9  
10 **Abstract.** One of the most important processes in the global mercury biogeochemical  
11 cycling is the deposition of atmospheric mercury, including gaseous elemental  
12 mercury (GEM), gaseous oxidized mercury (GOM), and particulate-bound mercury  
13 (PBM), to terrestrial surfaces. In this paper, methods for the observation of wet, dry,  
14 litterfall, throughfall, and cloud/fog deposition and models for mercury dry deposition  
15 are reviewed. Surrogate surface methods with cation exchange membranes are widely  
16 used for GOM dry deposition measurements, while observation methods for GEM dry  
17 deposition are more diverse. The methodology for Hg wet deposition is more mature,  
18 but the influence of cloud/fog scavenging is easy to neglect. Dry deposition models  
19 for speciated mercury have high uncertainties owing to the presence of sensitive  
20 parameters related to GOM chemical forms. Observation networks for mercury wet  
21 deposition have been developed worldwide, with the Global Mercury Observation  
22 System (GMOS) covering the northern hemisphere, the tropics, and the southern  
23 hemisphere. Wet deposition implies the spatial distribution of atmospheric mercury  
24 pollution, while GOM dry deposition depends highly on the elevation. Litterfall Hg  
25 deposition is crucial to forests. Urban areas have high wet deposition and PBM dry  
26 deposition because of high reactive mercury levels. Grasslands and forests have  
27 significant GOM and GEM dry deposition, respectively. Evergreen broadleaf forests  
28 bear high litterfall Hg deposition. Future research needs have been proposed based on  
29 the current knowledge of global mercury deposition to terrestrial surfaces.

30

## 31 1 Introduction

32 Mercury (Hg) is a global pollutant, characterized by its neurotoxicity, persistency and  
33 bioaccumulation effect. It undergoes regional or global long-range transport via  
34 atmospheric circulation, deposition to local or remote areas, methylation in  
35 ecosystems, and accumulation through food chain, posing high risks to human health  
36 and the environment (Obrist et al., 2018). Hg in the atmosphere has three major  
37 forms: gaseous elemental mercury (GEM), gaseous oxidized mercury (GOM), and  
38 particulate-bound mercury (PBM). The sum of the three Hg forms is named total  
39 mercury (TM). GOM and PBM are also known as reactive mercury (RM). GEM is the  
40 predominant form of atmospheric Hg (>90%) with a long residence time of several  
41 months to over one year due to its chemical inertness and low solubility. GOM  
42 accounts for less than 1% of atmospheric Hg, which is easily scavenged by wet  
43 deposition, resulting in a short residence time of hours to days. However, recent  
44 studies (Lyman et al., 2010; Gustin et al., 2013; McClure et al., 2014; Gustin et al.,  
45 2015) show that there could be a significant underestimation of GOM due to the low  
46 capture efficiency of the KCl denuder method adopted by most observation sites in  
47 the presence of ozone or moisture. PBM (<10% of atmospheric Hg) stays in the air for  
48 tens of hours to several weeks depending on particle size before scavenged by dry or  
49 wet deposition (Schroeder and Munthe, 1998; Lindberg et al., 2007; Ci et al., 2012;  
50 Fu et al., 2012; Zhang et al., 2016a).

51 Deposition is one of the most important processes in global Hg cycling, leading to  
52 the sink of atmospheric Hg (Obrist et al., 2018). Atmospheric Hg deposition can be  
53 broadly divided into wet and dry deposition. Hg wet deposition is associated with  
54 precipitation, cloud or fog, while Hg dry deposition is highly related to the underlying  
55 surfaces, including forest canopies, grasslands, wetlands, agricultural fields, deserts,  
56 background non-vegetated soils, contaminated sites, etc. (Zhang et al., 2009). Forest  
57 canopy is regarded as an important sink of atmospheric Hg for its special forms of  
58 deposition, litterfall and throughfall (Gustin et al., 2008). Litterfall is a form of  
59 indirect Hg dry deposition through foliar uptake of atmospheric Hg, and throughfall  
60 includes wet-deposited Hg above the canopy and a portion of dry-deposited Hg  
61 washed off from the canopy (Wright et al., 2016). Hg deposition through litterfall has  
62 recently been drawn much attention to by the study of Wang et al. (2016a). The sum  
63 of litterfall and throughfall represents the total Hg deposition on the forest canopy.

64 Significant efforts have been made in the past decade for quantifying atmospheric  
65 Hg deposition through both direct measurements and numerical models, especially on  
66 dry deposition (Lyman et al., 2009; Zhang et al., 2009; Holmes et al., 2011; Lai et al.,  
67 2011; Castro et al., 2012; Gustin et al., 2012; Peterson et al., 2012; Zhang et al., 2012;  
68 Fang et al., 2013; Sather et al., 2013; Lyman et al., 2014; Sather et al., 2014; Huang  
69 and Gustin, 2015a; Weiss-Penzias et al., 2016; Zhang et al., 2016b; Hall et al., 2017;  
70 Sprovieri et al., 2017). Yet large uncertainties still exist due to limitations of current  
71 methods for Hg deposition measurements and models (Gustin et al., 2015). The  
72 purpose of this paper is to give an overview of current understanding on the global  
73 deposition of speciated atmospheric Hg to terrestrial surfaces. In this paper, we  
74 reviewed methods adopted for Hg deposition measurements and modeling, results of  
75 Hg deposition observations from all over the world, and a summary of speciated  
76 atmospheric Hg deposition on different underlying surfaces.

## 77 **2 Methods for Hg deposition measurements**

### 78 **2.1 Methods for Hg dry deposition**

79 Three major categories of methods for direct Hg dry deposition measurements are the  
80 surrogate surface methods, the enclosure methods, and the micrometeorological  
81 methods (Zhang et al., 2009; Huang et al., 2014). Hg dry deposition can also be  
82 calculated based on Hg concentration measurements (Zhang et al., 2009; Wright and  
83 Zhang, 2015), which will be reviewed in Section 3.

#### 84 2.1.1 Surrogate surface methods

85 Passive samplers are deployed in the surrogate surface methods to quantify the dry  
86 deposition flux of GEM, GOM and PBM (Huang et al., 2014; Wright et al., 2016).

