at the TM5-MP vertical layer structure, so l refers to TM5-MP model layers.

3 Top-down NO_x emissions: methods

Satellite-detected NO₂ columns are sensitive to NO_x emissions at the surface. We exploit this dependence to derive satellite-based surface NO_x emissions using local OMI NO₂ columns. We apply an improved version of the mass balance procedure (Martin et al., 2003; Lamsal et al., 2011; Vinken et al., 2014b), which accounts for non-linear feedback from NO_x emission

5 changes on NO₂ concentrations via OH:

$$E_{td} = E_{bu} \left(1 + \beta(1 + \gamma) \frac{C_{OMI,bu} - C_{WC,bu}}{C_{WC,bu}} \right) \quad (2)$$

where E_{bu} and E_{td} represent NO_x emissions from the bottom-up inventory (bu) and the satellite-based top-down estimate (td), respectively. $C_{WC,bu}$ represents the monthly-averaged NO₂ vertical column density (VCD) simulated by WRF-Chem, and $C_{OMI,bu}$ is the monthly averaged modified QA4ECV OMI NO₂ VCD using air mass factors based on the original WRF-Chem
10 NO₂ vertical profile ($C_{WC,bu}$, see Section 2.4). WRF-Chem NO₂ VCDs are co-sampled with valid OMI observations. We only use OMI and WRF-Chem data for pixels with valid satellite observations for at least 4 days in July 2015 to minimize the random error in the satellite retrieval.

We account for the nonlinear NO_x-OH chemistry feedback via a dimensionless scaling factor β , for which we performed a perturbation simulation with surface emissions increased by 20%:

$$15 \quad \beta = \frac{\Delta E_{bu,1.2}/E_{bu}}{\Delta C_{bu,1.2}/C_{bu}} = \frac{0.2C_{bu}}{\Delta C_{bu,1.2}} \quad (3)$$

where C_{bu} are the NO₂ columns after a WRF-Chem simulation with bottom-up NO_x emissions, and $\Delta C_{bu,1.2}$ is the change in NO₂ columns after perturbing bottom-up NO_x emissions by +20%. In low-NO_x environments, this perturbation leads to higher OH levels and thus to more efficient NO_x loss to HNO₃, so that a $\beta > 1$ is needed to achieve column agreement. In NO_x-rich environments, however, OH levels are suppressed by enhanced NO_x emissions so that the relative increase in NO₂ columns
20 is larger than 20%, resulting in a $\beta < 1$. The use of β to account for the sensitivity of the NO₂ column to local emissions is essentially a linearization step of non-linear effects due to chemistry.

Application of Equations 2 and 3 would lead to updated NO_x emissions, and consequently also to modifications in the WRF-Chem NO₂ profile shapes in response to the updates (e.g. Vinken et al., 2014b). This is accounted for via γ , which we also obtain from the simulation with +20% perturbed emissions:

$$25 \quad \gamma = \frac{(C_{OMI,1.2} - C_{OMI,bu})/C_{OMI,bu}}{(C_{WC,1.2} - C_{WC,bu})/C_{WC,bu}} \quad (4)$$

where C_{WC} represents the WRF-Chem NO₂ vertical column density (VCD), and C_{OMI} represent the OMI NO₂ VCD retrieved using WRF-Chem NO₂ vertical profiles from the bottom-up simulation (C_{WC}), for the bottom-up (subscript bu) and emission perturbation simulation (subscript 1.2), respectively. Our approach to calculate γ differs from Vinken et al. (2014b), who

derived γ from a separate simulation after accounting for β . Our approach requires one less forward simulation and is thus computationally more efficient, with little impact (<3%) on total derived emissions compared to the approach by Vinken et al. (2014b).

We calculate the scaling factors β and γ for all land-based and shipping lane WRF-Chem cells based on monthly mean NO₂ columns (i.e., ocean-based pixels with emissions above a threshold value of 1 mol km⁻² h⁻¹). These pixels thus also include shipping lanes and offshore oil platforms. OMI-inferred emission changes are calculated locally, i.e. for each individual model cell for which the aforementioned data availability criteria are fulfilled. This differs from previous work where these factors were calculated for regions containing multiple model cells (Vinken et al., 2014a, b) or for individual pixels in global models with a coarse resolution (e.g. Lamsal et al., 2011).

We discard the effect of transport of NO₂ away from the source region ('smearing'). In July, solar intensity in Europe is close to its annual peak, which means that the NO₂ lifetime is short due to efficient oxidation. Therefore, the clear-sky monthly mean NO₂ column difference between model and satellite is indicative of local NO_x emission updates. Previous studies showed that this method reduces the model-satellite NO₂ column difference but does not resolve it completely (e.g. Vinken et al., 2014b; Ghude et al., 2013) as a result of the linearization that is applied in the perturbation calculation. Nonetheless, we will show in this study that the systematic bias between WRF-Chem and OMI NO₂ columns is largely removed after application of Eqns. 2-4.

4 Bottom-up model evaluation

4.1 Surface O₃

We start our evaluation of O₃ chemistry in WRF-Chem (with bottom-up NO_x emissions, i.e. not yet based on the OMI-inferred NO_x emissions) by a comparison of monthly-averaged, 24-hour mean surface ozone simulations with AirBase observations (Fig. 1, panels a and b, and Table 1). WRF-Chem reproduces the spatial distribution of surface ozone satisfactorily, with an increase in surface O₃ concentrations from north to south, as reported elsewhere (e.g. Mar et al., 2016). Highest concentrations are found around the Mediterranean basin. O₃ concentrations over Central and Southern Europe are underestimated in WRF-Chem. Simulated monthly-averaged concentrations do not exceed 110 µg m⁻³, while higher concentrations were observed at several stations in the southern part of the domain. Most notably, WRF-Chem does not capture observed high concentrations of ±130 µg m⁻³ in northern Italy. The good agreement between WRF-Chem and in situ data in the western part of the domain close to the model boundaries with a prevailing westerly circulation indicates that the model boundary conditions describe inflow of long-lived compounds such as O₃ from the western boundary well.

Monthly averaged ozone concentrations are an important and widely used metric to evaluate model skill, but are not necessarily indicative of the peak ozone concentrations that typically occur in the afternoon. These monthly averages include the nocturnal conditions with generally the presence of stable boundary layers, in which the titration of ozone in the NO_x-saturated regions is difficult to model (e.g. Im et al., 2015). The simulated and observed monthly averaged ozone concentrations at 12:00 h UTC (Fig. 1, panels c and d) demonstrate a similar geographical distribution compared to the monthly average, but with

higher values because photochemical ozone production generally peaks during daytime. This figure demonstrates that peak ozone values occur around the Mediterranean basin, most prominently in North Italy and Spain, where the levels of sunlight and ozone precursor concentrations are high. WRF-Chem shows elevated ozone with respect to adjacent areas, but maximum simulated ozone levels do not exceed $120 \mu\text{g m}^{-3}$. This underestimation of peak ozone concentrations is also apparent from in

5 Fig. 8b (discussed in more detail in Sect. 6), which shows the simulated versus the observed 12:00 h UTC ozone concentrations.

Our results are in agreement with previous regional chemistry model evaluations for Europe. Such studies typically focus on seasonal variability; we compare our results with the results for European summer (JJA) from those studies. Im et al. (2015) found that a model ensemble underestimates the daytime maximum O_3 concentration for sites where observed O_3 concentrations exceed $120\text{--}140 \mu\text{g m}^{-3}$, which agrees with our results. In that study, the ensemble mean model bias tends

10 to become more negative for observed concentrations above $80 \mu\text{g m}^{-3}$ (Im et al., 2015). The two ensemble members that use CBM-Z chemistry, similar to our WRF-Chem model set-up, are qualitatively in line with the ensemble mean, lending support to the use of CBM-Z in this study. Mar et al. (2016) compared two chemical mechanisms in a WRF-Chem evaluation study over Europe and reported large differences in the representation of peak summer (JJA) ozone: one chemistry model (MOZART) overestimates mean and MDA8 ozone, while simulations with the other chemistry scheme (RADM2) shows

15 underestimations of peak ozone that are in line with our findings. We will discuss the dependence of ozone simulation on the chemical mechanism choice in detail in Sect. 7. The ensemble model mean daytime ozone concentration in Solazzo et al. (2012) is underestimated by $10\text{--}30 \mu\text{g m}^{-3}$ in four sub-regions of the European continent. Tuccella et al. (2012) analyzed WRF-Chem O_3 concentrations for 2007 and found that yearly-averaged mid-day ozone is underestimated by approximately $10 \mu\text{g m}^{-3}$. The model performance in the aforementioned studies is qualitatively similar to our findings and the magnitude compares well.

20 Overall, most studies consistently show underestimated daytime O_3 , regardless of the chemical mechanism, model resolution and other model assumptions. To further explore the potential role of a model misrepresentation of NO_2 concentrations in explaining this model O_3 bias, the next sections will focus on a model comparison with in situ and remote sensing data for NO_2 .

4.2 Surface NO_2

25 Fig. 2 a and b present a comparison of monthly-averaged surface concentrations of NO_2 between WRF-Chem and AirBase (note the logarithmic scale). Performance statistics are shown in Table 1. We find that WRF-Chem reproduces the spatial distribution well, with peak NO_2 occurring in Northwest Europe and North Italy. In these regions with high NO_x emissions, average WRF-Chem-simulated concentrations are however underestimated by up to $10 \mu\text{g m}^{-3}$ compared to observations. AirBase concentrations show a region with elevated NO_2 concentrations in Southwest Germany. WRF-Chem also shows elevated NO_2

30 concentrations in this region, but does not reach such elevated concentrations. Overall, WRF-Chem shows more spatial heterogeneity in surface NO_2 concentrations than is apparent from the observations. Observed NO_2 concentrations in background areas in Spain, France and Eastern Europe are $2\text{--}5 \mu\text{g m}^{-3}$ or higher, while the model consistently simulates values $<2 \mu\text{g m}^{-3}$ in these regions. This overall underestimation is also seen in Fig. 8, where the simulated daily mean NO_2 concentration is shown against AirBase observations. The model performance of our WRF-Chem setup is in line with previous WRF-Chem studies.

