

## Responses to Reviewers' Comments on Manuscript ACPD-2019-316

### (Interactions between aerosol organic components and liquid water content during haze episodes in Beijing)

We are grateful for the two anonymous reviewers' comments that helped to improve this manuscript. We have addressed the comments in the following paragraphs and made corresponding changes in the revised manuscript. Comments are shown as *blue italic text* followed by our responses. Changes are **highlighted** in the revised manuscript and shown as underlined text in the responses. The references mentioned in the responses are listed at the end of this file.

#### **Reviewer #1:**

*Li et al. presented long-term measurements of chemical compositions for submicrometer particles in Beijing, used these measurement data to calculate aerosol liquid water (ALW), and discussed in feedback between ALW and aerosol chemical compositions. A novel aspect of this work is that the contribution of organics to ALW and the effect of chemical composition on hygroscopicity of organics were considered. This work could largely improve our understanding of formation and physiochemical properties of aerosol particles in Beijing. I would recommend it for final publication after the following comments are addressed.*

#### *Scientific Comments*

*1) Line 82-84: It is stated here that calculated ALW agreed well with measured ALW, as reported by previous work. However, no references are cited (the work by Zhang et al. (2007) only mentioned aerosol composition measurement, I presume). Proper references should be cited here, and preferably more quantitative results reported by previous work should be illustrated to support this statement.*

Response: Thanks for the suggestion. We add a reference here and show the quantitative results from that study. The relevant paragraph is revised as:

Line 82-84: ALW estimated by this method, which only requires aerosol chemical composition obtained from AMS measurements (Zhang et al., 2007), corresponds reasonably with measured ALW (The ratio of predicted ALW to measured ALW is 0.91, with  $R^2 = 0.75$ ) (Guo et al., 2015).

*2) My second comment is related to the first one. I agree that in principle it is better to use composition-dependent hygroscopicity, instead of fixed hygroscopicity, to calculate ALW associated with organic particles. However, it is not very clear to which extent the new approach would improve the agreement between measured and calculated ALW? Do the authors have access to measured ALW during some of these periods? A comparison between measurements and calculations using fixed and composition-dependent hygroscopicity should make this work more convincing.*

Response: Thanks for the suggestion. We agree that a comparison with real measurement would make the calculation more convincing, but we didn't have access to any of the ALW measurement during our sampling period. Theoretically, this method should work based on many studies related with the organic hygroscopicity as stated in the main text. We cannot evaluate the accurate uncertainty of the method, but the trend of  $ALW_{org}$  should be correct. An interesting finding of this study is that the increase of organic O/C (varies largely

between 0.2 and 1.3) during haze evolution can further promote the uptake of water. This finding relies more on the trend of  $ALW_{org}$  instead of the absolute value of  $ALW_{org}$ . In the “Results and Discussion” part, we recommend future studies with measured ALW to do the comparison.

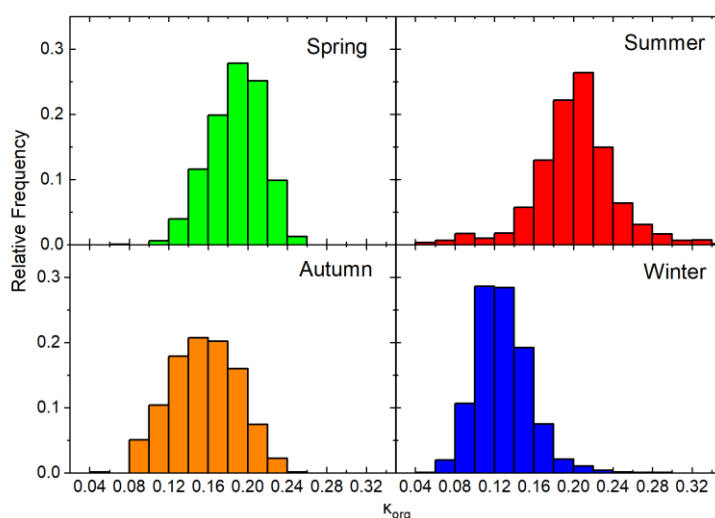

Line 300-301: As a result, we suggest that long term measurements of ALW and  $\kappa_{org}$  should be performed to test the results shown here and to establish a more reliable and accurate relationship between organic properties and ALW in the real atmosphere.

3) *Line 99: Please consider moving Figure S1 to the manuscript.*

Response: Our manuscript mainly focuses on the interactions between organic hygroscopicity and ALW. Figure S1 is only a support for the uncertainty of calculation method for  $ALW_{inorg}$ . In addition, similar statements with Figure S1 have already been discussed in previous studies, e.g., Song et al (2018).

4) *Line 194-195: please consider providing a figure which shows the frequency distribution of kappa values for organics.*

Response: The frequency distribution of kappa values for organics used in our study is as following (calculated using the method from Lambe et al., (2011)). This information has been included in Figure S2, where the 10th, 25th, 50th, 75th, 90th percentiles, and the mean value of the corresponding  $\kappa_{org}$  in each season were shown.

5) *Line 196-199: although kappa values calculated using different methods can be found in Fig. S2 and Table S2, it would be more convenient for readers if average values calculated using different methods can be stated in the main text.*

Response: Thanks for the suggestion. We add a sentence in the main text:

Line 200-201: As shown in Table. S2, the average  $\kappa_{org}$  calculated from other methods are  $0.22 \pm 0.07$  (Chang et al., 2010),  $0.19 \pm 0.06$  (Massoli et al., 2010), and  $0.21 \pm 0.12$  (Duplissy et al., 2011; Jimenez et al., 2009).

6) *Line 211: change “semi-volatile species” to “semi-volatile species (usually more oxidized)”, because it seems to be non-apparent linkage between volatility and O:C ratios, at least for people who are not experts in organic particles.*

Response: We agree. The sentence is revised as following:

Line 214-215: In addition, higher  $T$  promotes the partitioning of semi-volatile species (usually less oxidized than low-volatile species) from particle phase to gas phase, also resulting in an increase in particle organic O/C.

7) *Line 312: As Fig. S6 summarizes the concept proposed in this work, it may be worthy moving it to the main text.*

Response: Thanks for the suggestion. Figure S6 was moved to the main text as Figure 7.

Figure 7. The positive feedback loops between aerosol liquid water and organic evolution during high-ALW haze episode in Beijing.

#### Technical comments

1) *Line 33: the perspective paper by Wu et al. (2018) should also be cited here.*

Response: Thanks. The paper was added to the citations.

*The paper is very fluent; however, there are small grammatical errors which can be corrected. Perhaps the manuscript needs professional editing by a native speaker. Below I list some of the errors as examples:*

Response: Thanks for the suggestion. In the revised manuscript, we carefully checked the grammatical errors.

It was also edited by a native speaker.

2) *Line 24: change “ $T$ ” to “temperature ( $T$ )”.*

3) *Line 24: change “...concentration. Among which...” to “...concentration, among which...”*

4) *Line 48: change “rising” to “rises”.*

5) *Line 49: “transition” is a noun, please change it to a verb such as “change”.*

6) *Line 74: change “specific” to “Specific”.*

Response: Thanks, all of these are corrected in the revised manuscript.