87 The Hg dry deposition flux is determined using the following equation:

$$88 \quad F_{\text{dry,SS}} = \frac{M}{A \cdot t} \quad (1)$$

89 where  $F_{\text{dry,SS}}$  is the Hg dry deposition flux using the surrogate surface methods,  $M$   
90 is the total Hg amount collected on the material during the sampling period,  $A$  is the  
91 surface area of the collection material, and  $t$  is the exposure time.

92 Filter-based surfaces are widely used in passive samplers for Hg dry deposition flux  
93 measurements, with cation-exchange membrane (CEM) for GOM dry deposition  
94 (Lyman et al., 2007; Lyman et al., 2009; Castro et al., 2012; Huang et al., 2012;  
95 Peterson et al., 2012; Sather et al., 2012) and with gold-coated quartz fiber filter

96 (GcQFF) for TM dry deposition (Lai et al., 2011; Huang et al., 2012). The CEM  
97 method is believed to capture part of fine PBM as well (Huang et al., 2014). The CEM  
98 mounts for GOM dry deposition flux measurements are increasingly designed into  
99 aerodynamic shapes to minimize the impact of turbulence (Lyman et al., 2009).  
100 Water- or solution-based surfaces, e.g., static water surrogate surface (SWSS), collect  
101 GOM and PBM (Sakata and Marumoto, 2004; Marsik et al., 2007; Lai et al., 2011).  
102 GEM is not water soluble and hence unable to be captured by SWSS. Acidified  
103 solution captures part of GEM and has a higher measurement of Hg dry deposition  
104 than deionized (DI) water because in acidified solution GEM is oxidized to GOM  
105 which stabilizes the deposited Hg and decreases mass transfer resistance (Lai et al.,  
106 2011). SWSS was considered to measure TM dry deposition over ten years ago since  
107 RM (GOM and PBM) dry deposition was regarded as the dominance of TM dry  
108 deposition. In the recent decade, more and more studies found that GEM dry  
109 deposition accounts for a large proportion of TM dry deposition over grassland  
110 (Fritsche et al., 2008; Castro and Moore, 2016; Obrist et al., 2017). A newly  
111 developed artificial turf surrogate surface (ATSS) method has shown promising  
112 performance in measuring TM dry deposition and allows the interference of  
113 precipitation (Lynam et al., 2014; Hall et al., 2017). When Hg wet deposition is  
114 monitored simultaneously, the Hg dry deposition flux can be calculated as follows:

$$115 \quad F_{\text{dry,ATSS}} = \frac{(M_{\text{turf}} + M_{\text{throughfall}}) - M_{\text{wet}}}{A \cdot t} \quad (2)$$

116 where  $F_{\text{dry,ATSS}}$  is the TM dry deposition flux estimated from the ATSS method, and  
117  $M_{\text{turf}}$ ,  $M_{\text{throughfall}}$  and  $M_{\text{wet}}$  are the Hg amounts in turf, throughfall and wet deposition,  
118 respectively.

119 Although surrogate surface methods have limitation in temporal resolution, they are  
120 still widely used in recent years due to their low costs, high accuracy and applicability  
121 to different Hg forms.

### 122 2.1.2 Enclosure methods

123 Enclosure methods rely on the conservation of mass and have been used for most  
124 GEM flux measurements due to their relatively low costs, portability, versatility and  
125 intuitive nature (Eckley et al., 2011; Sommar et al., 2013a; Sommar et al., 2013b;  
126 Agnan et al., 2016; Zhu et al., 2016; Ma et al., 2018). The dynamic flux chamber  
127 (DFC) method is the most commonly used enclosure method. A vacuum pump is

128 applied to draw air through a low Hg blank chamber at a constant flow, and the GEM  
129 concentrations at the inlet and outlet of the chamber are measured sequentially by a  
130 mercury analyzer coupled with a switchable valve. The GEM dry deposition flux is  
131 calculated according to the following equation:

$$132 \quad F_{\text{dry,DFC}} = \frac{Q(C_{\text{inlet}} - C_{\text{outlet}})}{A} \quad (3)$$

133 where  $F_{\text{dry,DFC}}$  is the GEM dry deposition flux measured by the DFC method,  $Q$  is  
134 the flushing flow rate,  $C_{\text{inlet}}$  and  $C_{\text{outlet}}$  are the GEM concentrations at the chamber  
135 inlet and outlet, respectively, and  $A$  is the area of the chamber footprint.

136 Different flushing flow rates, chamber designs and materials, as well as the lack of  
137 standard operating protocol and blank correcting procedures, make it hard for  
138 comparison between different studies (Eckley et al., 2010; Agnan et al., 2016;  
139 Osterwalder et al., 2018). A novel aero-DFC was designed and utilized in recent  
140 studies (Lin et al., 2012; Zhu et al., 2015a; Zhu et al., 2015b; Osterwalder et al.,  
141 2018). The GEM dry deposition flux under atmospheric condition can be calculated  
142 based on the flux measured by the aero-DFC with the internal shear property precisely  
143 controlled and the surface shear property (Lin et al., 2012).

144 Enclosure methods have high temporal and spatial resolution, and are thus widely  
145 adopted for GEM dry deposition flux measurements. However, they are not applicable  
146 to RM dry deposition measurements.

### 147 2.1.3 Micrometeorological methods

148 Micrometeorological methods can be mainly divided into the direct flux measurement  
149 methods and the gradient methods. The most known one of the former is the relaxed  
150 eddy accumulation (REA) method, while the latter include the aerodynamic (AER)  
151 method and the modified Bowen-ratio (MBR) method (Zhang et al., 2009; Yu et al.,  
152 2018).

153 The REA method is based on sampling upward and downward moving eddies at  
154 constant flow rates, which relies on an ultrasonic anemometer to detect the vertical  
155 wind velocity and control the fast response valves. The GEM dry deposition flux  
156 based on the REA method is calculated as follows:

$$157 \quad F_{\text{dry,REA}} = \beta \sigma_w (C_{\text{down}} - C_{\text{up}}) \quad (4)$$

158 where  $F_{\text{dry,REA}}$  is the GEM dry deposition flux measured by the REA method,  $\beta$  is  
159 relaxation coefficient,  $\sigma_w$  is the standard deviation of the vertical wind speed, and

160  $C_{\text{down}}$  and  $C_{\text{up}}$  are the downward and upward GEM concentration, respectively.