Mar et al. (2016) found small overestimations ($0.67\text{--}2.96\ \mu\text{g m}^{-3}$) in mean NO_2 . Another study found an annual average mean bias of $-0.9\ \mu\text{g m}^{-3}$, caused by underestimations of peak NO_2 in WRF-Chem (Tuccella et al., 2012).

A comparison between WRF-Chem and AirBase monthly-averaged 12:00 h UTC NO_2 concentrations is presented in Figure 2c and d and Table 1. We find that WRF-Chem on average strongly underestimates mid-day NO_2 concentrations by $2.96\ \mu\text{g m}^{-3}$ (38.5%).

4.3 NO_2 VCD

Before we perform a comparison between NO_2 VCDs from WRF-Chem and OMI, we first discuss the effect of the NO_2 profile shape on the OMI-retrieved columns. Figure 3 shows the change in the monthly-averaged OMI NO_2 column density after replacing TM5-MP NO_2 profiles by WRF-Chem profiles using the procedure described in Sect. 2.4. The OMI NO_2 VCDs change most prominently over urban/industrial areas such as the Netherlands, Paris, Berlin, Madrid, Milano and Rome. The background areas are largely unaffected, or show small ($\pm 0.2 \times 10^{15}\ \text{molec. cm}^{-2}$) NO_2 VCD increases (e.g. Spain) or decreases (regions in France, Germany, Poland, Ukraine and Romania). The vertical NO_2 profile over sea regions in western Europe strongly peaks at the surface, because shipping NO_x in WRF-Chem is emitted in the lowermost model layer. Overall, the average NO_2 column change over non-land regions is small ($<2\%$).

We subsequently compare WRF-Chem to this modified OMI product. The monthly-averaged NO_2 vertical column densities from WRF-Chem and OMI are displayed in Fig. 4. The model is sampled at 12:00 h UTC, close to the OMI overpass time of $\pm 13:30$ h LT, and is co-sampled with valid satellite observations. There is good agreement in the spatial distribution of monthly-averaged NO_2 VCDs ($r^2 = 0.68$). NO_2 columns are underestimated by $0.3 \times 10^{15}\ \text{molec. cm}^{-2}$ on average, with strong underestimations of up to $2 \times 10^{15}\ \text{molec. cm}^{-2}$ in urban and industrial northwestern Europe. WRF-Chem overestimates NO_2 columns in some isolated urban areas with high NO_x emissions such as London, Madrid, Rome, and in parts of Eastern Europe.

We note that Fig. 4 shows small underestimations of the simulated NO_2 VCD compared to OMI ($\pm 0.2 \times 10^{15}\ \text{molec. cm}^{-2}$) in background regions (e.g. the Alps, rural Spain and France, Scandinavia) and over the oceans. Simulated NO_2 columns therefore show stronger spatial gradients than OMI-retrieved columns, which is in line with Huijnen et al. (2010). Other distinct underestimations in the simulated NO_2 columns compared to OMI indicate a misrepresentation of emissions. For example, the ~~region in Northern Spain where WRF-Chem underestimates the NO_2 column compared to OMI observations~~ simulated NO_2 column in northwestern Spain is underestimated by $2 \times 10^{15} \times 10^{15}\ \text{molec. cm}^{-2}$ suggests that emissions compared to OMI. The enhanced NO_2 columns in this region mainly reflect the contribution to atmospheric NO_x by power plant emissions. Although emissions from power plants in this region are still strong in should have decreased in recent years in this region (Zhou et al., 2012), these emissions seem to be underestimated in WRF-Chem. However, since these results are only representative of July 2015, despite previously reported reductions (Zhou et al., 2012) a more dedicated analysis is needed to further corroborate this hypothesis.

We have shown that our WRF-Chem set-up with bottom-up emissions underestimates NO_2 with respect to both surface and column measurements. To combine these model comparisons against different data sources, we already discuss parts of Fig. 9, which compares the agreement between simulations with bottom-up and top-down emissions. Fig. 9a shows the relative difference of WRF-Chem against AirBase and OMI NO_2 binned as a function of bottom-up anthropogenic emission

strength. This shows an overall underestimation of WRF-Chem at the surface and in the troposphere, except for regions with strongest emissions. There is a relatively larger model underestimation of surface NO_2 than of the NO_2 VCD in regions with ~~low emissions, suggesting comparatively low emissions. Given that the surface NO_2 mixing ratios are more sensitive to surface emissions than the NO_2 column (Li and Wang, 2019), this suggests~~ that emissions are generally too low in WRF-Chem, but especially that emissions in rural background regions, are underestimated. This, in turn, suggests that the representation of surface NO_x emissions in WRF-Chem (anthropogenic emissions for 2011 and on-line calculated natural soil emissions) are too low to explain the observations in July 2015. In the following section, we will derive satellite-constrained NO_x emissions and discuss potential reasons for this mismatch.

5 Satellite-derived NO_x emissions

5.1 Top-down emissions

We derive top-down NO_x emissions using the method described in Section 3. Fig. 5 shows the July total bottom-up and top-down surface NO_x emissions and their difference. Top-down NO_x emissions amount to 498 Gg N, which is 56% higher than the bottom-up inventory, and increases occur across the domain (Fig. 5c). NO_x emissions are reduced in several isolated grid cells that generally correspond to urban areas. The difference between top-down and bottom-up emissions is larger than the 16% increase reported by Miyazaki et al. (2017), although that study found strong (40-67%) local increases in areas with high NO_x emissions such as Belgium, western Germany and northern Italy.

Our top-down emissions are much higher than the bottom-up emissions over Germany and Poland. Over Belgium and the Netherlands, the difference between top-down and bottom-up emissions is also substantial, but notably smaller despite larger differences between OMI and WRF-Chem NO_2 columns over the low-countries (Fig. 4c). This reflects the chemical regime with very high bottom-up NO_x emissions in this region, resulting in suppressed mid-day OH concentrations, and consequently, longer NO_2 lifetimes (as diagnosed by low beta values over northwestern Europe in Supp. Fig. 1).

We subsequently replace bottom-up emissions with our observation-constrained top-down NO_x emissions and perform a new WRF-Chem simulation. As expected, the new NO_2 columns agree much better with the OMI NO_2 columns than those from the simulation with bottom-up emissions (Fig. 6). WRF-Chem with bottom-up emissions generally underestimates OMI NO_2 columns by 23.4%. As expected, the simulations with the top-down emissions agree better with OMI, and the slope of 0.98 between the new WRF-Chem and OMI NO_2 columns (Fig. 6b) suggests that the systematic underestimation in the model is effectively resolved by applying the top-down emissions. The mean relative error is reduced to -7.5%, and the spatial correlation coefficient between WRF-Chem and OMI NO_2 also improves considerably (from 0.68 to 0.84).

5.2 Attribution to emission sources

Fig. 7 shows the bottom-up and top-down NO_x emissions as a function of the bottom-up anthropogenic emission strength. This comparison demonstrates that top-down NO_x emissions are higher than bottom-up emissions regardless of the emission

strength. However, top-down emissions are 50-100% higher than bottom-up estimates for relatively weak emissions between 0.5-50 Mg N month⁻¹ cell⁻¹, and only up to 20% higher for some urban and industrial hotspots (Fig. 7b). This 0.5-50 Mg N month⁻¹ range is dominated by WRF-Chem grid cells located in the rural areas of Europe, excluding the largest urban agglomerations as well as low-emission regions such as mountainous areas. Our substantially larger top-down emissions partly reflect a required increase in NO_x emissions in areas where soil NO emissions are expected to be a dominant NO_x source. Soil NO emissions are simulated in WRF-Chem using an implementation of the MEGAN biogenic emission model. The observed discrepancy between the WRF-Chem-simulated and OMI-observed NO₂ VCD triggers to assess how much of this discrepancy can be attributed to this model's representation of soil NO emissions.

To separate the soil NO_x contribution from the anthropogenic emission updates, we perform a simple budget calculation as a first-order constraint on the partitioning of the top-down emissions between their anthropogenic and soil-based sources. We assume that the relative difference in anthropogenic sources is uniform over the emission bins in Fig. 7. This factor is calculated as the median of the relative change in emissions for the three highest bins (>50 Mg N cell⁻¹ for July, see Fig. 7), and amounts to 0.22. This allows us to attribute the remaining emission difference to soils. Based on this crude first estimate, we derive top-down soil NO_x emissions to be 112 Gg N month⁻¹, versus WRF-Chem/MEGAN-simulated bottom-up soil NO emissions of only 15 Gg N month⁻¹. The anthropogenic enhancement factor is relatively uncertain, but does not strongly impact our derived posterior soil NO_x emission estimate: if, instead of the median ($m = 0.22$), we use the mean relative change in emissions for the three highest bins ($\mu = 0.41$), our soil contribution is still a factor >4 larger (69.0 Gg N month⁻¹) compared to WRF-Chem's simulated bottom-up soil NO source. Therefore, this first-order estimation suggests that a substantial fraction (43-69%) of the NO_x emission increment after optimization can be attributed to soils.

To evaluate the derived total soil NO_x emissions, we perform a comparison with literature-based estimates in Table 2. We find that bottom-up soil NO_x emissions are underestimated by a factor 5-7 compared to previous studies. In some of those studies (e.g. Ganzeveld et al., 2010), land use management practices (fertilizer and manure application) provide a substantial contribution to European soil NO emissions, a feature that appears to be missing in the representation of soil NO emissions in WRF-Chem. This supports our hypothesis that a substantial fraction of the increase in surface NO_x emissions may be attributed to soils. We will discuss this further in Sect. 7.

6 Emission scaling impacts on surface NO₂ and O₃

6.1 Nitrogen dioxide

Table 1 summarizes the model performance of our bottom-up and top-down WRF-Chem simulations against a large number of AirBase NO₂ observations throughout Europe in July 2015. The simulation with top-down emissions improves upon the a priori run in all metrics. Most notably, the model index of agreement (d) improves by 0.10 (14%). The modified model set-up still slightly underestimates the ~~highest-monthly-averaged~~ monthly averaged observed NO₂ observations, as indicated by a slope of ~~0.86~~ 0.89. However, the low bias in WRF-Chem surface NO₂ concentrations with respect to AirBase improves from -2.5 to -1.1 $\mu\text{g m}^{-3}$.