#### Reviewer #2:

*This study reported the aerosol liquid water content contributed by organic components and its promotion on aerosol uptake. The results are very interesting. The manuscript is well-written and very clear. There are several questions should be addressed in the revised version.*

*Major Comments:*

- 1. The ALW contributed by organics is calculated based on the relationship between oxidation state and  $\kappa_{\text{org}}$ . This means O:C values have very strong effect on the results and conclusions. The O:C values obtained from  $f_{44}$  using the parameterization method for Q-ACSM may highly variable (Crenn et al., 2015). In addition, as given in Figure S2, different equations produced different  $\kappa_{\text{org}}$ . The relationship between O:C and  $\kappa_{\text{org}}$  may vary with sampling locations. Therefore, the uncertainties on O:C calculation and the selection of equation for calculating  $\kappa_{\text{org}}$  should be discussed in the manuscript.*

Response: Thanks, we agree that large uncertainties may be introduced during the Q-ACSM measurement, the conversion of  $f_{44}$  to O/C, and the conversion of O/C to  $\kappa_{\text{org}}$ . Although we cannot quantitatively evaluate the uncertainties, we believe the trend of  $\kappa_{\text{org}}$  we obtained in the study is reliable given the numerous organic hygroscopicity studies. We modified the paragraph that describes the uncertainty as following:

Line 196-203: We note higher  $\kappa_{\text{org}}$  could be introduced via the conversion from organic O/C (Eq. 2); though  $\kappa_{\text{org}}$  calculated from others parameterizations (Chang et al., 2010; Duplissy et al., 2011; Massoli et al., 2010; Peter et al., 2006; Raatikainen et al., 2010) are even higher than from the one used here (Fig. S2). The average  $\kappa_{\text{org}}$  calculated from other methods were  $0.22 \pm 0.07$  (Chang et al., 2010),  $0.19 \pm 0.06$  (Massoli et al., 2010), and  $0.21 \pm 0.08$  (Duplissy et al., 2011; Jimenez et al., 2009) (Table S2). Also, based on previous reports that Q-ACSM can report higher  $f_{44}$  values than the HR-ToF-AMS (Fröhlich et al., 2015) and that  $f_{44}$  reported by Q-ACSM may be highly variable between different instruments (Crenn et al., 2015), there is a possibility that positive deviations and large uncertainties of  $f_{44}$  were introduced via the Q-ACSM measurements.

- 2. Line 211-212, the authors didn't give explanations why the partitioning of semi volatile species from particle phase to gas phase lead to an increase in O:C.*

Response: Compared to low volatile species which tend to remain in particle phase in high ambient temperature, semi-volatile species usually correspond with low oxidation states and O/C ratio (Donahue et al., 2011). As a result, the repartitioning of less volatile species (with low O/C ratio) back to the gas phase may lead to an increase of O/C in particle phase. The sentence was revised as:

Line 214-215: In addition, higher  $T$  promotes the partitioning of semi-volatile species (usually less oxidized than low-volatile species) from particle phase to gas phase, also resulting in an increase in particle organic O/C.

- 3. Line 141-145, the calculation of VGF assume the total volume equals to the addition of volumes of all components. If the irregular particles lead to a bias? What is the difference between VGF and mass-based growth factor? Why mass-based growth factor is not used here?*

Response: The irregular particles will lead to a bias in the calculation of size growth factor, but will not lead to a bias in VGF unless the density of the mixture is significantly different from the weighted average density of each species. The conversion to VGF is for better comparison with previous studies as VGF is more oftenly used in literature (e.g., Bian et al., 2014; Fajardo et al., 2016; Stanier et al., 2004) than mass-based growth

factor. What's more, the rates of aqueous processes are more directly related with volume concentration than mass concentration. The mass-based growth factor will be lower than VGF because the density of water is smaller than other particle species, but the trend should be in consistent with VGF.

**Abstract:** Aerosol liquid water (ALW) is ubiquitous in ambient aerosol and plays an important role in the formation of both aerosol organics and inorganics. To investigate the interactions between ALW and aerosol organics during haze formation and evolution, ALW was modelled based on long-term measurement of submicron aerosol composition in different seasons in Beijing. ALW contributed by aerosol inorganics ( $ALW_{inorg}$ ) was modelled by ISORROPIA-II, and ALW contributed by organics ( $ALW_{org}$ ) was estimated with  $\kappa$ -Köhler theory, where real-time hygroscopicity parameter of the organics ( $\kappa_{org}$ ) was calculated from the real-time organic oxygen-to-carbon ratio (O/C). Overall particle hygroscopicity ( $\kappa_{total}$ ) was computed by weighting component hygroscopicity parameters based on their volume fractions in the mixture. We found that  $ALW_{org}$ , which is often neglected in traditional ALW modelling, contributes a significant fraction (18-32%) to the total ALW in Beijing. The  $ALW_{org}$  fraction is largest in the cleanest days when both the organic fraction and  $\kappa_{org}$  are relatively high. The large variation of O/C, from 0.2 to 1.3, indicates the wide variety of organic components. This emphasizes the necessity of using real-time  $\kappa_{org}$ , instead fixed  $\kappa_{org}$ , to calculate  $ALW_{org}$  in Beijing. The significant variation of  $\kappa_{org}$  (calculated from O/C), together with highly variable organic or inorganic volume fractions, leads to a wide range of  $\kappa_{total}$  (between 0.20 and 0.45), which has great impact on water uptake. The variation of organic O/C, or derived  $\kappa_{org}$ , was found to be influenced by temperature (T), ALW, and aerosol mass concentrations, among which, T and ALW both have promoting effects on O/C. During high-ALW haze episodes, although the organic fraction decreases rapidly, O/C, and derived  $\kappa_{org}$ , increase with the increase in ALW, suggesting the formation of more soluble organics via heterogeneous uptake or aqueous processes. A positive feedback loop is thus formed: during high-ALW episodes, increasing  $\kappa_{org}$ , together with decreasing particle organic fraction (or increasing particle inorganic fraction), increases  $\kappa_{total}$ , thus further promotes the ability of particles to uptake water.

## 1 INTRODUCTION

Aerosol liquid water (ALW) is a ubiquitous component of ambient aerosol and exerts great influences on aerosol physical and chemical properties, especially in regions with high relative humidity (RH) (Cheng et al., 2016; Cheng et al., 2008; Covert et al., 1972; Ervens et al., 2014; Nguyen et al., 2016; Pilinis et al., 1989; Wu et al., 2018; Zheng et al., 2015). From the perspective of aerosol physical processes, ALW influences particle lifetime, optical properties, radiative forcing, and the ability of particles to deposit in the humid human respiratory tract (Andreae and Rosenfeld, 2008; Cheng et al., 2008; Covert et al., 1972; Löndahl et al.,

2008). ALW also promotes partitioning of some of the inorganic gases and water-soluble organic gases to the condensed phase, thus directly increasing aerosol mass loadings (Asa-Awuku et al., 2010; Parikh et al., 2011). From the perspective of aerosol chemical processes, ALW can serve as a reactor for heterogeneous/aqueous reactions, facilitating the formation of both secondary inorganics (Cheng et al., 2016; Sievering et al., 1991; Wang et al., 2016) and organics (Carlton et al., 2009; Ervens et al., 2014; Song et al., 2019). As a result, understanding ALW content is critical in clarifying the formation and evolution of ambient aerosols as well as their impacts on air quality and climate, especially in urban cities like Beijing where severe haze events take place frequently with elevated RH (Sun et al., 2013; Zheng et al., 2015).