161 The REA method conducts upward and downward sampling at the same height,  
162 eliminating the footprint difference and potential GEM formation and loss (Zhu et al.,  
163 2016). Dual inlets were recommended and applied in recent studies due to advantages  
164 of synchronous concentration determination (Sommar et al., 2013b; Zhu et al., 2015b;  
165 Kamp et al., 2018; Osterwalder et al., 2018).

166 The gradient methods (AER and MBR) sample air at different height to get the  
167 vertical GEM concentration gradient. For the AER method, the GEM dry deposition  
168 flux is calculated using the following equation (Fritsche et al., 2008; Baya and Van  
169 Heyst, 2010; Yu et al., 2018):

$$170 \quad F_{\text{dry,AER}} = K \frac{\partial C}{\partial z} \quad (5)$$

171 where  $F_{\text{dry,AER}}$  is the GEM dry deposition flux measured by the AER method,  $K$  is  
172 the turbulent transfer coefficient (Yu et al., 2018), and  $\partial C/\partial z$  is the gradient of the  
173 vertical GEM concentration.

174 For the MBR method, the GEM dry deposition flux is calculated based on the  
175 theory that the ratio of GEM and the reference scalar (e.g., H<sub>2</sub>O) fluxes is proportional  
176 to their concentration gradients (Obrist et al., 2006; Converse et al., 2010; Zhu et al.,  
177 2015a):

$$178 \quad F_{\text{dry,MBR}} = F_r \frac{\partial C_{\text{Hg}}}{\partial C_r} \quad (6)$$

179 where  $F_{\text{dry,MBR}}$  is the GEM dry deposition flux measured by the MBR method,  $F_r$  is  
180 the flux of the reference scalar, and  $\partial C_{\text{Hg}}/\partial C_r$  is the concentration gradient ratio of  
181 GEM over the reference scalar.

182 Micrometeorological methods are relatively reliable with high temporal resolution  
183 and represent the ecosystem scale due to less interference from the microenvironment  
184 (Zhu et al., 2016). The direct flux measurement methods generally have more  
185 complex installment and high expenses than the gradient methods, but could reduce  
186 uncertainties due to the elimination of the sampling height difference (Sommar et al.,  
187 2013b; Pierce et al., 2015).

## 188 2.2 Methods for Hg wet deposition

189 Hg wet deposition through precipitation is easier to measure than dry deposition and  
190 usually more reliable. The Hg wet deposition flux is calculated as follows:

$$191 \quad F_{\text{wet}} = \sum_{i=1}^n C_i \cdot D_i \quad (7)$$

192 where  $F_{\text{wet}}$  is the total Hg wet deposition flux,  $n$  is the number of precipitation  
193 events during a certain period,  $C_i$  is the total Hg concentration in precipitation water  
194 during Event  $i$ , and  $D_i$  is the precipitation depth of Event  $i$ .

195 Both manual and automatic precipitation sample collectors were used in previous  
196 studies (Fu et al., 2010a; Gratz and Keeler, 2011; Marumoto and Matsuyama, 2014;  
197 Zhu et al., 2014; Brunke et al., 2016; Chen et al., 2018). Automatic precipitation  
198 sample collectors cover the lid automatically when it is not raining to prevent  
199 potential contamination, while manual collectors require manually placing collectors  
200 before precipitation events and retrieving them after events. All collector sections  
201 exposed to rainwater should be made by teflon or borosilicate glass due to potential  
202 Hg adsorption (Fu et al., 2016). The collected samples need to be acidified and then  
203 preserved in a cool and dark environment before analysis. The total Hg concentration  
204 in precipitation water is analyzed by oxidation, purge and trap, and cold vapor atomic  
205 fluorescence spectrometry (CVAFS) following EPA Method 1631E. GOM and PBM  
206 are the main Hg forms removed by precipitation due to high solubility. Usually, GOM  
207 and PBM contribute equivalently to Hg wet deposition (Cheng et al., 2015).

### 208 **2.3 Methods for Hg deposition in forests**

209 In forest ecosystems, Hg dry and wet depositions are not able to be distinguished  
210 markedly. Litterfall and throughfall are commonly used to evaluate the Hg deposition  
211 in forests (Wang et al., 2016b; Wright et al., 2016). Cloud and fog are also important  
212 forms of Hg deposition in forest regions, especially at high-elevation sites (Blackwell  
213 and Driscoll, 2015).

#### 214 **2.3.1 Litterfall**

215 Hg dry deposition in forests includes uptake of Hg by leaf stomata and cuticle, tree  
216 bark, and underlying soil. Some of the deposited Hg in the soil may emit back into the  
217 atmosphere and be captured by leaves, while some of the deposited Hg in leaves may  
218 be translocated to branches, stems and roots. Litterfall Hg deposition includes the  
219 remaining dry-deposited Hg in leaves and bark as well as the captured Hg emitted  
220 from the soil (Blackwell and Driscoll, 2015; Wright et al., 2016). Litterfall Hg  
221 deposition flux is calculated as follows:

$$F_{\text{litterfall}} = \frac{E_A \cdot C_l \cdot M_l}{A \cdot t} \quad (8)$$

where  $F_{\text{litterfall}}$  is the litterfall Hg deposition flux,  $E_A$  is the litterfall trap area expansion factor,  $C_l$  is the Hg mass concentration in litterfall,  $M_l$  is the total dry weight of litterfall,  $A$  is the litterfall trap area, and  $t$  is the sampling time (Fisher and Wolfe, 2012).

Litterfall is collected during the leaf-growing or -falling seasons with litterfall traps or collectors (Fisher and Wolfe, 2012). It should be noted that the Hg concentration in leaves has an approximately linear correlation with time during the growing season (Bushey et al., 2008; Fu et al., 2010a; Gong et al., 2014). Litterfall is collected on a regular basis to prevent potential weight loss and changes in chemical composition caused by rain leaching and decomposition. The litterfall samples collected are then air-dried, ground and stored under a low temperature and dark environment for analysis (Zhou et al., 2017). The Hg content in litterfall can be determined by thermal decomposition, amalgamation, and cold vapor atomic absorption spectrophotometry (CVAAS) following EPA Method 7473 (Richardson and Friedland, 2015; Fu et al., 2016; Zhou et al., 2017; Risch et al., 2017). Alternatively, the litterfall samples can be digested into solution, and the extracted Hg in the solution can be analyzed following EPA Method 1631E (Fu et al., 2010a; Fisher and Wolfe, 2012).