Compared to the monthly average, we find little improvement in WRF-Chem's skill to predict surface NO_2 at 12:00 h UTC. The model's low bias in NO_2 reduces from -3.0 to $-2.6 \mu\text{g m}^{-3}$ and the index of agreement improves by only 0.02 (4%). This more modest improvement in performance can be understood from mid-day surface NO_2 concentrations being more strongly driven by photochemical removal processes and boundary layer development than the 24-hour mean NO_2 levels, that are more sensitive to NO_x emissions due to strongly reduced mixing and photochemistry at night. Fig. 8 displays WRF-Chem monthly, 24-hour mean NO_2 concentrations against AirBase observations, for the bottom-up (black) and top-down (red) simulations. The model orthogonal distance regression (ODR) slope improves considerably, while the explained variance of the model improves slightly to 0.46.

Fig. 9 shows the relative biases between WRF-Chem and observed NO_2 as a function of (binned) bottom-up anthropogenic NO emission strength. Both the WRF-Chem simulations with bottom-up emissions (Fig. 9a) as well as the simulation with top-down emissions (Fig. 9b) show a low bias against OMI and AirBase for regions with low emissions, and a positive relative bias in regions with stronger emissions. The relative bias is however considerably reduced in the simulation with top-down NO_x emissions, both at the surface and in the column. However, WRF-Chem still displays a stronger relative bias compared to AirBase than compared to OMI. This feature can likely be attributed to a difference in spatial scales between the $20 \times 20 \text{ km}^2$ -resolution model versus the footprint area of local AirBase measurements, which can be easily influenced by a nearby NO_x source that is less well captured in the model, due to instantaneous mixing over a larger volume. Another potential explanation for lower relative bias of WRF-Chem compared to AirBase than compared to OMI is interference of in situ measurements with molybdenum converters (see Sect. 2.2). This is in line with our previous finding that the slope of the top-down NO_2 column regression fit approaches 1, while the slope of the fit for in situ NO_2 observations is still below 1. We also note that the spread in the relative bias compared to AirBase increased for the top-down simulation, with more positive relative bias values for all bins. Nonetheless, the results shown in Fig. 9 provide confidence regarding application of the model as a tool to reconcile local-scale bottom-up emissions and concentrations with larger-scale remote sensing-based NO_2 measurements.

6.2 Ozone

Next, we address our main question whether the improved simulation of NO_2 leads to better model performance for surface ozone simulations. We find that WRF-Chem with top-down emissions improves upon the bottom-up simulation for both the 24-hour mean, as well as the 12:00 h UTC and MDA8 ozone metrics. The model index of agreement improves by 0.08-0.11 (13-17 %, Table 1). However, the top-down model still simulates too low surface O_3 , especially over southern, eastern and central Europe, where observed surface O_3 exceeds $80 \mu\text{g m}^{-3}$ at 12:00 h UTC (see Fig. 11).

A comparison between monthly averaged mid-day O_3 concentrations from the bottom-up and top-down simulation (Fig. 11, panels a and b, respectively) shows that ozone increases across the model domain. This particularly improves the WRF-Chem-AirBase agreement in large parts of western and Central Europe. The simulated ozone values in northern Italy remain underestimated.

Surface ozone concentrations display a strong increase due to the use of top-down NO_x emissions (Fig. 11). The areas where ozone concentrations increase by $>10 \mu\text{g m}^{-3}$ largely coincide with regions where top-down NO_x emissions are much higher

than the bottom-up emissions (Fig. 5c), such as in northern Spain, southern Germany, southern Poland, Croatia, Serbia, western Greece and southern Romania. There are also strong simulated ozone increases in central France and over the Adriatic Sea. These regions are all characterized as (rural) background areas, where ozone formation is strongly sensitive to the increases introduced in the NO_x emissions for the relatively low bottom-up anthropogenic and soil emissions. We find decreases in

5 ozone around the main shipping lanes, where the higher NO_x emissions further enhance ozone titration. The enhanced titration also reduced simulated surface ozone around urban regions such as Barcelona, Rome, and Paris. The increases in surface NO_x emissions in the BeNeLux and western Germany slightly increase simulated mid-day surface ozone. Ozone production is less sensitive to NO_x emissions in these high NO_x -emitting regions compared to the unpolluted background (Beekmann and Vautard, 2010; Mar et al., 2016; Jin et al., 2017).

10 Fig. 8 shows that O_3 simulations with the higher top-down NO_x emissions lead to a somewhat better match between modeled and observed surface O_3 , with an improvement in spatial correlation coefficient from 0.43 to 0.57, and an increase in slope from 0.33 to ~~0.40~~0.41. Overall, the model low bias has reduced from -15 to -8 $\mu\text{g m}^{-3}$, which indicates that the use of OMI NO_2 VCD data to constrain WRF-Chem surface NO_x emissions results in a considerable improvement regarding simulation of surface layer O_3 concentrations.

15 We additionally analyzed changes in the temporal evolution of ozone concentrations resulting from NO_x emission changes (Fig. 10). Daytime median O_3 concentrations are better captured in the Po Valley, Central Spain and Poland. The NO_x emission changes lead to a model overestimation of surface O_3 concentrations for Central France and South Germany, while concentrations change only slightly in the BeNeLux and Ruhr areas. In those regions, the mean bias error increases, while the hourly correlation coefficient and RMSE values improve for all regions (Supplementary Table 4). In all areas, changes

20 in NO_x emissions lead to increased ozone concentrations particularly during daytime. Enhancements in simulated night-time concentrations are only observed in Central Spain. In other areas, night-time O_3 concentrations are overestimated in both simulations. Peak daytime O_3 concentrations are better captured in all areas, as evidenced by the increase of the 75th percentile of simulated O_3 concentrations with top-down emissions. However, peak O_3 concentrations remain underestimated in the Po Valley, Central Spain and South Germany. Additionally, nighttime O_3 concentration overestimations remain, likely due to issues

25 related to model resolution and vertical mixing. Overall, the NO_x emission changes most effectively increase O_3 concentrations during periods with elevated ozone (Supplementary Fig. 3), which coincide with high solar radiation and temperatures and thus have a strongly NO_x -dependent O_3 formation.

7 Discussion

In this study we demonstrate the added value of deriving satellite-based NO_x emissions in (regional) air pollution models for

30 simulations of summertime ozone, focusing on July 2015 over Europe. We use a modified version of the mass balance approach introduced by Martin et al. (2003), with further improvements by Lamsal et al. (2011) and Vinken et al. (2014b). Although many studies report differences in simulated (surface) ozone concentrations after applying this mass balance approach (e.g. Ghude et al., 2013), we are aware of only one other study that used observations to validate subsequent ozone changes. Verstraeten

et al. (2015) used TES O₃ observations in the global chemistry model TM5 in a study on trans-continental transport of Asian air pollution, and found an improved model-satellite agreement in lower-tropospheric ozone. However, their approach did not allow for an evaluation of model performance closer to the surface.

The mass balance approach that we used to derive observation-constrained European NO_x emissions has several important advantages over more formal inversion methods that are applied in the literature (e.g. Miyazaki et al., 2014, 2017). The method is highly traceable due to the simple calculation of scaling parameters from model output for a baseline and perturbation simulation, and column NO₂ measurements. However, the linearization (see Sect. 3) oversimplifies the nonlinearity of the NO_x-O₃ chemistry, which means that the model-satellite discrepancy is not resolved completely after one iteration. Additionally, the approach is only applicable on a pixel-basis when the NO_x lifetime is sufficiently short to discard the contribution of transport from adjacent model NO₂ columns. The model-satellite difference for a simulation we performed for March 2015 (not shown) shows less spatial heterogeneity over regions with a diffuse spatial distribution of NO_x sources (e.g. Germany). These shortcomings can be resolved by averaging the signal over multiple grid cells, or by applying more formal inversion methods.

Our results demonstrate that surface NO_x emissions in our WRF-Chem configuration are increased substantially after applying an emission scaling approach. In a first-order budget calculation we derive that 43-69% of this total increase can be attributed to soil NO_x. This is diagnosed from the notably higher relative increase in emissions in regions with moderate anthropogenic emissions compared to regions with low and high anthropogenic emissions. We therefore conclude that the contribution of soil NO_x to total surface emissions is likely underestimated in our model set-up. Additionally, our top-down soil NO_x emission estimate, derived with a budget calculation, agrees well with previous estimates for European summer (Table 2). Our findings are in line with a previous study (Oikawa et al., 2015) that, using WRF-Chem with MEGAN soil NO_x emissions, found a strong underestimation of NO_x emissions in a high-temperature agricultural region.

Several studies previously investigated the relation between soil NO_x emissions and O₃ formation. For example, one study estimated that European soil NO_x emissions contribute 4 ppb to the daily maximum concentration (Stohl et al., 1996). A sensitivity study by Li et al. (2019) indicates that a strong up-scaling of soil NO_x emissions by a factor 5 indeed leads to a better representation of the peak ozone concentration. It has further been shown that an improved process-based representation of soil NO_x emissions leads to MDA8 O₃ changes by up to 6 ppb (Rasool et al., 2016), and a reduced mean bias for ozone concentrations, particularly in agricultural areas (Rasool et al., 2019). Together, these findings provide support for the hypothesis that underestimated soil NO_x emissions, in particular those from agricultural areas, contribute to underestimated peak ozone concentrations.

The comparison against in situ NO₂ observations from the AirBase network may be hindered by interference of reactive N species for measurements with molybdenum converters. The type of converter is not reported in the database. Literature-reported estimates of measurement overestimations due to this interference are 22% (Dunlea et al., 2007) and 5-18% (Boersma et al., 2009) at urban sites, and 20-42% at a rural site (Steinbacher et al., 2007). A correction factor can be applied to obtain corrected NO₂ measurements from observations using a molybdenum converter, which is on average 0.4-0.6 in summer, but with a large spread (0.2-0.8) (Lamsal et al., 2008, 2010). The strongest corrections of molybdenum-based in situ NO₂ measure-

ments are needed in remote environments, where NO_x is a relatively smaller component of the total reactive nitrogen budget compared to areas closer to NO_x sources (Lamsal et al., 2008). We hypothesize that this can partially explain the remaining model-observation mismatch for NO_2 after the use of top-down emissions.