The interaction between ALW and aerosol chemical composition is a key issue for haze formation but remains uncertain, especially regarding the interaction between ALW and aerosol organics. Studies have demonstrated that secondary inorganic aerosol (SIA) and secondary organic aerosol (SOA) surpass primary species during haze formation in China (Huang et al., 2014; Sun et al., 2016; Zheng et al., 2016). SOA or SIA-driven haze formation is widely observed to be associated with elevated relative humidity (RH), especially in winter. In Beijing, as RH rises from below 40% to above 60%, the following has been reported: (1) aerosol mass loadings increase significantly; (2) particle phase changes from solid/semisolid to liquid phase (Liu et al., 2017); (3) both sulfur and nitrogen oxidation ratios increase (Cheng et al., 2016; Sun et al., 2013; Zheng et al., 2015); (4) water-soluble inorganics increase faster than organics (Liu et al., 2015; Quan et al., 2015; Sun et al., 2013; Zheng et al., 2015). RH affects secondary species via heterogeneous uptake or aqueous processes. During haze episodes, gas phase photochemical formation of SIA and SOA is largely suppressed by the weakened solar radiation (Zheng et al., 2015). Formation of SIA and SOA is thus suggested to be dominated by heterogeneous uptake or aqueous processes (Xu et al., 2017), which are largely dependent on ALW. Based on ALW measurements, previous studies have proposed positive feedback loops in which elevated RH increases particle concentration and particle inorganic fraction; increased particle concentration and inorganic fraction in turn increase the water uptake (Cheng et al., 2016; Liu et al., 2017; Wu et al., 2018). However, whether or how elevated ALW affects the evolution of SOA during haze episodes remains less understood than that of SIA because of the complexity of SOA species.

Long-term data are needed to evaluate the amount of ALW and its interactions with aerosol organic compositions. So far, short-term ALW data in Beijing (Bian et al., 2014; Fajardo et al., 2016) have been collected by directly measuring size-resolved aerosol hygroscopic volume growth factors (VGF) and particle size distributions using hygroscopicity-tandem differential mobility analyzer (H-TDMA) (Rader and McMurry, 1986) or dry-ambient aerosol size spectrometer (DAASS) (Engelhart et al., 2011; Stanier et al., 2004). However, long-term measurements of ALW are rare because of the challenge in maintaining these instruments. Another approach to obtain ALW is to combine aerosol chemical composition measurements and model predictions. ALW contributed by inorganics can be modelled by inorganic thermodynamic equilibrium models, such as ISORROPIA-II (Fountoukis and Nenes, 2007; Nenes et al., 1998, 1999), E-AIM (Clegg and Pitzer, 1992; Clegg et al., 1992), and SCAPE II (Kim et al., 1993a, b). Modelled inorganic water content is usually regarded as the total ALW because inorganic salts contribute to a large fraction of the total particle

loading and the hygroscopicity of inorganic salts is much larger (~6 times) than those of organic species (Bian et al., 2014; Hennigan et al., 2008). Although this approximation provides reasonable ALW in many ambient conditions, it fails in some cases. Especially when organics contribute a dominant fraction to particle loading, large discrepancies arise between the modelled inorganic water and the actual ALW content (Fajardo et al., 2016). Therefore, it is important to take the organic contribution to ALW into consideration. **Some specific models** include the calculation of organic ALW; e.g., aerosol diameter dependent equilibrium model (ADDEM)(Topping et al., 2005b, a). However, application of such models is hindered by lack of long-term measurements of specific OA species.

Recent studies have proposed a method to predict total ALW using the non-refractory submicron particulate matter (NR-PM<sub>1</sub>, particle diameter between 40 nm and 1 μm) composition measured with the widely used Aerosol Mass Spectrometer (AMS). The inorganic contribution to ALW ( $ALW_{inorg}$ ) was modelled by ISORROPIA-II; organic contribution to ALW ( $ALW_{org}$ ) was estimated with  $\kappa$ -Köhler theory (Petters and Kreidenweis, 2007; Su et al., 2010). The total aerosol liquid water (ALW) is then the sum of  $ALW_{inorg}$  and  $ALW_{org}$ . ALW estimated by this method, which only requires aerosol chemical composition obtained from AMS measurements (Zhang et al., 2007), corresponds reasonably with measured ALW **(The ratio of predicted ALW to measured ALW is 0.91, with  $R^2 = 0.75$ )** (Guo et al., 2015). Thus, this method can be used to predict long-term ALW from aerosol chemical composition and to explore interactions between ALW and organic evolution during haze events.

In this study, long-term NR-PM<sub>1</sub> chemical composition measurement was used to predict ALW in Beijing during various seasons (292 days in 5 years).  $ALW_{org}$  and  $ALW_{inorg}$  were estimated using  $\kappa$ -Köhler theory and ISORROPIA-II, respectively. A real-time organic hygroscopic parameter ( $\kappa_{org}$ , calculated from organic O/C ratio) was used to estimate  $ALW_{org}$ . The relationship between the total ALW and  $\kappa_{org}$  was explored. Within this long-term dataset, 12 high-ALW haze episodes and 8 low-ALW haze episodes were identified. Chemical evolution during high-ALW and low-ALW haze episodes was found to differ significantly. Positive feedback among organic hygroscopicity, organic volume fraction, overall particle hygroscopicity, and ALW is proposed to be a driving factor for severe haze formation in Beijing during high-ALW episodes.

## **2 METHODOLOGY**

### **2.1 Long-term measurements of particle chemical composition**

Long-term measurements were carried out between December 2013 and August 2017 at an urban site located on the campus of Tsinghua University in Beijing. The monitoring site is located on the top floor of a four-storey building without other tall buildings nearby with detailed information provided elsewhere (Cai and Jiang, 2017; Cao et al., 2014; He et al., 2001). Data from 292 days were used, including 2-3 months' data from each of the four seasons (Table S1). The average NR-PM<sub>1</sub> mass concentrations from spring to winter were 81.1, 54.2, 63.9, and 63.2 μg m<sup>-3</sup>, respectively. Note that PM<sub>2.5</sub> concentrations in Beijing were decreasing

during this period (<http://www.bjepb.gov.cn/>).

Chemical composition of NR-PM<sub>1</sub>, including sulfate (SO<sub>4</sub><sup>2-</sup>), nitrate (NO<sub>3</sub><sup>-</sup>), ammonium (NH<sub>4</sub><sup>+</sup>), chloride (Cl<sup>-</sup>), and total organics (Org), was measured using a quadrupole aerosol chemical speciation monitor (Q-ACSM)(Ng et al., 2011). The Q-ACSM was calibrated before each measurement following the procedure described by Ng et al., (2011). The meteorological conditions, including temperature (*T*), relative humidity (RH), and other routine meteorological parameters, were recorded by a meteorological station.