### 2.3.2 Throughfall

Throughfall Hg deposition includes wet-deposited Hg above the canopy and a portion of dry-deposited Hg washed off from the canopy (Blackwell and Driscoll, 2015; Wright et al., 2016). Throughfall Hg deposition flux is calculated as follows:

$$F_{\text{throughfall}} = \frac{E_A \cdot C_t \cdot V_t}{A \cdot t} \quad (9)$$

where  $F_{\text{throughfall}}$  is the throughfall Hg deposition flux,  $E_A$  is the throughfall funnel area expansion factor,  $C_t$  is the Hg mass concentration in throughfall,  $V_t$  is the total volume of throughfall,  $A$  is the throughfall funnel area, and  $t$  is the sampling time (Fisher and Wolfe, 2012).

Throughfall under canopy is usually collected using a passive bulk throughfall collector with a funnel connected a bottle for water storage (Wang et al., 2009; Fisher and Wolfe, 2012; Åkerblom et al., 2015) or collected as open-field rain collection if the environmental condition permits (Choi et al., 2008; Fu et al., 2010a; Fu et al., 2010b; Han et al., 2016). Attention should be paid to potential litterfall contamination

254 and cloud/fog deposition influence at high elevation sites if the collector is not  
255 sheathed (Fisher and Wolfe, 2012; Wright et al., 2016). Throughfall samples are  
256 usually analyzed following EPA Method 1631E (Fisher and Wolfe, 2012).

### 257 2.3.3 Cloud/fog

258 At high elevation sites, besides litterfall and throughfall deposition, cloud/fog Hg  
259 deposition could account for a large proportion of the total deposition (Lawson et al.,  
260 2003; Sheu and Lin, 2011; Stankwitz et al., 2012; Blackwell and Driscoll, 2015).

261 Quantifying Hg in cloud/fog at high elevation helps better understand the impact of  
262 long-range transport and local sources on global Hg cycling (Malcolm et al., 2003).  
263 Both active and passive collectors are used to collect cloud/fog. The passive collector  
264 has two round disks with teflon wires strung in between. Cloud/fog water collides  
265 onto the teflon wires and slides down to a sampling bottle (Lawson et al., 2003;  
266 Malcolm et al., 2003; Sheu and Lin, 2011; Schwab et al., 2016). Active cloud/fog  
267 water samplers use a fan to blow cloud/fog to teflon strings which are used to gather  
268 cloud/fog droplets (Kim et al., 2006; Weiss-Penzias et al., 2018). The collected  
269 cloud/fog water samples are usually analyzed using EPA Method 1631E (Blackwell  
270 and Driscoll, 2015). Cloud/fog Hg deposition flux is calculated as follows:

$$271 \quad F_{\text{cloud/fog}} = F_d \cdot C_{\text{Hg}} \quad (10)$$

272 where  $F_{\text{cloud/fog}}$  is the cloud/fog Hg deposition flux,  $F_d$  is the deposition flux of  
273 cloud/fog, and  $C_{\text{Hg}}$  is the Hg concentration in cloud/fog.  $F_d$  can be estimated using  
274 resistance models, analytical models or sophisticated atmosphere-soil-vegetation  
275 models (Katata, 2014).

## 276 3 Models for Hg dry deposition

277 Dry deposition fluxes of speciated Hg can also be estimated by coupling speciated Hg  
278 concentrations and dry deposition models (Wright et al., 2016). Here we summarize  
279 dry deposition models for different Hg forms.

### 280 3.1 Resistance model for GOM

281 It is assumed that GOM dry deposition flux is proportional to the GOM concentration  
282 (Seinfeld and Pandis, 2016):

$$283 \quad F_{\text{dry,GOM}} = v_d \cdot C_z \quad (11)$$

284 where  $F_{\text{dry,GOM}}$  is the GOM dry deposition flux,  $C_z$  is the GOM concentration at  
285 reference height  $z$ , and  $v_d$  is the dry deposition velocity which can be calculated using

286 the following equation:

$$287 \quad v_d = \frac{1}{R_a + R_b + R_c} \quad (12)$$

288 where  $R_a$  is the aerodynamic resistance depending on the meteorological conditions  
289 and the land use category,  $R_b$  is the quasi-laminar resistance, a function of friction  
290 velocity and the molecular diffusivity of each chemical species (Zhang et al., 2002),  
291 and  $R_c$  is the canopy resistance which can be further parameterized as follows:

$$292 \quad R_c = \left( \frac{1 - W_{st}}{R_{st} + R_m} + \frac{1}{R_{ns}} \right)^{-1} \quad (13)$$

293 where  $W_{st}$  is the fraction of stomatal blocking under wet conditions,  $R_{st}$  is the  
294 stomatal resistance,  $R_m$  is the mesophyll resistance, and  $R_{ns}$  is the non-stomatal  
295 resistance which is comprised of in-canopy, soil, and cuticle resistances. Cuticle and  
296 soil resistances for GOM can be scaled to those of SO<sub>2</sub> and O<sub>3</sub> using the following  
297 equation:

$$298 \quad R_{x,GOM} = \left( \frac{\alpha_{GOM}}{R_{x,SO_2}} + \frac{\beta_{GOM}}{R_{x,O_3}} \right)^{-1} \quad (14)$$

299 where  $R_x$  is the cuticle or soil resistance,  $\alpha$  and  $\beta$  are two scaling parameters (Zhang  
300 et al., 2003; Zhang et al., 2012). Among the numerous parameters in the resistance  
301 model the two scaling factors for the non-stomatal resistance components regarding  
302 the solubility and reactivity of the chemical species are the most sensitive ones. The  
303 values for HNO<sub>3</sub> ( $\alpha=\beta=10$ ) used to be applied in the model for GOM (Marsik et al.,  
304 2007; Castro et al., 2012; Zhang et al., 2012). However, some other studies found the  
305 values for HONO ( $\alpha=\beta=2$ ) are probably more suitable for GOM due to equivalent  
306 effective Henry's Law constants ( $H^*$ ) between HONO and HgCl<sub>2</sub> (Lyman et al.,  
307 2007). Huang and Gustin (2015) indicated that no single value could be used to  
308 calculate GOM dry deposition due to the unknown GOM compounds. Various values  
309 for the two scaling parameters ( $\alpha=\beta=2, 5, 7$  and 10) were used in Huang et al. (2017)  
310 to identify dominant GOM deposition species.