Despite the demonstrated improvement in ozone simulations, our simulation with OMI-derived top-down NO_x emissions still misrepresents the high tail of the ozone distribution. We believe that there is a potential explanatory role for local to regional meteorological processes. The representation of several mesoscale phenomena requires a higher model resolution than $20 \times 20 \text{ km}^2$. For example, Millán et al. (1997) demonstrated that local re-circulation of residual air masses from higher aloft, containing elevated O_3 transported aloft during previous days, can be entrained in the boundary layer and contribute substantially to air pollution episodes in southern Europe. This is supported by an analysis of measured ozone (precursors) in northeast Spain by Querol et al. (2017), where this mesoscale circulation pattern was found to contribute to concentrations that exceed the information threshold value set by the European Union ($180 \mu\text{g m}^{-3}$), alongside contributions from locally emitted NO_x and biogenic VOCs.

Simulations of surface ozone in AQ models are also impacted by the choice of chemical parameterization. Recently, several studies have investigated the influence of the chemical mechanism on simulated NO_x and O_3 concentrations. Regarding ozone chemistry, chemical mechanisms differ predominantly in two aspects: 1) the grouping of VOC species in species categories ("lumping") according to their chemical structure or number of C-atoms, and 2) the inorganic rate coefficients involved in the catalytic cycling of NO_x , HO_x and O_x . Especially the latter aspect has a strong influence on simulated NO_2 concentrations, and can therefore influence the derivation of top-down emission estimates using satellite observations (Stavrakou et al., 2013). Coates et al. (2016) investigated the maximum ozone formation potential in different chemical mechanisms and found that mechanisms with lumped VOC categories led to lower ozone mixing ratios compared to a mechanism with a near-explicit treatment of VOCs. Knote et al. (2015) found small differences in inorganic rate constants among mechanisms and thus concluded that VOC representation was the dominating source of uncertainty among mechanisms. However, Mar et al. (2016) performed a WRF-Chem sensitivity study where MOZART inorganic rate constants were applied within RADM2, leading to mean O_3 concentration differences of $8 \mu\text{g m}^{-3}$ between those mechanisms.

In order to test the importance of inorganic NO_x - HO_x - O_x reaction rates for ozone formation, we implemented inorganic rate constants from three different mechanisms (CBM-Z, RADM2 and MOZART) in a mixed layer model with simplified chemistry (Janssen et al., 2012). Further details are given in Sect. 5 of the Supplement. Our analysis shows that varying the temperature-dependent rate constant of HNO_3 formation ($k_{\text{NO}_2 + \text{OH}}$) can lead to a spread of 2 ppb for end-of-afternoon ozone values on a typical summer day in a polluted boundary layer. CBM-Z uses the lowest $k_{\text{NO}_2 + \text{OH}}$ among the considered mechanisms, and thus leads to a higher NO_2 lifetime and more O_3 formation than in other mechanisms. Therefore, we conclude that modification of inorganic reaction rate constants has a modest effect on simulated O_3 , but is not likely to lead to increases in simulated O_3 in our WRF-Chem configuration. Nevertheless, the model representation of ozone chemistry should be carefully considered in NO_x and O_3 air quality studies, besides the representation of NO_x emissions.

Several studies have considered the resolution dependence of air quality simulations. This is especially relevant for NO_2 , since NO_x emissions display strong variation on the $20 \times 20 \text{ km}^2$ scale applied in this study. Increasing model resolution leads

to better representation of these local gradients and therefore improves simulations of NO_2 concentrations (Schaap et al., 2015). Valin et al. (2011) found that an accurate representation of mid-day NO_2 columns from highly localized sources requires a high model resolution, but regions with more diffuse sources can be simulated at a coarser resolution of $\pm 10 \times 10 \text{ km}^2$. Although ozone production regimes do not strongly depend on the model resolution in regional models, high resolution models perform better at simulating local O_3 titration in freshly emitted NO plumes (Cohan et al., 2006).

Besides the representation of meteorological processes, there is an additional uncertainty related to surface-atmosphere exchange of pollutants. Dry deposition constitutes 17% of the tropospheric sink of ozone, and is the second most important removal process after chemical removal (Hu et al., 2017). Several studies have recently investigated the role of meteorological drivers that determine ozone removal at the surface. However, these meteorological controls are oversimplified in deposition parameterizations. The vapour pressure deficit strongly controls stomatal uptake of ozone, thereby affecting surface ozone levels in spring to summer in the United States (Kavassalis and Murphy, 2017). Analysis of 10-year O_3 flux observations in the northeastern United States revealed that the removal of ozone by the land surface exhibits a strong inter-annual variability, which is not captured in dry deposition parameterizations (Clifton et al., 2017). Lastly, the role of soil moisture has been proposed as a regulator of surface ozone uptake (Tawfik and Steiner, 2013) and is often neglected in parameterizations of dry deposition, even though a recent study found that it can significantly reduce simulated ozone uptake (Anav et al., 2017). Improving the biophysical representation of the dry deposition process in WRF-Chem will be one of our foci in the future.

Future studies that apply satellite-based constraints on surface NO_x emissions can benefit from observations from the recently launched TROPOMI instrument (Veefkind et al., 2012), which delivers NO_2 column data at an unprecedented resolution of $7 \times 3.5 \text{ km}^2$. This has the potential to lead to important improvements in satellite-constrained NO_x emissions. Recent work (Lorente et al., 2019, in review) has applied TROPOMI observations in a column model study to derive emissions from Paris. The resolution of the instrument additionally enables the focus on more local areas with one dominating source such as soils in agricultural or bare-soil regions.

8 Conclusions

We performed a WRF-Chem simulation of NO_x and ozone over Europe for July 2015 and assessed its performance with AirBase in situ observations and OMI NO_2 column measurements. We find that WRF-Chem underestimates high surface ozone concentrations in central and southern Europe, and overestimates lower ozone concentrations in northern Europe. The model also underestimates the spread. The monthly averaged mean bias error (MBE) is relatively small ($-2.4 \mu\text{g m}^{-3}$, 10%). WRF-Chem underestimates daytime increases in ozone concentrations, as evidenced by substantial negative MBE values for the mid-day (12 h UTC) O_3 concentration and MDA8 O_3 ($-15.1 \mu\text{g m}^{-3}$ and $-14.2 \mu\text{g m}^{-3}$, respectively). We relate the low bias in surface ozone to biases in ozone precursor concentrations. Of particular relevance are nitrogen oxides, which drive ozone production in much of NO_x -limited summertime Europe.

For NO_2 , we find that WRF-Chem underestimates surface and column NO_2 values for most of the domain, with exception of some high-emission regions. With respect to AirBase, WRF-Chem monthly averaged surface NO_2 is biased low by $-2.5 \mu\text{g m}^{-3}$

(-73%). The spatial distribution of WRF-Chem column NO₂ agrees well with OMI ($r^2 = 0.68$), and a mean underestimation of 0.3×10^{15} molec. cm⁻² (-23%). We attribute the low bias in WRF-Chem NO₂ concentrations to underestimations in surface NO_x emissions in WRF-Chem. We subsequently derive optimized NO_x emissions based on the WRF-Chem/OMI relative difference using a mass balance approach. Overall emissions increase from 0.32 to 0.50 Tg N, an increase of 0.18 Tg N (+56%), for July 2015. The updates indicate that NO_x emissions should be scaled up across the domain. The relative increase in emissions is largest for regions with moderate emission strength (up to 50 Mg N month⁻¹ cell⁻¹) and coincides with regions where agricultural soil NO_x emissions are substantial. Our optimized soil NO_x emissions amount to 0.1 Tg N, in much better agreement with values from the literature.

A WRF-Chem simulation with optimized NO_x emissions removes the model's systematic bias with respect to OMI NO₂, and leads to an improved spatial agreement (slope = 0.98, $r^2 = 0.84$). An evaluation against AirBase NO₂ reveals that the top-down simulation improves particularly in the monthly average, where the systematic mismatch is reduced (slope = 0.89 instead of 0.73) and the mean bias is reduced by 50%. For ozone, the model skill improves particularly for mid-day and MDA8 O₃, when local ozone formation occurs and the sensitivity of ozone formation to NO_x concentrations is highest. On average, surface O₃ concentrations increase by 6 µg m⁻³ (6%). Still, peak (mid-day) ozone values are underestimated after NO_x emission optimization.

Overall, our findings demonstrate that air quality model simulations combined with in situ and remote sensing observations can be used to infer missing sources of NO_x at the surface. By optimizing NO_x emissions with satellite observations, substantial improvements in simulated ozone can be achieved. Our work shows that this helps to reduce the persistent biases in O₃ that most air quality models are suffering from. Projected decreasing trends in anthropogenic NO_x emissions will mean that the contribution of soils to total European NO_x emissions will likely increase in the future, and thus deserves careful attention in (European) air quality assessments, along with detailed assessments of emissions of volatile organic compounds and wildfires, boundary layer mixing, and chemistry.

Code and data availability. WRF-Chem output and re-calculated OMI NO₂ columns are available upon request, as well as scripts to re-calculate the tropospheric AMF and the resulting changes in satellite NO₂ columns.

Author contributions. AV, KFB and LG designed the experiment. AV performed the model simulations and analysis, with support from all co-authors. AV wrote the manuscript, with contributions from all co-authors.

Acknowledgements. AV acknowledges funding from NWO's program "Gebruikersondersteuning Ruimteonderzoek" (GO) project ALW-GO/16-17 SASODIE: Space-based assessment of ozone deposition and its impact on ecosystem functioning. The authors acknowledge the free availability of the WRF-Chem model (<https://www2.aom.ucar.edu/wrf-chem>, last access: 5 February 2019), in situ data from AirBase (<http://discomap.eea.europa.eu/map/fme/AirQualityExport.htm>, last access: 14 March 2019), and satellite NO₂ column observations from the
5 OMI instrument (<http://www.qa4ecv.eu>, last access: 12 March 2019). We additionally thank John Paton for his help downloading AirBase in situ measurements.