## 2.2 Aerosol liquid water modelling

ALW<sub>inorg</sub> was modelled by ISORROPIA-II using meteorological conditions and the Q-ACSM measured inorganic compositions. The model was carried out with “reverse” and “metastable” mode. Compared to the “stable” mode, “metastable” mode assumes that particles are always aqueous droplets, even at low RH. Although some earlier studies observed phase transitions of ambient particles, recent studies suggest that ambient aerosols tend to be in “metastable” states due to the coexistence of organic compounds that inhibit or cover up the deliquescence and efflorescence behavior of inorganic compounds (Martin et al., 2008; Rood et al., 1989). The “metastable” mode predicts more water than predicted from “stable” mode when RH is between 40% and 70%, while similar with the latter when RH is above 70% or below 40% (Fig. S1), consistent with previous work (Song et al., 2018). In a few of the modelling results in summer and autumn, high acid/base ratio caused some of the NO<sub>3</sub><sup>-</sup> and Cl<sup>-</sup> to enter the gas phase in the form of HNO<sub>3</sub> and HCl, resulting in disagreement between the output liquid phase NO<sub>3</sub><sup>-</sup> and Cl<sup>-</sup> and the input aerosol phase NO<sub>3</sub><sup>-</sup> and Cl<sup>-</sup>. These points were removed.

ALW<sub>org</sub> was estimated using a simplified equation of  $\kappa$ -Köhler theory where Kelvin effect was neglected (Petters and Kreidenweis, 2007) (Eq. 1),

$$ALW_{org} = V_{org} \kappa_{org} \frac{a_w}{1-a_w} \quad (1)$$

where  $a_w$  is the water activity and was assumed to be the same as RH (Bassett and Seinfeld, 1983) and  $V_{org}$  is the volume concentration of organics measured by Q-ACSM (the density of organics was assumed to be 1.2 g cm<sup>-3</sup>). In previous studies, a fixed  $\kappa_{org}$  in the range of 0.06-0.13 was used for urban, urban downwind, and rural sites (Gunthe et al., 2011; Nguyen et al., 2016; Rose et al., 2011). However, the hygroscopicity of organics is highly variable and  $\kappa_{org}$  can vary between 0 and 0.3 for different species (Lambe et al., 2011; Massoli et al., 2010).  $\kappa_{org}$  was found to have a positive linear relationship with organic O/C ratio (Chang et al., 2010; Dick et al., 2000; Duplissy et al., 2011; Gunthe et al., 2011; Petters et al., 2009), which likely reflects combined effects of molecular weight, volatility, and surface activity (Nakao, 2017; Wang et al., 2019). Previous studies proposed several empirical methods to calculate  $\kappa_{org}$  from O/C derived from a series of chamber and field experiments (Chang et al., 2010; Duplissy et al., 2011; Jimenez et al., 2009; Lambe et al., 2011; Massoli et al., 2010). Comparing these methods (Table S2), Eq. 2 was used to calculate

real-time  $\kappa_{org}$  over a broad O/C range (0.05-1.42) (Lambe et al., 2011),

$$\kappa_{org} = (0.18 \pm 0.04) \times O/C + 0.03 \quad (2)$$

where real-time O/C was calculated from Q-ACSM measured  $f_{44}$  (the fraction of  $m/z$  44 fragments signal to total organic signal,  $O/C = 0.079 + 4.31 \times f_{44}$ ) which has been widely used to study the aging process of OA species (Canagaratna et al., 2015; Ng et al., 2010).

The Zdanovskii-Stokes-Robinson (ZSR) mixing rule was used to calculate the total ALW. According to ZSR, the total water uptake into internally mixed particles is the sum of water content uptake by each pure component (Jing et al., 2018).

Particle hygroscopic volume growth factor (VGF) is the ratio of the volume of the wet particle to the corresponding particle volume at dry conditions. The size-independent VGF was calculated using Eq. 3,

$$VGF = \frac{\sum \frac{m_{i,ACSM}}{\rho_i} + (ALW_{inorg} + ALW_{org})/\rho_{water}}{\sum \frac{m_{i,ACSM}}{\rho_i}} \quad (3)$$

where  $m_{i,ACSM}$  is the mass concentration of species “i” measured by Q-ACSM. The densities were assumed to be 1.75, 1.75, 1.75, 1.52, 1.2, and 1.0 g cm<sup>-3</sup> for sulfate, nitrate, ammonium, chloride, organics, and water, respectively (Salcedo et al., 2006).

Overall particle hygroscopicity ( $\kappa_{total}$ ) was calculated by weighting component hygroscopicity parameters by their volume fractions in the mixture (Dusek et al., 2010; Gunthe et al., 2009; Petters and Kreidenweis, 2007) (Eq. 4),

$$\kappa_{total} = \kappa_{inorg} \cdot frac_{inorg} + \kappa_{org} \cdot frac_{org} \quad (4)$$

where  $frac_{inorg}$  and  $frac_{org}$  are the inorganic and organic volume fractions in NR-PM<sub>1</sub>, respectively. Inorganic species are mainly in the form of NH<sub>4</sub>NO<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub>, NH<sub>4</sub>HSO<sub>4</sub>, and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> (Liu et al., 2014); corresponding hygroscopic parameters were 0.68, 0.68, 0.56, and 0.52, respectively. As a result, an average value of 0.6 was used as the hygroscopicity parameter of the inorganic components ( $\kappa_{inorg}$ ), with the assumption that the relative abundance of NH<sub>4</sub>NO<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub>, NH<sub>4</sub>HSO<sub>4</sub>, and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub> does not change significantly. Thus in our study, variation of  $\kappa_{total}$  with RH only reflects changes in  $frac_{org}$  and  $\kappa_{org}$ .

## 2.3 Haze episode identification

The haze pollution in Beijing have shown typical evolution pattern where a pollution episode usually starts with a clean day, then accumulates for 2-7 days, and eventually disappears within 1-2 days (Guo et al., 2014; Jia et al., 2008; Zheng et al., 2016). In this study, 22 haze episodes were identified (Table S3). Only episodes containing 4 or more than 4 calendar days were taken into consideration. The haze episodes were further classified according to ALW volume fraction; that is, the ratio of ALW volume to the wet particle total volume (ALW volume fraction =  $V_{ALW} / (V_{ALW} + V_{NR-PM1})$ ). 12 were distinguished as high-ALW haze episodes (ALW volume fraction > 0.3 for at least 50% of the haze period), while 8 were distinguished as low-ALW haze episodes. All 20

distinguished episodes were associated with growing RH, the other 2 with irregular RH variations were classified as undefined. Average NR-PM<sub>1</sub> mass concentrations for the high-ALW and low-ALW episodes were 100.8  $\mu\text{g m}^{-3}$  and 76.2  $\mu\text{g m}^{-3}$ , respectively.

The relative daily increments of  $\text{frac}_{org}$ ,  $\kappa_{org}$ ,  $\kappa_{org}:\text{frac}_{org}$  (indicates the contribution of organics to  $\kappa_{total}$ ), and  $\kappa_{total}$  during the classified 12 high-ALW haze episodes and 8 low-ALW haze episodes were averaged separately. Daily increments were used, rather than hourly increments, to avoid the impact of diurnal variability. The first and last day of the episodes were not included in the analysis as they were usually clean days, so that the chemical evolution was different from the hazy days. To minimize the influence of transport or large local primary emissions, the relative  $\kappa_{org}$  daily increments of more than 40% were not included in further analysis.