### 311 3.2 Resistance model for PBM

312 For PBM dry deposition, a size-segregated resistance model is more and more widely  
313 applied, based on the theory that  $v_d$  for atmospheric particles strongly depend on  
314 particle size distributions (Dastoor and Larocque, 2004; Zhang et al., 2009; Zhang and  
315 He, 2014). Many independent studies (Fang et al., 2012; Zhu et al., 2014) showed that

316 Hg in coarse particles constitutes a large mass fraction of the total PBM, which was  
317 previously neglected. PBM measured by Tekran 2537/1130/1135 only considers fine  
318 particles. Based on available measurements of PBM size distributions and fine/coarse  
319 PBM mass ratios, Zhang et al. (2016b) assumed 30% of the total PBM mass to be  
320 coarse particles in order to estimate total PBM dry deposition flux based on the theory  
321 that PBM has the same proportion in both fine and coarse particles.

322 The total PBM dry deposition can be calculated as follows:

$$323 \quad F_{\text{dry,PBM}} = C_f \left( v_f + \frac{f}{1-f} v_c \right) \quad (15)$$

324 where  $F_{\text{dry,PBM}}$  is the total PBM dry deposition flux,  $C_f$  is the mass concentration of  
325 PBM in fine particles,  $v_f$  and  $v_c$  are the dry deposition velocities of PBM for fine and  
326 coarse particles, respectively, and  $f$  is the mass fraction of PBM in coarse particles.  $v_f$   
327 and  $v_c$  can be calculated using the following equation:

$$328 \quad v_x = v_g + \frac{1}{R_a + R_s} \quad (16)$$

329 where  $v_x$  is  $v_f$  or  $v_c$ ,  $v_g$  is the gravitational settling velocity,  $R_a$  is the aerodynamic  
330 resistance, and  $R_s$  is the surface resistance which can be parameterized as a function of  
331 collection efficiencies from Brownian diffusion, impaction, and interception  
332 mechanisms (Zhang et al., 2012; Zhang et al., 2016b). Zhang and He (2014) have  
333 developed an easier bulk algorithm based on the  $v_x$  scheme of Zhang et al. (2001) to  
334 make this model more widely applicable in monitoring networks.

### 335 3.3 Bidirectional air-surface exchange model for GEM

336 GEM dry deposition can also be calculated using the resistance model with different  
337 parameters. However, the re-emission and natural emission of GEM must be taken  
338 into consideration. Net GEM dry deposition is estimated from the difference between  
339 the estimated unidirectional deposition flux and the modeled total re-emission plus  
340 natural emission in the resistance model (Zhang et al., 2012).

341 A bidirectional air-surface exchange model modified from the resistance model is  
342 more and more recommended in recent years (Zhang et al., 2009; Bash, 2010; Wang  
343 et al., 2014; Zhang et al., 2016b; Zhu et al., 2016). In the bidirectional scheme, the  
344 GEM dry deposition flux can be calculated as follows:

$$345 \quad F_{\text{dry,GEM}} = \frac{\chi_a - \chi_c}{R_a + R_b} \quad (17)$$

$$\chi_c = \left( \frac{\chi_a}{R_a + R_b} + \frac{\chi_{st}}{R_{st} + R_m} + \frac{\chi_g}{R_{ac} + R_g} \right) \left( \frac{1}{R_a + R_b} + \frac{1}{R_{st} + R_m} + \frac{1}{R_{ac} + R_g} + \frac{1}{R_{cut}} \right)^{-1} \quad (18)$$

where  $F_{\text{dry,GEM}}$  is the net GEM dry deposition flux;  $\chi_a$  is the GEM concentration at a reference height;  $R_a$ ,  $R_b$ ,  $R_{st}$ ,  $R_m$ ,  $R_{ac}$ ,  $R_g$  and  $R_{cut}$  are aerodynamic, quasi-laminar, stomatal, mesophyll, in-canopy aerodynamic, ground surface and cuticle resistances, respectively (Zhang et al., 2016b); and  $\chi_{st}$  and  $\chi_g$  are canopy, stomatal and ground surface compensation points, respectively. Based on observations on different land use categories, Wright and Zhang (2015) have proposed a range of  $\chi_{st}$  and  $\chi_g$ .

#### 4 Global observation network of Hg deposition

There have been several observation networks of Hg wet deposition. The Global Mercury Observation System (GMOS) is so far the only global scale network covering the northern hemisphere, the tropics, and the southern hemisphere (Sprovieri et al., 2017). The Mercury Deposition Network (MDN) of the National Atmospheric Deposition Program (NADP) in North America is the earliest continental scale network specifically for Hg deposition (Prestbo and Gay, 2009; Weiss-Penzias et al., 2016). Hg wet deposition is also monitored in the European Monitoring and Evaluation Programme (EMEP) for Europe (Tørseth et al., 2012; Bieser et al., 2014). A new Asia–Pacific Mercury Monitoring Network has recently been established (Obrist et al., 2018). Since the methods of measurements still have high uncertainties, there is not yet any tangible monitoring network for Hg dry deposition.

##### 4.1 Wet deposition

Sprovieri et al. (2017) reported a 5-year record (2011–2015) of Hg wet deposition at 17 selected GMOS monitoring sites, which provided a global baseline of the Hg wet deposition flux including regions in the southern hemisphere and tropical areas where Hg wet deposition had never been investigated before. The average Hg wet deposition fluxes in the northern hemisphere, the tropics, and the southern hemisphere were 2.9 (0.2–6.7), 4.7 (2.4–7.0), and 1.9 (0.3–3.3)  $\mu\text{g m}^{-2} \text{yr}^{-1}$ , respectively. Precipitation volume was found to be the key factor for the inter-annual differences in total Hg wet deposition. The MDN network has a much longer history which dates back to the 1990s. Weiss-Penzias et al. (2016) analyzed records from 19 sites in the United States (U.S.) and Canada between 1997 and 2013, and discovered trends of Hg concentration in wet deposition, with the early time period (1998–2007) producing a significantly

377 negative trend ( $-1.5 \pm 0.2\% \text{ yr}^{-1}$ ) and the late time period (2008–2013) a flat slope (not  
378 significant). Therefore, the MDN data of 136 sites (<http://nadp.slh.wisc.edu/mdn>) for  
379 the time period of 2008–2015 was summarized in this study to represent the recent  
380 background Hg wet deposition level in North America. Fu et al. (2016) summarized  
381 wet deposition measurements from 7 monitoring sites in China. Hg wet deposition  
382 fluxes at rural sites in forest and grassland were averagely  $6.2$  and  $2.0 \mu\text{g m}^{-2} \text{ yr}^{-1}$ ,  
383 respectively, while the flux at an urban site was as high as  $12.6 \pm 6.5 \mu\text{g m}^{-2} \text{ yr}^{-1}$ .