Table 1. Performance statistics of WRF-Chem bottom-up and top-down simulations for July 2015 for several conventionally applied performance metrics (MBE, RMSE, slope and intercept of a linear regression fit of simulations against observations, and r^2 from orthogonal distance regression), as well as the index of agreement ($d = 1 - \frac{\sum_{i=1}^N (P_i - O_i)^2}{\sum_{i=1}^N (|P_i| + |O_i|)^2}$, Willmott, 1982), where P_i and O_i represent simulations and observations, respectively. MBE, RMSE and intercept have unit $\mu\text{g m}^{-3}$, slope, r^2 and d are unitless.

	n	Bottom-up						Top-down					
		MBE	RMSE	slope	intercept	r^2	d	MBE	RMSE	slope	intercept	r^2	d

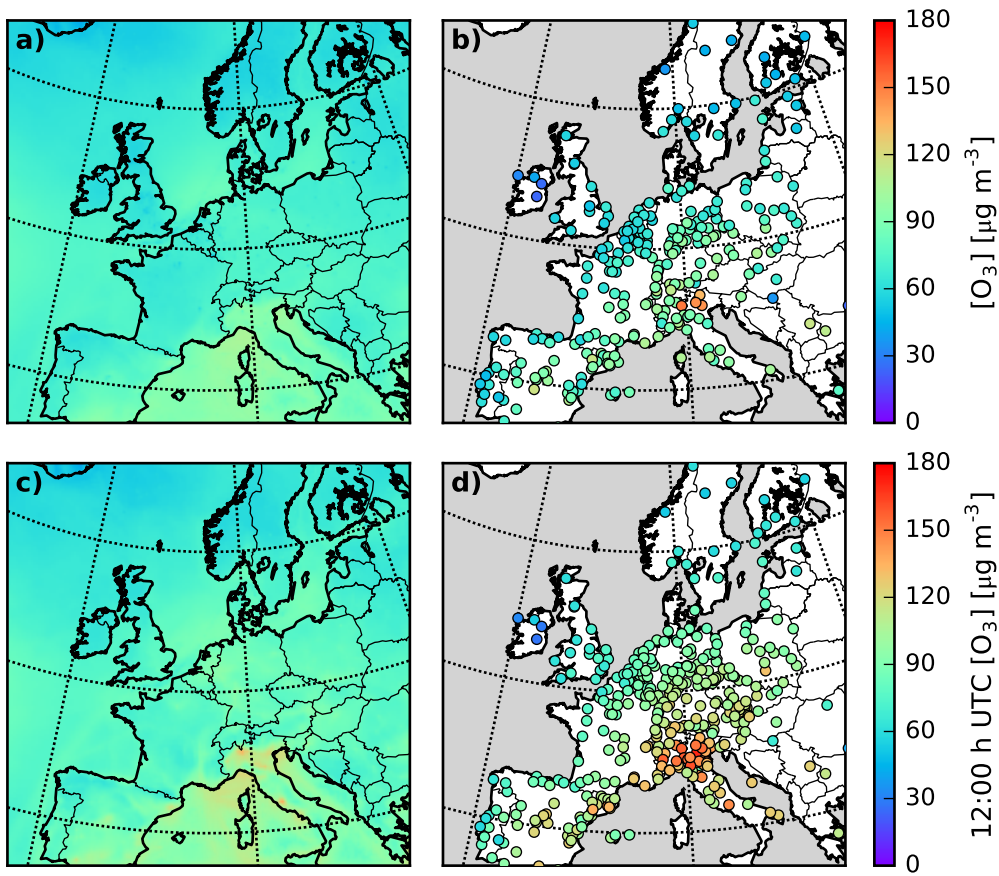

Figure 1. Monthly averaged surface O_3 and simulated by WRF-Chem with bottom-up NO_x emissions (a & c) and observed at AirBase stations (b & d). Panels a) and b) are monthly averages, and b) and d) are sampled at 12:00 h UTC.

Figure 2. As Fig. 1, but for NO₂.

Figure 3. Change in monthly-averaged OMI-retrieved NO₂ columns after using WRF-Chem vertical NO₂ profiles to calculate the Air Mass Factors (AMFs) in the OMI retrieval, as described in Sect. 2.4.

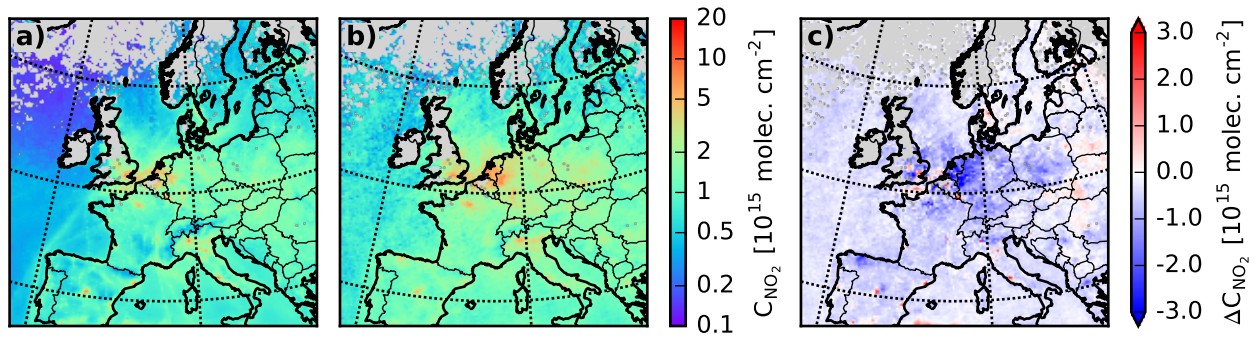

Figure 4. Monthly-averaged tropospheric NO₂ vertical column densities from a) WRF-Chem with bottom-up NO_x emissions, b) OMI and c) their difference (WRF-Chem - OMI). WRF-Chem NO₂ columns have been co-sampled with OMI, and pixels are shown when $n_{\text{obs}} \geq 4$.

Figure 5. Surface NO_x emissions for a) the a bottom-up simulation (TNO-MACC-III anthropogenic + MEGAN soil NO_x), and b) the top-down simulation; c) depicts the change in surface NO_x emissions after the recalibration procedure.

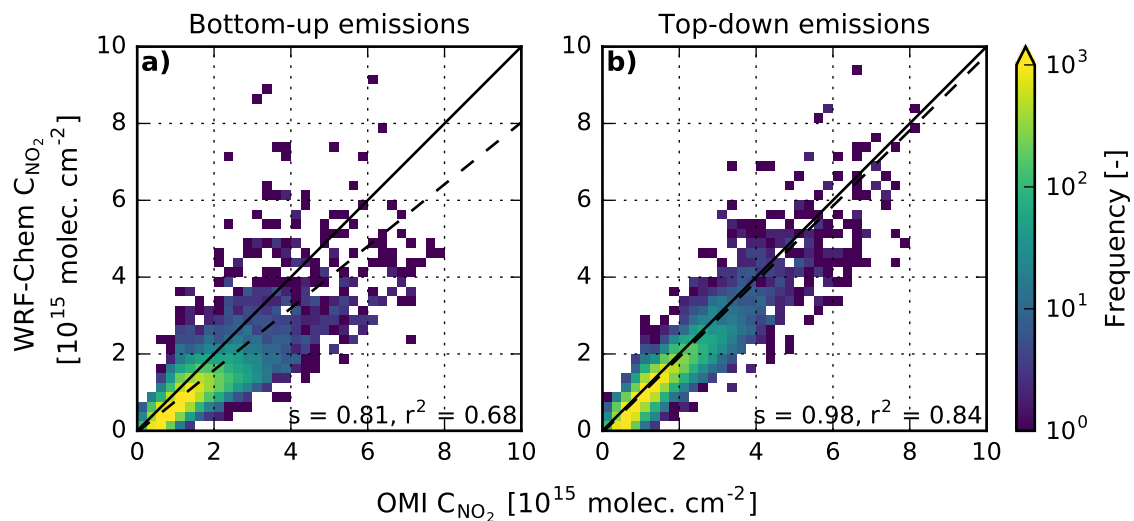

Figure 6. NO_2 vertical column density scatter plots of WRF-Chem against OMI, presented as a heat map with a bin size of 0.25×10^{15} molec. cm^{-2} , for WRF-Chem with bottom-up emissions (a), and WRF-Chem with OMI-derived top-down surface NO_x emissions (b). The OMI NO_2 VCDs in panels a) and b) are calculated with AMFs based on NO_2 vertical profiles of the WRF-Chem simulations against which they are compared, to ensure a consistent model-satellite comparison. The solid black lines represent the 1:1 line, and the dashed lines display the orthogonal distance regression fits.

Table 2. Comparison of WRF-Chem surface NO_x emissions in July (~~in Tg N month⁻¹~~) (in Tg N month⁻¹, unless indicated otherwise) with literature-reported values.

	Year	Region	Surface	Anthropogenic	Soils	<u>Soil (%)</u>

¹ This estimate is based on summer (JJA) estimates.

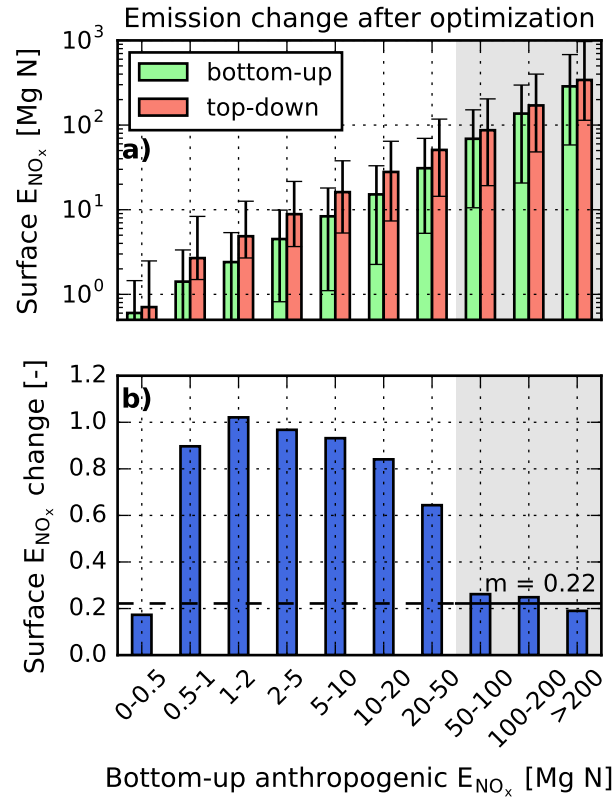

Figure 7. Difference between bottom-up and top-down surface NO_x emissions, expressed as a) a bar plot (note the logarithmic scale) of median emissions binned by bottom-up anthropogenic NO_x emissions (error bars indicate the inter-quartile range), and b) a bar plot of relative emission differences $\left(\frac{\text{posterior} - \text{prior}}{\text{prior}}\right)$ between the bars in panel a). In panel b) we define the relative anthropogenic emission difference to be the median of the relative change between top-down and bottom-up emissions in anthropogenic-dominated regions (shaded, with bottom-up emissions $> 50 \text{ Mg N month}^{-1} \text{ cell}^{-1}$).