### 3. RESULTS AND DISCUSSION

#### 3.1 Aerosol liquid water contributed by organics

The contribution of ALW<sub>org</sub> to ALW is the highest when NR-PM<sub>1</sub> mass concentrations are below 25  $\mu\text{g m}^{-3}$ . In this low mass loading, ALW<sub>org</sub>/ALW varies widely between ~10% and ~80%, with an average of 32% (Fig. 1a). The high ALW<sub>org</sub>/ALW in low aerosol mass concentrations can be explained by high organics/NR-PM<sub>1</sub> mass fractions ( $57 \pm 15\%$ ) (as shown in Fig. 1b) and high  $\kappa_{org}$  (as shown in Fig. 2). The striking variability in ALW<sub>org</sub>/ALW is the result of highly variable chemical compositions during clean days. In addition, higher uncertainties in NR-PM<sub>1</sub> measurements of low NR-PM<sub>1</sub> loadings and in ALW modelling at low RH may also contribute to the large variability. High ALW<sub>org</sub>/ALW in low aerosol mass concentrations is consistent with previous studies (Dick et al., 2000; Fajardo et al., 2016). Those studies showed that modelled ALW<sub>inorg</sub> was much lower than measured total ALW under low aerosol mass loadings in Beijing (Fajardo et al., 2016) and that ALW<sub>org</sub> was comparable to ALW<sub>inorg</sub> in low RH (Dick et al., 2000).

As NR-PM<sub>1</sub> mass concentrations increase from below 25  $\mu\text{g m}^{-3}$  to above 100  $\mu\text{g m}^{-3}$ , average ALW<sub>org</sub>/ALW fraction decreases from an average of 32% to 18% in Beijing (Fig. 1a). This decrease is mainly caused by the decrease of organics/NR-PM<sub>1</sub> mass fractions from an average of 57% to 34% (Fig. 1b), and the decrease in organic/NR-PM<sub>1</sub> correlates with elevated RH, as indicated by the color of the scattered points. Although organic concentration increases with rising RH and NR-PM<sub>1</sub>, the concentration of inorganic water-soluble salts increases even more, leading to a decreased fraction of organics. Variation of ALW<sub>org</sub>/ALW narrows as NR-PM<sub>1</sub> mass concentration increase. During high aerosol concentration, the aerosols are aged and dominated by secondary species (Huang et al., 2014); while during low concentration, the origins of aerosol are more complex and variable. As a result, the chemical composition of NR-PM<sub>1</sub> become more homogeneous with the increase in NR-PM<sub>1</sub>.

ALW<sub>org</sub> calculated using the real-time  $\kappa_{org}$  is much higher than that using a fixed  $\kappa_{org}$  (0.08), which has often been used to represent the hygroscopicity of urban organic aerosols (Nguyen et al., 2016). However,  $\kappa_{org}$  in Beijing varies remarkably between 0.06 and

0.26, with an average of  $0.16 \pm 0.04$ , much higher than 0.08. This higher  $\kappa_{org}$  results in a higher  $ALW_{org}$  fraction (18-32%) calculated in our study than predicted in previous ones (Nguyen et al., 2016; Wu et al., 2018). We note higher  $\kappa_{org}$  could be introduced via the conversion from organic O/C (Eq. 2); though  $\kappa_{org}$  calculated from others parameterizations (Chang et al., 2010; Duplissy et al., 2011; Massoli et al., 2010; Peter et al., 2006; Raatikainen et al., 2010) are even higher than from the one used here (Fig. S2). As shown in Table. S2, the average  $\kappa_{org}$  calculated from other methods are  $0.22 \pm 0.07$  (Chang et al., 2010),  $0.19 \pm 0.06$  (Massoli et al., 2010), and  $0.21 \pm 0.08$  (Duplissy et al., 2011; Jimenez et al., 2009). Also, based on previous reports that Q-ACSM can report higher  $f_{44}$  values than the HR-ToF-AMS (Fröhlich et al., 2015) and that  $f_{44}$  reported by Q-ACSM may be highly variable among different instruments (Crenn et al., 2015), there is a possibility that positive deviations and large uncertainties of  $f_{44}$  were introduced via the Q-ACSM measurements. Despite these possibilities, the large variations in  $\kappa_{org}$  emphasize the need to use real-time  $\kappa_{org}$  instead of a fixed value. When real-time  $\kappa_{org}$  is not available, at least a localized average  $\kappa_{org}$  for a given site should be considered.

### 3.2 Influence of temperature, ALW, and NR-PM<sub>1</sub> mass concentrations on organic hygroscopicity

Organic O/C ratio and the derived organic hygroscopicity increase with an increase in the ambient temperature for all the four seasons (Fig. 2). This positive correlation is more significant when  $T$  is below 15 °C. For the different seasons, average O/C ratios for summer, spring, autumn, and winter are 0.96, 0.82, 0.70, and 0.55, with corresponding average  $T$  of 27.6, 14.6, 10.0, and 2.3 °C, respectively. Diurnally, organic O/C show clear peaks at 14:00-16:00 which matches the diurnal variation of  $T$  well (Fig. S3). Similar diurnal changes of organic O/C have been previously observed (Hu et al., 2016; Sun et al., 2016). The promoting effect of  $T$  on O/C can be attributed to multiple processes. On one hand,  $T$  often correlates with higher solar radiation and higher atmospheric oxidative capacity. On the other hand, higher  $T$  accelerates gas phase and heterogeneous uptake or aqueous processes and thus increases O/C. In addition, higher  $T$  promotes the partitioning of semi-volatile species (usually less oxidized than low-volatile species) from particle phase to gas phase, also resulting in an increase in particle organic O/C.

Fig. 3 shows the influence of ALW and NR-PM<sub>1</sub> mass concentration on organic O/C, and organic hygroscopicity. The cross-impact of  $T$  to O/C was separated by looking at the same color in Fig. 3. When ALW volume fraction is high (above 0.2-0.3), organic O/C tends to increase with increasing ALW volume fraction; the increasing trend was most significant for spring and autumn, while less significant for winter (Fig. 3a, c, d). The area between the two black lines in Fig. 3a, c, d is dominated by the influence of ALW. Elevated ALW facilitates heterogeneous uptake or aqueous processes and promotes the formation of more oxidized organics, such as dicarboxylic acids, thus increases O/C.

When ALW volume fraction is low (below 0.2-0.3), organic O/C decreases with lower NR-PM<sub>1</sub> mass concentration, indicated by the size of the scattered points; this was observed in spring, autumn, and winter. One reason might be that at extremely low aerosol mass concentrations, new particle formation events frequently occur and smaller particles dominate size distribution (Cai et al., 2017; Guo et al., 2014). During formation and initial growth of new particles, extremely low volatile organic compounds with the

highest O/C ratio dominate; while subsequent growth involves organics with higher volatility and lower O/C ratio (Donahue et al., 2013; Ehn et al., 2014). As a result, particle organic O/C decreases with growth of aerosol mass concentration during new particle formation and growth events. Another possibility is that increased aerosol mass often coincides with diminished solar radiation which suppresses photochemistry and may decrease organic O/C. In addition, a fraction of the particles during clean periods are transported from less populated mountain areas. During such long-range transport, atmospheric oxidation can increase O/C. Low ALW volume fraction correlates with low NR-PM<sub>1</sub> mass loadings, which makes it look like organic O/C is decreasing with increasing ALW volume fraction. Overall, the apparent opposite trends during high and low ALW volume fraction periods can actually be explained by a competition between the opposite impact of ALW and NR-PM<sub>1</sub> mass loadings on organic evolution. However, summer was an exception, where no obvious dependence of organic O/C on ALW volume fraction or NR-PM<sub>1</sub> mass concentration was observed.