384 Figure 1 summarizes the global distribution of Hg wet deposition based on existing  
385 studies. Hg wet deposition flux is not significantly related to elevation. Overall, East  
386 Asia has the highest wet deposition flux (averagely  $16.1 \mu\text{g m}^{-2} \text{ yr}^{-1}$ ), especially in the  
387 southern part of China where the GEM concentration level is relatively high (Fu et al.,  
388 2008; Guo et al., 2008; Wang et al., 2009; Fu et al., 2010; Ahn et al., 2011; Huang et  
389 al., 2012; Seo et al., 2012; Huang et al., 2013; Sheu and Lin, 2013; Marumoto and  
390 Matsuyama, 2014; Xu et al., 2014; Zhu et al., 2014; Huang et al., 2015; Zhao et al.,  
391 2015; Han et al., 2016; Fu et al., 2016; Ma et al., 2016; Nguyen et al., 2016; Qin et al.,  
392 2016; Sommar et al., 2016; Cheng et al., 2017; Chen et al., 2018; Lu and Liu, 2018).  
393 North America has the most complete deposition observation network with an average  
394 Hg wet deposition flux of  $9.1 \mu\text{g m}^{-2} \text{ yr}^{-1}$ , and exhibits a decreasing spatial profile  
395 from the southeastern part to the northwestern part, which is consistent with the  
396 distribution of the atmospheric Hg concentration (Zhang et al., 2012; Gichuki and  
397 Mason, 2014; Lynam et al., 2017). Europe has the lowest Hg wet deposition flux  
398 (averagely  $3.4 \mu\text{g m}^{-2} \text{ yr}^{-1}$ ) according to the available dataset (Connan et al., 2013;  
399 Bieser et al., 2014; Siudek et al., 2016). Observation sites in the tropics and the  
400 southern hemisphere are scarce with large variation in Hg wet deposition flux  
401 (Wetang'ula, 2011; Gichuki and Manson, 2013; Sprovieri et al., 2017). Precipitation  
402 could be the main cause of the differences.

403 The relationship between the annual precipitation and the Hg wet deposition flux is  
404 shown in Fig. 2. The wet deposition flux is basically positively related to the annual  
405 precipitation, except for 8 sites in southwestern China which are close to former Hg  
406 mining area and 3 urban or suburban sites in southeastern China. These 11 sites have  
407 an average Hg wet deposition flux of  $34.5 \mu\text{g m}^{-2} \text{ yr}^{-1}$ . The one exceptional tropical  
408 site with a wet deposition flux of  $16.8 \mu\text{g m}^{-2} \text{ yr}^{-1}$  is in Kenya while the other sites in  
409 the tropics are all in Mexico (Wetang'ula, 2011; Hansen and Gay, 2013). The two sites

410 in the southern hemisphere with annual precipitation of over 4000 mm are in Australia  
411 and have wet deposition fluxes of 29.1 and 18.2  $\mu\text{g m}^{-2} \text{yr}^{-1}$ , respectively (Dutt et al.,  
412 2009). The slope of the relationship implies the Hg concentration in precipitation.  
413 Europe has the flattest slope among all regions, indicating its lowest Hg pollution  
414 level around the world.

#### 415 **4.2 Dry deposition**

416 The Hg dry deposition network is immature compared to the wet deposition network  
417 due to the inconsistency in methods of measurements. GOM dry deposition fluxes  
418 were either measured by the surrogate surface method using CEMs or estimated from  
419 measurements of GOM concentrations. PBM dry deposition fluxes were mainly  
420 estimated from the measurements of total or size-resolved PBM concentrations. GEM  
421 dry deposition fluxes were measured by different types of methods, the surrogate  
422 surface methods, the enclosure methods, and the micrometeorological methods.

423 Figure 3 shows the global distribution of the GOM, PBM and GEM dry deposition  
424 fluxes. Although large uncertainties still exist in the methods for Hg dry deposition  
425 measurements, it should be noted that GEM dry deposition is non-negligible  
426 compared to GOM and PBM.

427 The data of GOM dry deposition fluxes concentrate in North America and Europe,  
428 among which direct observations of GOM dry deposition are mainly from North  
429 America (Lyman et al., 2007; Lyman et al., 2009; Weiss-Penzias et al., 2011; Lombard  
430 et al., 2011; Castro et al., 2012; Gustin et al., 2012; Peterson et al., 2012; Zhang et al.,  
431 2012; Sather et al., 2013; Bieser et al., 2014; Huang et al., 2014; Sather et al., 2014;  
432 Wright et al., 2014; Huang and Guatin, 2015; Enrico et al., 2016; Han et al., 2016;  
433 Zhang et al., 2016; Huang et al., 2017). Regardless of the evaluating methods, the  
434 mean GOM dry deposition flux in North America ( $6.4 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) is higher than in  
435 Europe ( $3.0 \mu\text{g m}^{-2} \text{yr}^{-1}$ ). Han et al. (2016) used knife-edge surrogate surface (KSS)  
436 samplers with quartz filters to measure GOM dry deposition at a remote site in Korea,  
437 and found an average GOM dry deposition flux of  $4.78 \mu\text{g m}^{-2} \text{yr}^{-1}$ . Huang et al.  
438 (2012a) used KSS samplers with CEMs in several polluted areas and got a much  
439 higher average ( $52.9 \mu\text{g m}^{-2} \text{yr}^{-1}$ ). A significant correlation ( $R^2=0.532$ ,  $p<0.01$ ) was  
440 found between the elevation and the GOM dry deposition flux (Fig. 4). Huang and  
441 Gustin (2014) found that measured dry deposition of GOM was significantly high at  
442 sites over 2000 m above sea level, and attributed it to high GOM concentrations at

443 high elevation and atmospheric turbulence.