Figure 8. Scatter plots of monthly averaged simulated concentrations of a) NO₂ and b) O₃ against AirBase observations. Panel a) shows monthly averages for 0-23 h UTC, while panel b) is sampled at 12 h UTC. The black solid lines represent the 1:1 line.

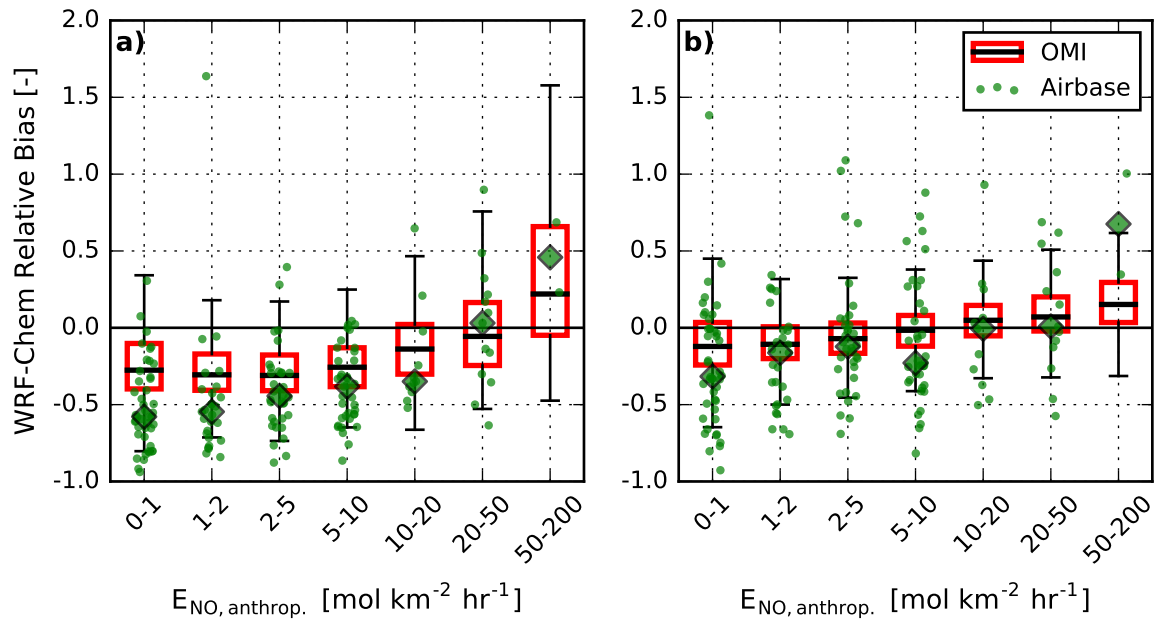

Figure 9. Relative bias ($RB = \frac{\text{model} - \text{observations}}{\text{observations}}$) of WRF-Chem against land-based OMI NO₂ vertical column densities (box plots) and Air-Base in situ NO₂ measurements (green scatter), binned by bottom-up anthropogenic NO emission strength, for the bottom-up (a) and top-down WRF-Chem simulation (b). Green diamonds indicate the median WRF-Chem RB against AirBase observations for pixels within every emissions bin.

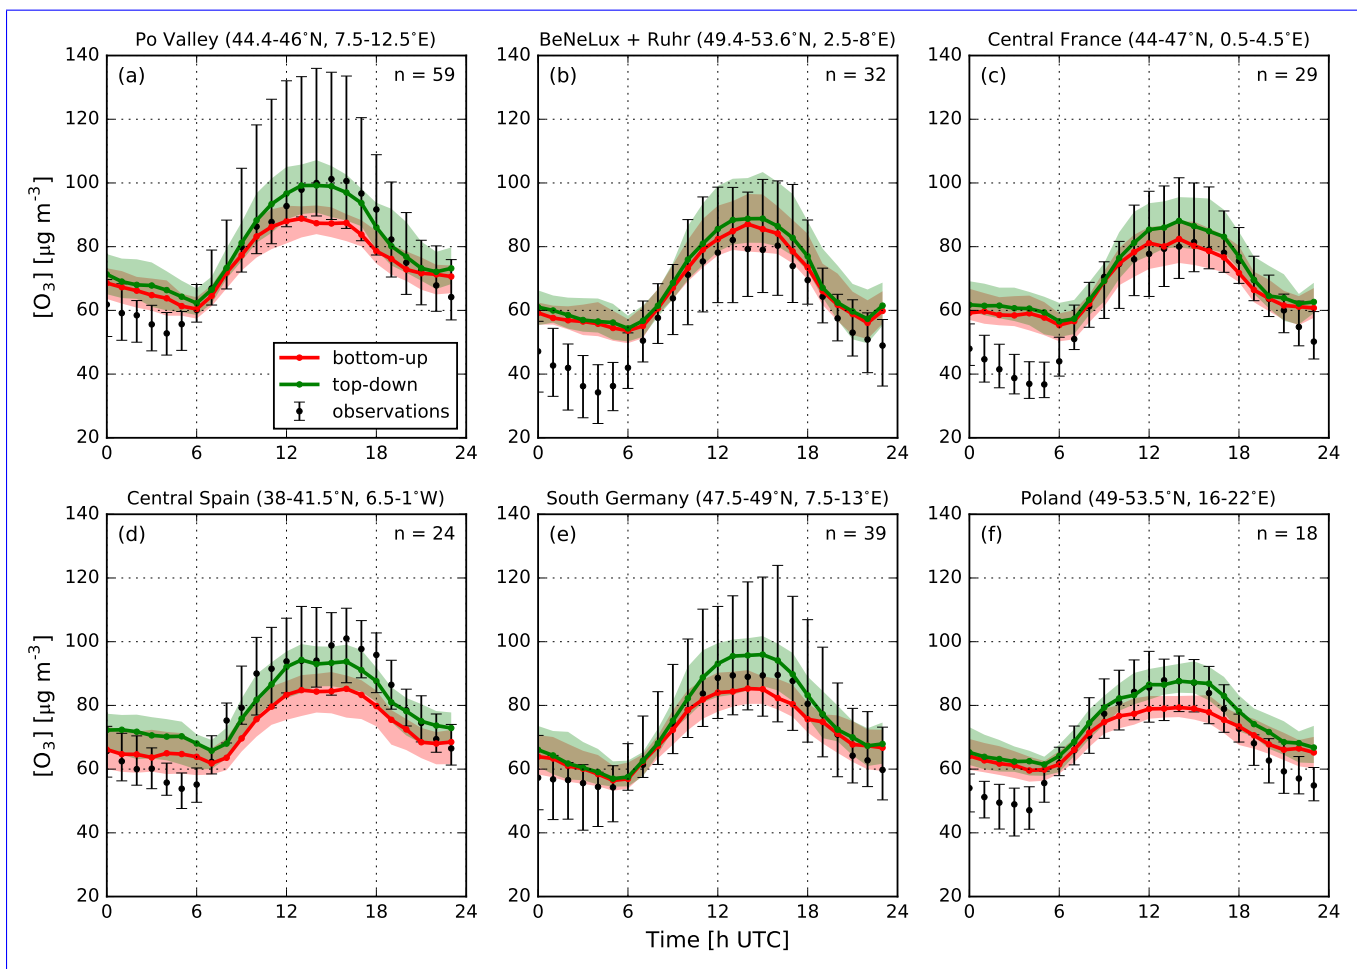

Figure 10. July 2015 monthly median diurnal ozone concentrations for six representative regions in Europe, as simulated by WRF-Chem with bottom-up NO_x emissions (green line) and top-down NO_x emissions (red line), and as observed at AirBase stations in these regions. Shaded areas and whiskers indicate the inter-quartile range. Results represent the median over all model-observation comparisons per region. The sample size for the comparison is displayed on the top right of each subplot.

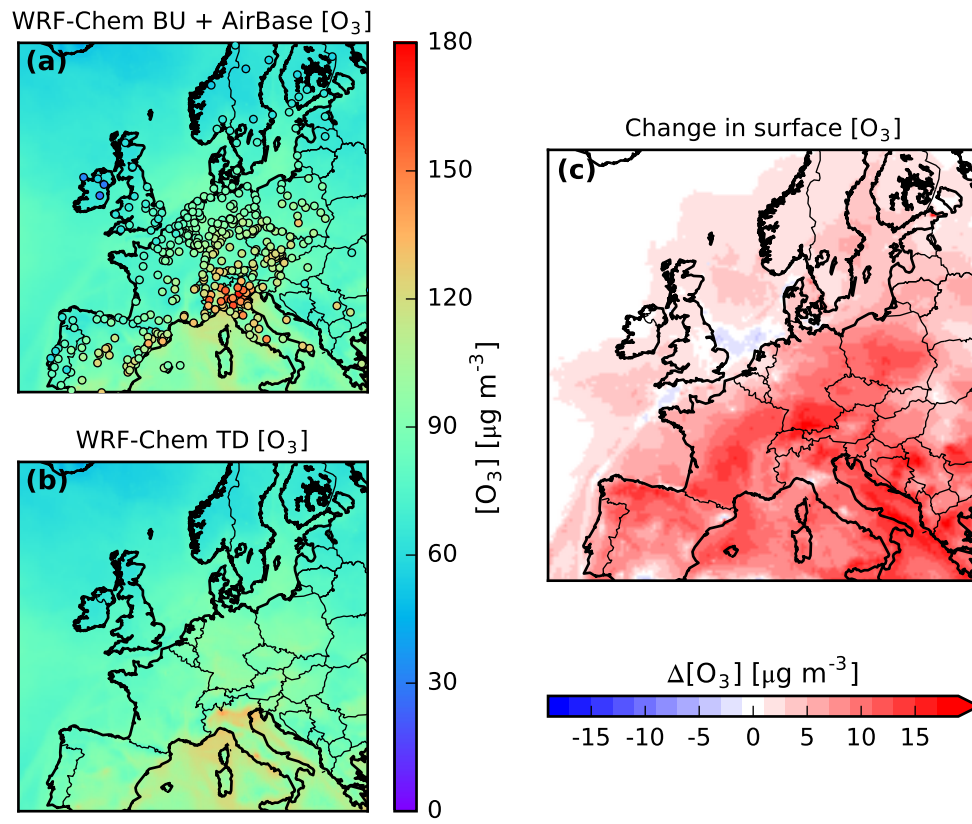

Figure 11. Monthly-averaged 12:00 h UTC surface O_3 concentration with bottom-up (BU, panel a) and top-down (TD, panel b) NO_x emissions. Panel c shows the difference between the two monthly averages (TD - BU).