The competing effects of ALW volume fractions and NR-PM<sub>1</sub> mass concentrations on organic O/C were further confirmed by comparing organic evolution during the high and low-ALW haze episodes. Fig. 4 shows two typical haze episodes in Beijing, with more chemical and meteorological information given in Fig. S5. During the high-ALW episode, where ALW contributes 0.2 - 0.75 to the total aerosol volume, organic O/C increases with haze accumulation. The increase of nighttime O/C is more striking than that of daytime, likely due to the more abundant ALW at night (see Fig. S4). On the contrary, during the low-ALW episode, where ALW volume fraction does not exceed 30%, daytime organic O/C decreases despite the increasing ALW and *T*; this indicates that the decrease in O/C introduced by reduced photo-oxidation process and gas-particle partitioning is larger than the O/C increase from heterogeneous uptake or aqueous processes. Nighttime O/C remains relatively constant, suggesting that the promoting effect of heterogeneous uptake or aqueous processes on O/C is comparable to the reducing effects on O/C.

### 3.3 The influence of RH and particle hygroscopicity on particle hygroscopic volume growth factor

Particle volume growth factor increases rapidly with RH and particle hygroscopicity (Fig. 5). When RH is less than 80%, particle VGF increases slowly from 1 to 2.5 with rising RH; when RH exceeds 80%, VGF increases rapidly to above 5. This is generally consistent with previous studies (Bian et al., 2014). As shown in Fig. 5, significant variation of  $\kappa_{total}$  also plays an important role on the change of water uptake. The dispersion of points in the vertical direction represents the influence of particle chemical compositions to ALW. For instance, when RH is fixed at 60%, VGF increases from 1.2 to 1.9 when  $\kappa_{total}$  increases from  $\sim 0.20$  to  $\sim 0.45$ .

The seasonal variations also reflect a combined promoting effect of RH and  $\kappa_{total}$  on VGF. The average VGFs for spring, summer, autumn, and winter are 1.4, 1.6, 1.3, and 1.3, respectively. The highest VGF in summer is attributed to a combination of the higher frequency for high RH (red step line, compared to green, orange, and blue step line in Fig. 5b) and the relatively high particle

hygroscopicity,  $\kappa_{total}$  (0.35, compared to 0.38, 0.30, and 0.33 for other seasons).

A consequence of the high RH and high ALW is the higher particle overall hygroscopicity,  $\kappa_{total}$ , as compared with that at the low RH (Fig. 5). Aerosols are dominated by less hygroscopic particles ( $\kappa_{total} < 0.3$ ) for RH below ~40% while aerosols are dominated by more hygroscopic particles ( $\kappa_{total} > 0.4$ ) for RH above ~80% (Fig. 5). This suggests positive feedback between overall particle hygroscopicity and ALW. Higher  $\kappa_{total}$  leads to higher ALW in similar RH while higher ALW, or higher RH, in turn corresponds to higher  $\kappa_{total}$ .

### 3.4 Interactions between organic evolution and particle hygroscopicity during high and low-haze episodes

During high-ALW episodes, the organic volume fraction decreases and organic hygroscopicity increases substantially during the accumulation of pollution. The average  $frac_{org}$  is 0.51 and the daily increment of  $frac_{org}$  is -11% (Fig. 6). The negative  $frac_{org}$  increment indicates decreasing  $frac_{org}$  which reflects the larger increase of inorganic soluble compounds (sulfate, nitrate, ammonium, and chloride) compared to that of organics during haze episodes. The average  $\kappa_{org}$  is 0.165 and the relative daily increment of  $\kappa_{org}$  is 8%. The positive  $\kappa_{org}$  increment during high-ALW episodes reflects increasing  $\kappa_{org}$  due to the effect of heterogeneous uptake or aqueous processes. To sum up, although the organic fraction decreases during the high-ALW haze episodes, the organic hygroscopicity increases. As a result, the contribution of  $ALW_{org}$  to total ALW does not decrease as fast as the decrease of organic fraction.

During low-ALW episodes, the decrease in organic volume fraction is slower than that during high-ALW episodes, and organic hygroscopicity is relatively stable in the haze evolution process. The average  $frac_{org}$  is 0.63 and the daily increment of  $frac_{org}$  is -4% (Fig. 6), of which both are higher than those in high-ALW episodes. This suggests that organic is still the dominating component as haze accumulated during low-ALW episodes. The average  $\kappa_{org}$  is 0.152 and the relative daily increment of  $\kappa_{org}$  is -1%, both of which are lower than those in high-ALW episodes. The near zero increment of  $\kappa_{org}$  is a consequence of the competition between heterogeneous uptake or aqueous processes and other processes. To sum up, the effects of ALW on chemical compositions during low-ALW episodes are limited compared to high-ALW episodes.

As a consequence of the more significant changes in chemical composition during high-ALW episodes, the increase in particle hygroscopicity is larger for high-ALW episodes than for low-ALW episodes. The relative daily increments of  $frac_{org} \cdot \kappa_{org}$  during high-ALW and low-ALW episodes are -4% and -3%, respectively (Fig. 6c). These negative increments indicate the negative effect of the organic hygroscopic term on  $\kappa_{total}$  during haze episodes. For high-ALW episodes, this means that the increase in organic hygroscopicity in high-ALW episodes does not compensate for the effect of decreasing organic fraction. However, the average daily

increments of  $\kappa_{total}$  during high-ALW and low-ALW haze episode are 8% and 2%, respectively (Fig. 6d). As  $\kappa_{inorg}$  is fixed to 0.6 and the increment of  $frac_{inorg}$  is opposite to that of  $frac_{org}$ , the positive  $\kappa_{total}$  increment is a result of the positive increment of the term  $frac_{inorg} \cdot \kappa_{inorg}$ .

The rapid decrease in  $frac_{org}$  and increase in  $\kappa_{org}$  during high-ALW episodes increase  $\kappa_{total}$ , which in turn promotes the ability of particles to uptake water, forming positive feedbacks with ALW, as the conceptual diagram shows (Fig. 7). The decrease of  $frac_{org}$  or increase of  $frac_{inorg}$  plays a dominating role while the increase in  $\kappa_{org}$  plays a minor but non-negligible role in increasing  $\kappa_{total}$ . During low-ALW episodes, the positive feedbacks are weak or does not exist because both  $frac_{org}$  and  $\kappa_{org}$  do not change significantly.

There are other factors, not taken into consideration here, that might also affect ALW. These factors include the presence of crustal material or trace metals, detailed particle size distributions, interactions between inorganic and organic compounds, organic surfactants, and the particle phase state (Bian et al., 2014; Fountoukis and Nenes, 2007; Nakao, 2017; Ovadnevaite et al., 2017). As a result, we suggest that long term measurements of ALW and  $\kappa_{org}$  should be performed to test the results shown here and to establish a more reliable and accurate relationship between organic properties and ALW in the real atmosphere.