444 Due to the severe particulate matter (PM) pollution in East Asia, many independent  
445 size-resolved PM measurements were conducted in recent years with analysis of Hg  
446 in PM accordingly. Results from size-resolved PBM analysis and PBM dry deposition  
447 models show that East Asia has a much higher average of PBM dry deposition flux  
448 ( $45.3 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) than North America ( $1.1 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) with coarse-particle PBM dry  
449 deposition not considered (Fang et al., 2012a; Fang et al., 2012b; Zhu et al., 2014;  
450 Zhang et al., 2015; Huang et al., 2016; Guo et al., 2017).

451 The mean GEM dry deposition is lower in Europe ( $4.3 \pm 8.1 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) while  
452 higher and more variable in North America ( $5.2 \pm 15.5 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) (Castelle et al.,  
453 2009; Baya and Heyst, 2010; Converse et al., 2010; Miller et al., 2011). The four  
454 Asian sites using micrometeorological methods all show negative values ( $-36.3 \pm 19.6$   
455  $\mu\text{g m}^{-2} \text{yr}^{-1}$ ) (Luo et al., 2015; Luo et al., 2016; Ci et al., 2016; Sommar et al., 2016),  
456 indicating natural GEM emission sources rather than GEM deposition sinks, but the  
457 GEM dry deposition data in Asia is very limited. No GEM, GOM or PBM dry  
458 deposition data were found for the tropics or the southern hemisphere.

459 Large uncertainties still exist in the evaluating methods. Significant discrepancies  
460 were found between observed and simulated GOM dry deposition fluxes (Fig. 5).  
461 Some recent studies used a scaling factor of 3 to adjust GOM concentrations (Huang  
462 and Gustin, 2014; Huang et al., 2017), trying to offset the underestimation due to the  
463 low capture efficiency of the widely adopted KCl denuder method for measurements  
464 of GOM concentrations (Huang and Gustin, 2015).

### 465 **4.3 Forest deposition**

466 Hg deposition in forests is mainly in the form of litterfall and throughfall. Wang et al.  
467 (2016) made a comprehensive assessment of the global Hg deposition through  
468 litterfall, and found litterfall Hg deposition an important input to terrestrial forest  
469 ecosystems ( $1180 \pm 710 \text{Mg yr}^{-1}$ ). South America was estimated to bear the highest  
470 litterfall Hg deposition ( $65.8 \pm 57.5 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) around the world. This was partially  
471 because some studies were conducted in the Amazonian rainforest (Fostier et al.,  
472 2015), mainly semi-deciduous or evergreen tropical forest, which account for over  
473 40% litterfall deposition globally (Shen et al., 2019). Another reason was that some  
474 sampling sites were very close to large cities or polluted areas, which could lead to  
475 more Hg accumulation (Teixeira et al., 2012; Buch et al., 2015; Teixeira et al., 2017;

476 Fragoso et al., 2018). There have been numerous forest Hg deposition studies in the  
477 recent decade in East Asia with the second highest average litterfall Hg deposition  
478 flux ( $35.5 \pm 27.7 \mu\text{g m}^{-2} \text{yr}^{-1}$ ). The forest type varies among different studies, but East  
479 Asia has much higher Hg concentrations in litterfall ( $42.9\text{--}62.8 \text{ ng/g}$ ) compared to  
480 other regions (Wan et al., 2009; Wang et al., 2009; Fu et al., 2010a; Fu et al., 2010b;  
481 Gong et al., 2014; Luo et al., 2015; Ma et al., 2015; Han et al., 2016; Fu et al., 2016;  
482 Ma et al., 2016; Wang et al., 2016; Zhou et al., 2016; Zhou et al., 2017). Lower levels  
483 of litterfall Hg deposition fluxes were found in North America ( $12.3 \pm 4.9 \mu\text{g m}^{-2} \text{yr}^{-1}$ )  
484 and Europe ( $14.4 \pm 5.8 \mu\text{g m}^{-2} \text{yr}^{-1}$ ) (Larssen et al., 2008; Obrist et al., 2009; Fisher and  
485 Wolfe, 2012; Juillerat et al., 2012; Obrist et al., 2012; Benoit et al., 2013; Navrátil et  
486 al., 2014; Gerson et al., 2017; Risch et al., 2017; Risch and Kenski, 2018). According  
487 to Risch et al. (2017), the litterfall Hg deposition flux in the eastern U.S. decreased  
488 year by year during 2007–2014 with a decline rate of  $0.8 \mu\text{g m}^{-2} \text{yr}^{-1}$ . From 2007 to  
489 2009 the decrease occurred more rapidly due to the Hg emission control strategies  
490 during this period of time.

491 Most studies on Hg deposition in forests in North America use rainfall instead of  
492 throughfall since dry deposition in North American forests has limited contribution  
493 (Risch et al., 2017), while Asian studies found large discrepancy between throughfall  
494 and rainfall Hg deposition fluxes ( $32.9 \pm 18.9$  and  $13.3 \pm 8.6 \mu\text{g m}^{-2} \text{yr}^{-1}$ , respectively),  
495 indicating a high dry deposition level in Asian forests (Wan et al., 2009; Wang et al.,  
496 2009; Fu et al., 2010a; Fu et al., 2010b; Luo et al., 2015; Ma et al., 2015; Han et al.,  
497 2016; Fu et al., 2016; Ma et al., 2016; Wang et al., 2016; Zhou et al., 2016). Litterfall  
498 and throughfall Hg deposition fluxes are equivalent. Wright et al. (2016) summarized  
499 previous studies and reported the mean litterfall and throughfall Hg deposition,  
500 respectively,  $42.8$  and  $43.5 \mu\text{g m}^{-2} \text{yr}^{-1}$  in Asia,  $14.2$  and  $19.0 \mu\text{g m}^{-2} \text{yr}^{-1}$  in Europe,  
501 and  $12.9$  and  $9.3 \mu\text{g m}^{-2} \text{yr}^{-1}$  in North America.

502 Studies of cloud/fog Hg deposition are very limited so far. Stankwitz et al. (2012)  
503 and Gerson et al. (2017) found the average cloud/fog Hg deposition fluxes of two  
504 North American forests to be  $7.4$  and  $4.3 \mu\text{g m}^{-2} \text{yr}^{-1}$ , respectively. In California  
505 coastline, fog Hg deposition, with only 2% volume proportion, accounts for 13% of  
506 the total wet deposition (Weiss-Penzias et al., 2016). At high-elevation observatories  
507 the contribution of cloud/fog Hg deposition is non-negligible. Converse et al. (2014)  
508 found the annual Hg deposition to dew/frost at a high-elevation site in the U.S. to be

509 about  $0.12 \mu\text{g m}^{-2} \text{yr}^{-1}$ , 2–3 orders of magnitude smaller than wet deposition. More  
510 studies and a more standardized method for cloud/fog water sampling are needed.