1 WRF-Chem namelist

Table 1: Parameterization schemes used in the WRF-Chem setup.

WRF-Chem option	Parameterization scheme (reference)
Physics	
Microphysics	Morrison double-moment (Morrison <i>et al.</i> , 2009)
Longwave radiation	CAM (Collins <i>et al.</i> , 2004)
Shortwave radiation	CAM (Collins <i>et al.</i> , 2004)
Surface layer	MYNN2 (Nakanishi & Niino, 2006)
Land surface physics	Noah land surface model (Tewari <i>et al.</i> , 2004)
Boundary layer physics	MYNN2 (Nakanishi & Niino, 2006; Nakanishi & Niino, 2009)
Cumulus parameterization	Grell 3D Ensemble Scheme (Grell & Devenyi, 2002)
Lightning physics	PR92 neutral buoyancy (Price & Rind, 1993)
Chemistry	
Gas-phase chemistry	CBM-Z (Zaveri & Peters, 1999)
Photolysis parameterization	Madronich F-TUV (Tie <i>et al.</i> , 2003)

2 Meteorology evaluation

2.1 Meteorological reanalysis data

A European-wide meteorology evaluation performed by Mar *et al.* (2016) and numerous other studies demonstrated the skill of WRF-Chem to simulate several meteorological variables relevant to O₃ formation (radiation, temperature, wind speed and wind direction, boundary layer height). We further evaluated WRF-Chem’s performance to simulate meteorology by comparing to the ERA-Interim reanalysis product (Dee *et al.* , 2011), for five variables that are important for surface ozone: surface pressure, 2m temperature, relative humidity, wind speed and wind direction. This complements the comparison with meteorological station observations (e.g. Mar *et al.* , 2016), and has the additional advantage that it is continuous in space.

2.2 Results

To evaluate the meteorology in WRF-Chem we perform a comparison with the state-of-the-art ECMWF operational reanalysis product (hereafter referred to as ECMWF reanalysis). Model performance metrics for the meteorological evaluation for the two simulated months are shown in Table 2, for which show the monthly average of single-day comparisons. We only calculate performance metrics for land-based pixels, as the oceanic pixels generally contribute less to the overall bias. Overall, WRF-Chem shows good performance compared to ECMWF-reanalysis data, and WRF-Chem-ECMWF differences between March and July are consistent in sign.

WRF-Chem performs best at simulating surface temperature and pressure, but relative humidity and wind speed and -direction are simulated with less accuracy. Surface temperature is slightly underestimated, which agrees well with the cold bias generally found in WRF(-Chem) (e.g. Holtslag *et al.* , 2013; Kleczek *et al.* , 2014). Surface pressure is in general slightly underestimated, although we must note that this comparison is limited by terrain height differences in ECMWF reanalysis compared to WRF-Chem. Relative humidity is overestimated substantially in WRF-Chem, by approximately 10%. This potentially impacts simulated surface ozone in WRF-Chem, as there is an important role for surface atmospheric humidity, which governs the VPD in combination with temperature, in describing ozone removal at the surface (Kavassalis & Murphy, 2017).

We found an approximately linear increase in the model bias (defined in this section as WRF-Chem - ECMWF reanalysis) for RH in July, with a slope of 0.2% d⁻¹. This coincides with a linear decrease in the bias from 0.12 K to -0.98 K, which would suggest that the domain-averaged latent energy flux is overestimated, leading to an enhanced moisture flux to the atmosphere and underestimated temperatures. For all other variables we did not observe a clear change in domain-average model biases with time, indicating that model performance is robust over the simulation period. Overall, this evaluation, in combination with recent WRF-Chem meteorology evaluation studies (e.g. Mar *et al.* , 2016) provides confidence in WRF-Chem’s skill to reproduce domain-averaged surface meteorological conditions.

Table 2: Meteorological evaluation of two one-month WRF-Chem simulations with ECMWF operational reanalysis fields for five key surface meteorological variables. Only land-based pixels are used in the evaluation.

	March					July				
	μ_{ERA}	μ_{WRF}	r^2	MB	RMSE	μ_{ERA}	μ_{WRF}	r^2	MB	RMSE
T_{2m} [K]	281.51	280.52	0.77	-0.95	2.86	296.33	295.38	0.87	-0.95	2.69
P_{sfc} [hPa]	978.90	976.61	0.83	-2.29	18.56	972.94	972.28	0.96	-0.67	7.98
RH [%]	61.74	71.55	0.41	9.81	18.19	53.21	63.81	0.42	10.60	19.11
WS_{10m} [$m\ s^{-1}$]	4.78	5.45	0.56	0.68	2.08	3.34	4.51	0.50	1.17	1.95
WD_{10m} [$^{\circ}$]	181.70	180.39	0.44	1.30	82.53	215.18	209.83	0.34	-5.35	85.71

3 Emission speciation

Table 3: Distribution of TNO-MACC non-methane VOC emission categories over VOC species in CBM-Z.

CBM-Z	TNO-MACC-III
e_ch3oh	alcohols
e_c2h5oh	alcohols
e_hc3	propane, butanes, ethyne
e_hc5	pentanes
e_hc8	hexanes & higher alkanes
e_ol2	ethene
e_olt	propene
e_oli	other alk(adi)enes & alkynes
e_tol	benzene, toluene, other aROUatics
e_xyl	xylene, trimethylbenzenes
e_hcho	methanal
e_ald	other alkanals, ethers
e_ket	ketones
e_ora2	acids

4 Spatial plots of emission scaling parameters

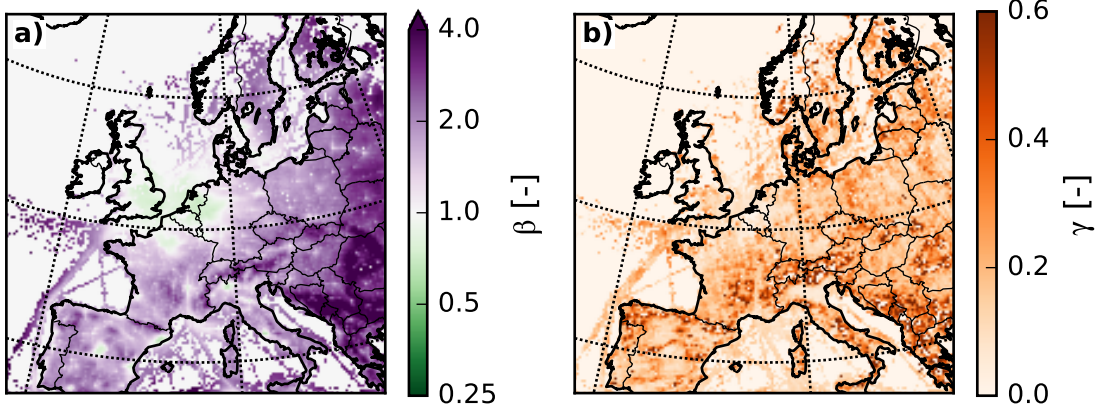

Figure 1: Spatial plots of monthly-averaged values of a) β and b) γ , calculated following Eqns. 3 and 4 (in main text), respectively.

5 Sensitivity study on inorganic reaction rates

A recent study investigated the representation of inorganic rate constants for tropospheric O_3 formation in WRF-Chem, and found a strong impact on the monthly average of $8 \mu g m^{-3}$ when using MOZART inorganic rate constants in RADM2 (Mar *et al.*, 2016). To evaluate the potential impact of this on our simulations, we apply the mixed-layer and chemistry model MXLCH (Janssen *et al.*, 2012), which uses a simplified version of the MOZART mechanism. We set up this case as follows in order reproduce polluted conditions occurring in the Mediterranean, in order to determine the impact of inorganic reaction rates on the production of ozone in a well-mixed boundary layer: The location is set at $45.5^\circ N / 3.4^\circ E$ (Southern France), initial O_3 concentrations in the mixed layer and the free troposphere are set to 62 ppbv and 78 ppbv, respectively, initial NO and NO_2 concentrations in the mixed layer are set to 1.6 ppb and 4.0 ppb, respectively, we apply NO and CO emission fluxes representative for relatively polluted conditions (0.15 ppb s^{-1} and 2.0 ppb s^{-1} , respectively), and we add two reactions to this mechanism representing HO_x cycling via reaction with O_3 .

From a comparison of rate constants among the mechanisms CBM-Z, RADM2 and MOZART, we found the largest differences in rate constants for the reaction forming HNO_3 ($NO_2 + OH + M \rightarrow HNO_3 + M$), while other inorganic rate constants are much more comparable. This is in line with the rate constant comparison by Knote *et al.* (2015). We modify the temperature-dependent rate constants of the reaction forming HNO_3 ($k_{NO_2 + OH}$) according to Fig. 2 (panel a), and subsequently we study the sensitivity of afternoon ozone concentrations to $k_{NO_2 + OH}$.

The NO_2 concentration and lifetime increase with decreasing rate constants, but the impact of $k_{NO_2 + OH}$ on NO_2 concentrations is rather small (Fig. 2c). The relative impact on OH is stronger (Fig. 2d): the NO_2 availability in combination with $k_{NO_2 + OH}$ drives OH loss, causing increasing OH concentrations for a decrease in $k_{NO_2 + OH}$.

HNO_3 formation in CBM-Z has a somewhat lower rate constant compared to other mechanisms, and therefore leads to a longer NO_2 lifetime. This accelerates O_3 formation, and thus leads to higher afternoon O_3 concentrations. The upper right panel of Fig. 2 shows that the inter-mechanism spread

is ± 2 ppbv. From this sensitivity analysis with a simplified representation of atmospheric chemistry within the atmospheric boundary layer, we conclude that there is some sensitivity of afternoon O_3 concentrations to the representation of inorganic reactions, particularly HNO_3 formation, involved in O_3 chemistry.