## 4 Conclusion

Our study emphasizes the need to include aerosol liquid water contributed by organics ( $ALW_{org}$ ) in ALW modelling in Beijing, instead of only using the inorganic contribution to total ALW. The reason is that  $ALW_{org}$  contributes an average of 18-32% to the total ALW in Beijing, according to our modelling results with ISORROPIA-II,  $\kappa$ -Köhler theory, and the ZSR mixing rule. It is also necessary to use a real-time  $\kappa_{org}$  to evaluate  $ALW_{org}$ . Since organic O/C, which has been shown in previous studies to have a linear relationship with  $\kappa_{org}$ , varies from 0.2 to 1.3 in different seasons in Beijing. Using a fixed  $\kappa_{org}$  (0.08) for typical urban areas underestimates  $ALW_{org}$  by a factor of  $\sim 2$  in Beijing. When real-time  $\kappa_{org}$  is not available, a localized average  $\kappa_{org}$  should be used. O/C, or  $\kappa_{org}$ , generally increases with rising temperature and rising ALW in spring, autumn, and winter in Beijing.

Positive feedback loops were found between  $\kappa_{total}$  (which was determined by  $frac_{org}$  and  $\kappa_{org}$ , as  $\kappa_{inorg}$  was assumed to be 0.6) and ALW during high-ALW episodes. During high-ALW haze episodes, RH, NR-PM<sub>1</sub>, and ALW increase rapidly. The strong heterogeneous uptake and aqueous processes lead to a rapid decrease in  $frac_{org}$  and an increase in  $\kappa_{org}$ . These variations increase  $\kappa_{total}$ , thus further promote the uptake of water and form positive feedbacks. These positive feedbacks were much weaker in low-ALW episodes. The positive feedback loop between chemical composition evolution (mainly indicated by  $frac_{org}$  and  $\kappa_{org}$ ) and ALW during high ALW-episodes is a driver for the severe haze episodes in Beijing.

B.: Exploring the severe winter haze in Beijing: the impact of synoptic weather, regional transport and heterogeneous reactions, *Atmos Chem Phys*, 15, 2969-2983, 10.5194/acp-15-2969-2015, 2015.

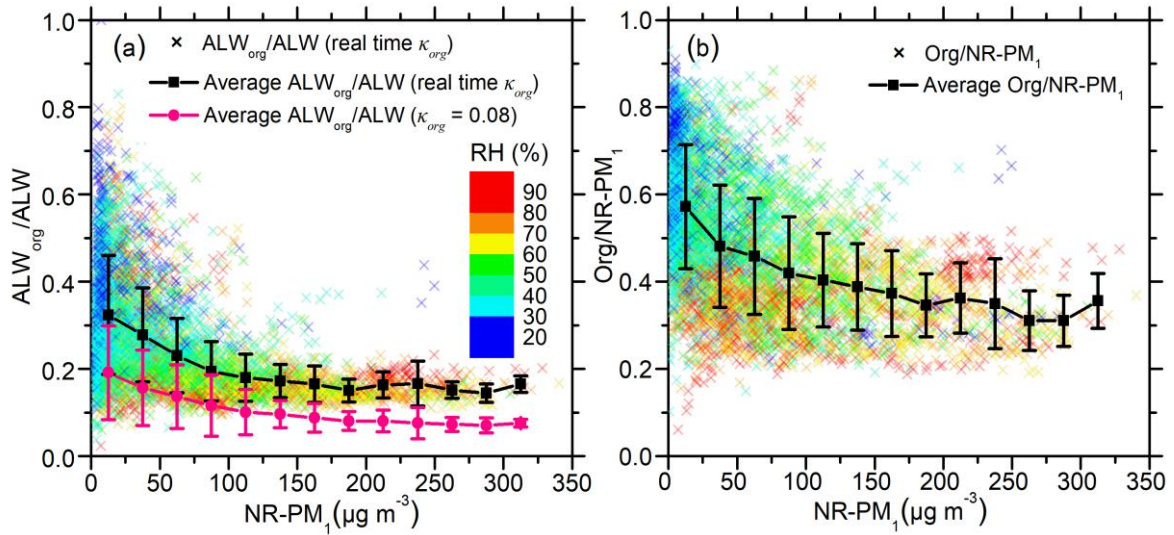

Figure 1. (a) The colored scatter points represent the fraction of aerosol liquid water contributed by organics ( $\text{ALW}_{\text{org}}/\text{ALW}$ ), which was calculated using real-time  $\kappa_{\text{org}}$ . The black line shows the average of the colored points in each NR-PM<sub>1</sub> mass concentration bin. The pink line is the average  $\text{ALW}_{\text{org}}/\text{ALW}$  calculated using a fixed  $\kappa_{\text{org}}$  (0.08) in each NR-PM<sub>1</sub> mass concentration bin. (b) The colored scatter points represent the organic mass fraction in non-refractory submicron aerosol (NR-PM<sub>1</sub>). The black line is the average of the colored points in each NR-PM<sub>1</sub> mass concentration bin. All the scattered points in both figures are colored with relative humidity (RH).