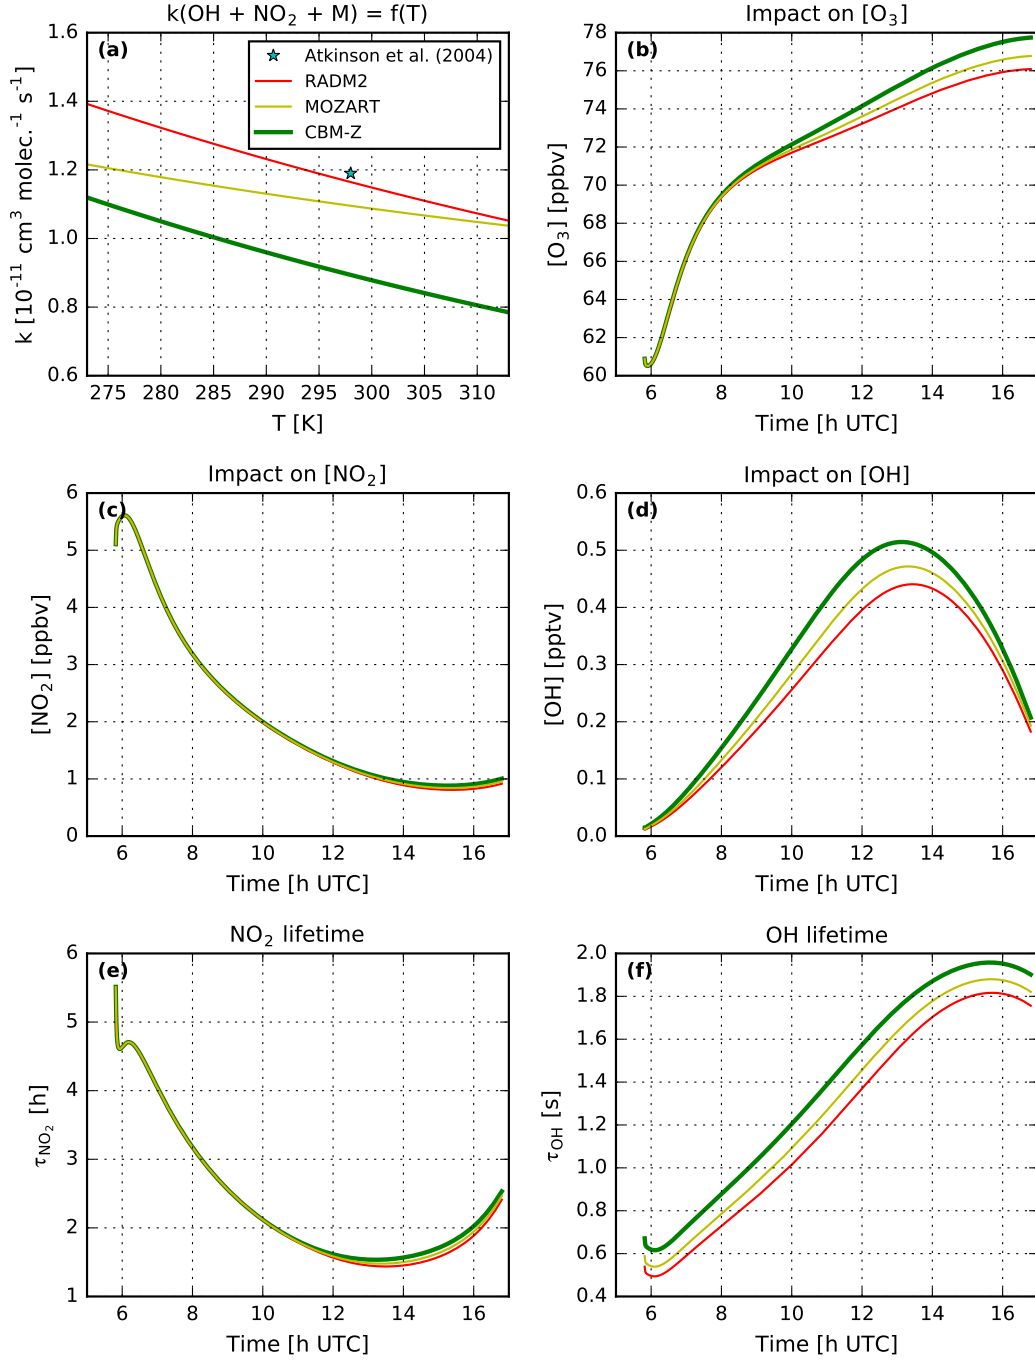

Figure 2: Temperature-dependence of rate constants for the reaction $\text{NO}_2 + \text{OH} + \text{M} \rightarrow \text{HNO}_3 + \text{M}$ from three different mechanisms (panel a), and the resulting impacts on O_3 (panel b), NO_2 (c) and OH (d). Panel a additionally gives the IUPAC-recommended value under standard conditions ($P = 1 \text{ bar}$, $T = 298 \text{ K}$) given by Atkinson *et al.* (2004). The lifetimes of NO_2 and OH are given in panels e and f, respectively.

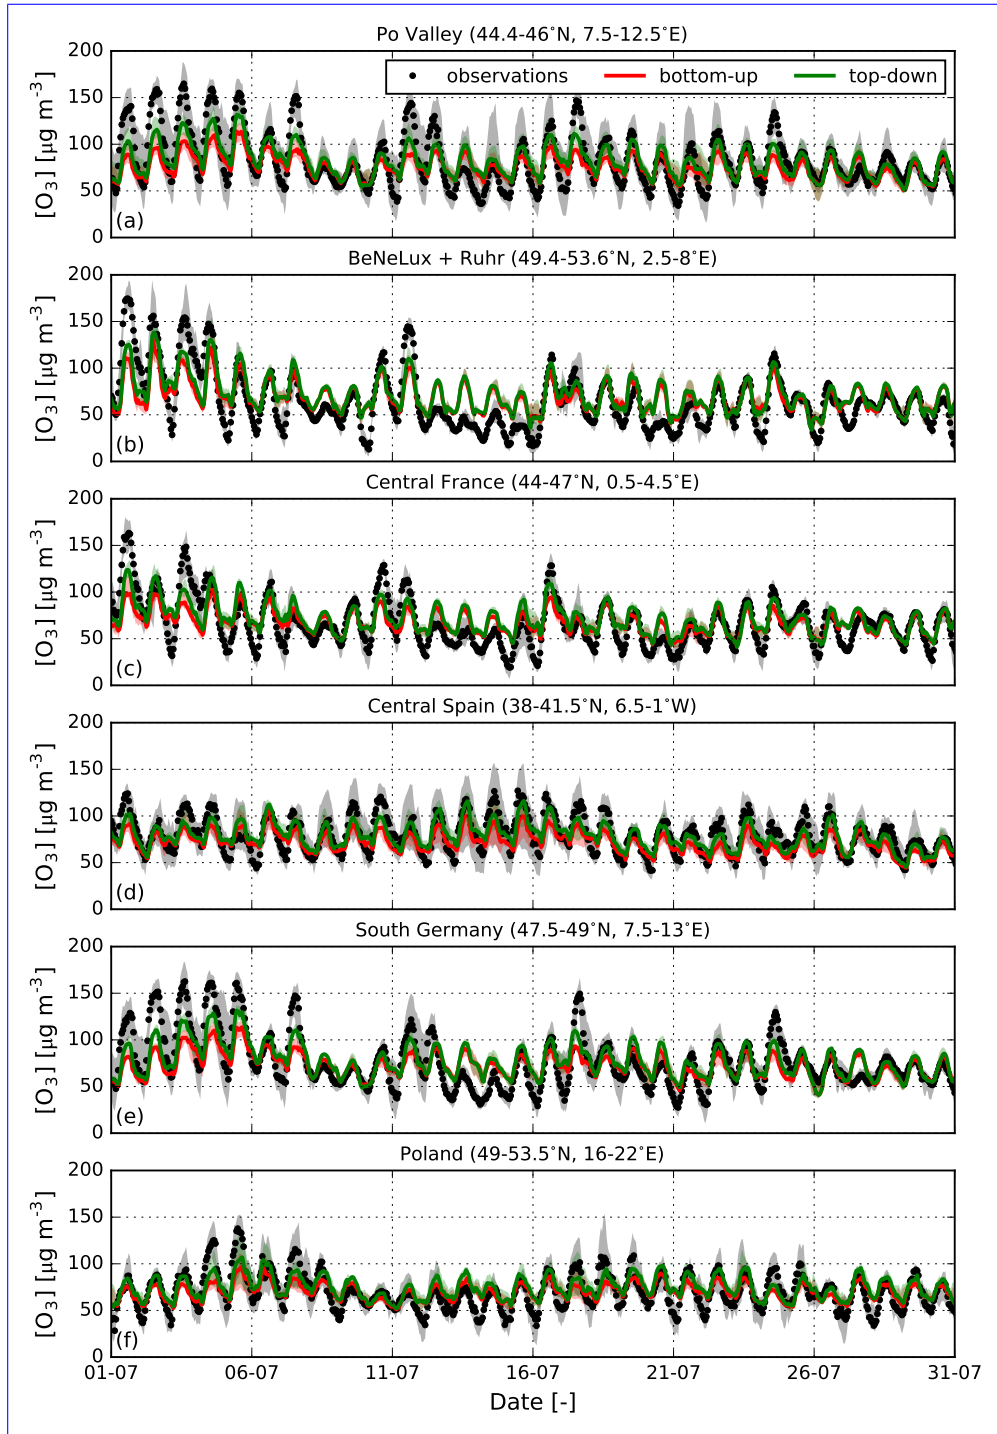

Figure 3: July 2015 time series of the median (shaded areas show inter-quartile range) O_3 concentrations as observed at AirBase stations (black dots), and as simulated by WRF-chem with bottom-up (red) and top-down emissions (green). Medians are calculated by including all stations (resp. co-sampled simulations) in the latitude/longitude range specified in the subplot titles.

Table 4: Model performance statistics for surface ozone concentration time series of the WRF-Chem simulation with bottom-up and top-down emissions for six European regions.