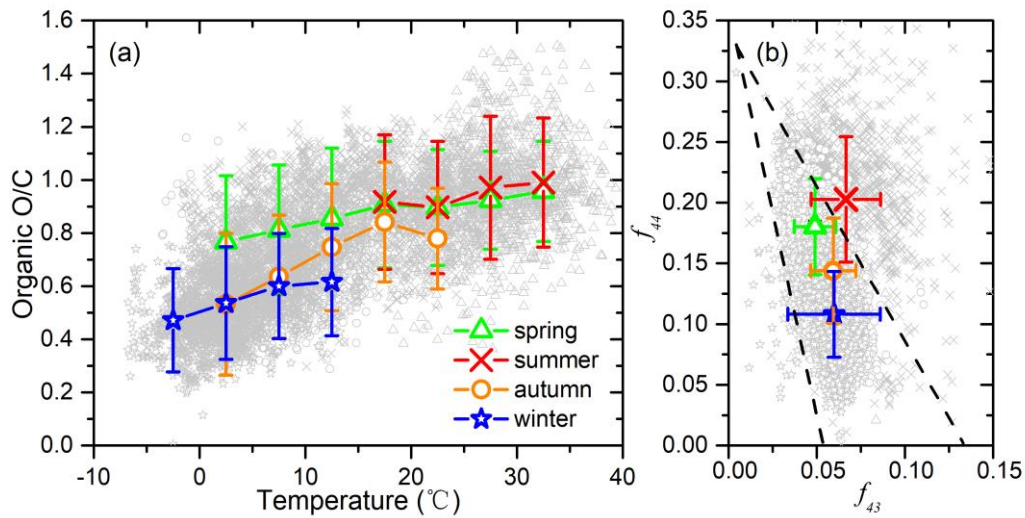

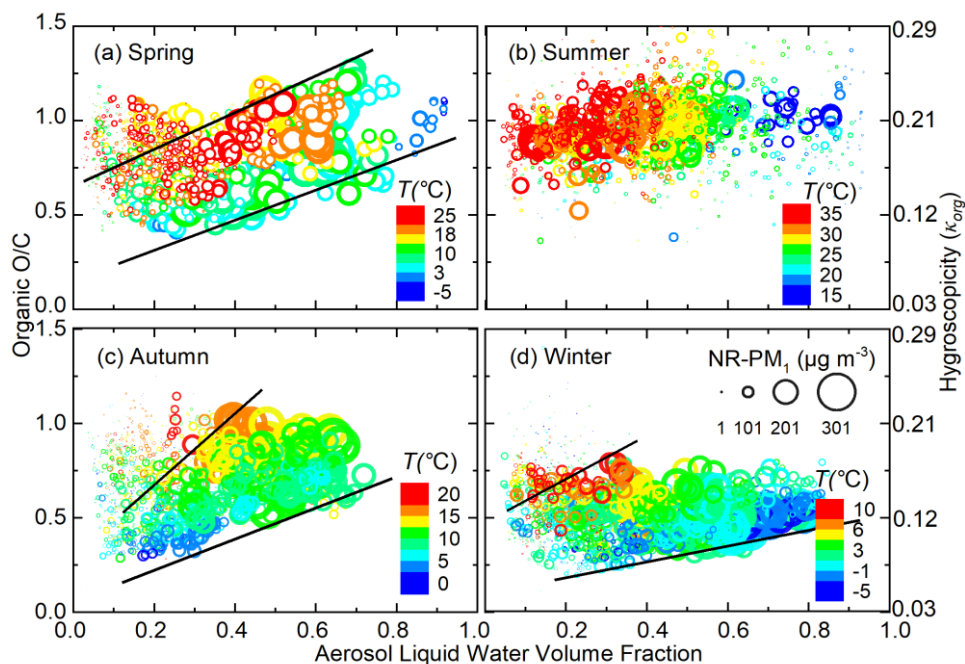

Figure 2. (a) O/C ratio as a function of temperature in different seasons of Beijing; (b) triangle plot ( $f_{44}$  vs  $f_{43}$ ) measured by the Q-ACSM in different seasons of Beijing

**Figure 3.** Variation of organic O/C ratio (calculated from Q-ACSM measured  $f_{44}$ ) as a function of aerosol liquid water (ALW) volume fraction in different seasons of Beijing. The size and color of the points represent the corresponding NR-PM<sub>1</sub> mass concentration and ambient temperature, respectively. For spring, autumn, and winter, the areas between the two black lines represent the points less affected by the gas-particle partitioning under low aerosol mass loadings.

**Figure 4.** Variations of aerosol liquid water contributed by organics (ALW<sub>org</sub>), aerosol liquid water contributed by inorganics (ALW<sub>inorg</sub>), the volume fraction of total wet particle compositions, organic O/C during (a) a typical high-ALW episode and (b) a typical low-ALW episode.

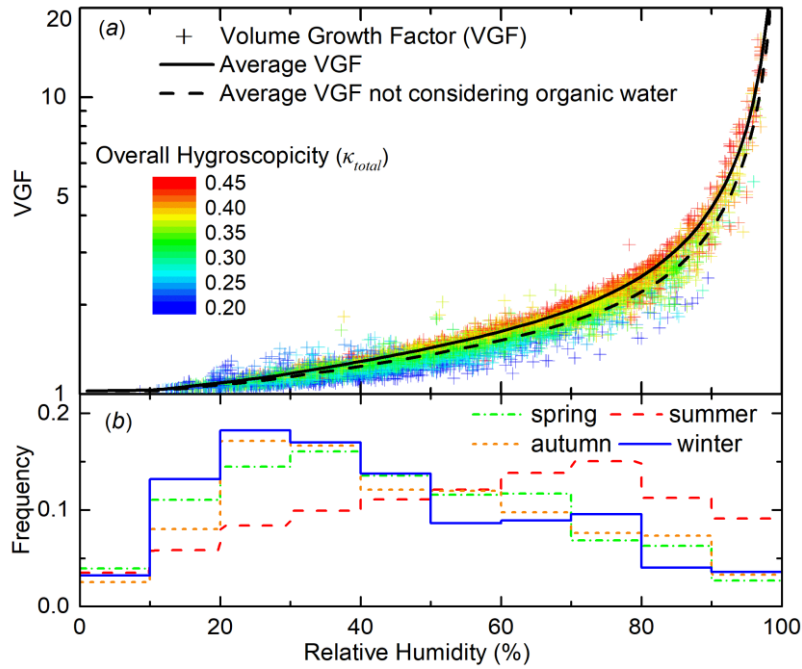

Figure 5. (a) Volume growth factor (VGF, scattered points, calculated by Eq. 3) from the four seasons as a function of relative humidity (RH). The points are colored by overall particle hygroscopicity ( $\kappa_{total}$ ) calculated from aerosol bulk composition (Eq. 4). The black line is the averaged VGF in different RH. Black dashed line is the average VGF without considering organic water. (b) RH frequency during four seasons is expressed in step line.

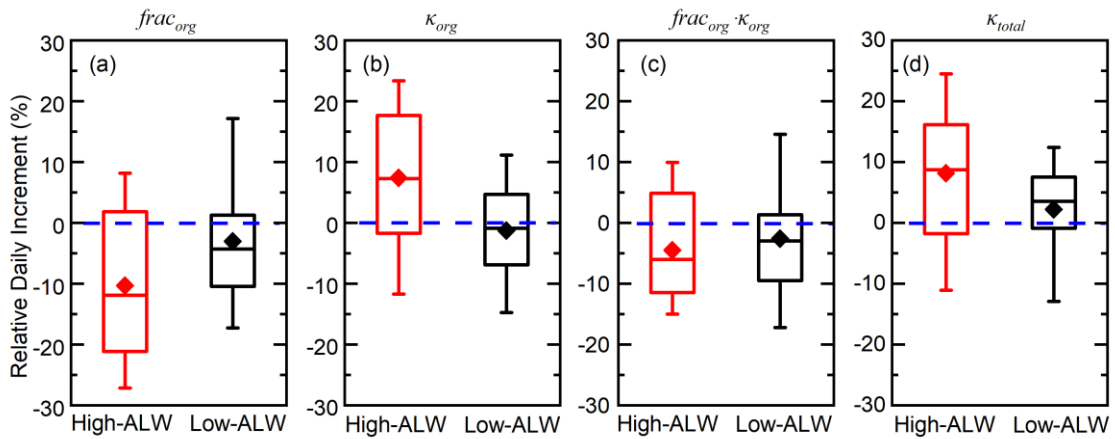

Figure 6. Episode-based relative day increment of organic hygroscopicity ( $\kappa_{org}$ ), organic volume fraction ( $frac_{org}$ ), the hygroscopicity term contributed by organics ( $\kappa_{org} \cdot frac_{org}$ ), and overall particle hygroscopicity ( $\kappa_{total}$ ) during high-ALW haze episodes and low-ALW haze episodes. The box plots represent the 10th, 25th, 50th, 75th, and 90th percentiles of the corresponding data. The rhombus represents the mean value of the corresponding data.

Figure 7. The positive feedback loops between aerosol liquid water and organic evolution during high-ALW haze episodes in Beijing.