## 511 **5 Global Hg deposition on different terrestrial surfaces**

512 Terrestrial surface type is a key factor for global Hg deposition. We summarized  
513 existing studies to make comparisons for Hg deposition on different terrestrial  
514 surfaces. Figures 6–8 exhibit wet, dry, and litterfall Hg deposition fluxes for different  
515 terrestrial surface types.

516 As shown in Fig. 6a, the average Hg wet deposition flux follows the ascending  
517 sequence of grasslands, croplands, savannas, and urban areas, which is mainly linked  
518 to the precipitation levels on these surfaces. Barren areas have the lowest Hg wet  
519 deposition flux due to their lowest precipitation. Water surfaces, e.g., coastal,  
520 offshore, and lakeside sites, have a lower wet deposition level than the surfaces with a  
521 similar amount of precipitation. This is possibly related to fog deposition. The  
522 relatively low Hg concentration in precipitation on water surfaces could be caused by  
523 fog scavenging, not only in high-elevation regions, but also in the near water areas.  
524 Fog deposition is not considered in Hg wet deposition. Forests have a similar  
525 precipitation level as urban areas, but exhibit much lower wet deposition fluxes. This  
526 is probably because most forests are in remote areas with low total atmospheric Hg  
527 concentration levels. It is the reactive Hg (GOM and PBM) that determines the Hg  
528 concentration in precipitation. Hg wet deposition fluxes for different forest types are  
529 shown in Fig. 6b. Forests have a similar precipitation level. The high wet deposition  
530 fluxes for deciduous needle leaf and evergreen broadleaf forests are both induced by  
531 samples from Chongqing, a city with a relatively high atmospheric Hg concentration  
532 in China (Wang et al., 2009; Qin et al., 2016). In general, the Hg wet deposition flux  
533 does not vary significantly among the five forest types.

534 The distribution of Hg dry deposition on various terrestrial surfaces is quite  
535 different among the three atmospheric Hg forms (Fig. 7). GEM dry deposition is  
536 equivalent to GOM and PBM dry deposition, even significantly higher than in forests.  
537 As shown in Fig. 7a, the Hg oxidation process plays a more important role at sites  
538 with higher elevations (more halogen free radicals) or more intensive solar radiations,  
539 resulting in high GOM dry deposition levels for grasslands (including alpine meadow)  
540 and savannas, respectively. Urban areas with high GOM concentrations also have  
541 relatively high GOM dry deposition fluxes. The low GOM dry deposition fluxes on

542 moist surfaces (water and croplands) might be partially because of dew/fog  
543 scavenging (Malcolm and Keeler, 2002; Zhang et al., 2009). The PBM dry deposition  
544 flux is high on surfaces with high human activities (urban areas and croplands) and  
545 low in vegetative areas implying the heavier PM pollution in urban and rural areas  
546 than in remote areas (Fig. 7b). Agnan et al. (2015) and Zhu et al. (2016) made detailed  
547 summaries of campaign-based GEM dry deposition observations, and addressed the  
548 importance of natural Hg emission sources. Due to the lack of long-term observations  
549 (no less than one year), we summarized model evaluations and one annual observation  
550 dataset (Zhang et al., 2012; Bieser et al., 2014; Zhang et al., 2016; Enrico et al., 2016),  
551 and found that the GEM dry deposition does not only depend on GEM concentration,  
552 but also on the air–soil Hg exchange compensation point. Regarding the annual air–  
553 surface Hg exchange, instead of an important natural source, forests tend to be a net  
554 sink of atmospheric Hg (Fig. 7c). Therefore, long-term studies of GEM dry deposition  
555 are of urgent need.

556 The litterfall Hg deposition flux and the Hg concentration in litterfall are shown in  
557 Fig. 8. In general, evergreen forests have higher litterfall Hg concentrations than  
558 deciduous forests due to longer accumulation time (Wright et al., 2016). Evergreen  
559 broadleaf forests have not only high litterfall Hg concentrations but also high litterfall  
560 rates (Shen et al., 2019), and consequently exhibit significantly high litterfall Hg  
561 deposition fluxes. Comparing the levels of wet, dry, and litterfall Hg depositions in  
562 forests, litterfall markedly takes the lead, especially for evergreen broadleaf forests.  
563 This is consistent with the budget of global litterfall Hg deposition developed by  
564 Wang et al. (2016a).

## 565 **6 Summary and recommendations**

566 Hg wet and dry depositions to terrestrial surfaces, as well as litterfall, throughfall and  
567 cloud/fog depositions in forests, have been measured globally over the last two  
568 decades to improve our understanding on the sink of atmospheric Hg. Owing to the  
569 unified and reliable methodology, a global Hg wet deposition monitoring network has  
570 been established, especially the matured network in North America. Dry deposition of  
571 speciated atmospheric Hg (GEM, GOM and PBM), however, has diverse methods for  
572 measurements, including the surrogate surface methods, the enclosure methods, and  
573 the micrometeorological methods. For the Hg deposition forms in forests, litterfall and  
574 throughfall are easy to observe, while the measurements of cloud/fog deposition are

575 still preliminary. The Hg dry deposition flux can also be estimated based on speciated  
576 Hg concentrations in the atmosphere using resistance models or bidirectional air–  
577 surface exchange models. Key parameters (e.g., the two scaling factor,  $\alpha$  and  $\beta$ , for  
578 cuticle or soil resistance) still generate large uncertainties. The land use category is an  
579 important factor in modeling Hg deposition. Therefore, we compared the data for  
580 different terrestrial surfaces. Water surfaces could affect Hg wet deposition through  
581 fog scavenging. Hg wet deposition is an indicator of the atmospheric Hg pollution  
582 level for a certain region. Altitude is a key factor for GOM dry deposition. GEM dry  
583 deposition is non-negligible compared to GOM and PBM dry deposition, especially  
584 for forests. Litterfall could be the dominant form of Hg deposition in forests.

585 Based on current understanding on global Hg deposition, we think future research  
586 needs lie in the following aspects:

587 (1) Different chemical forms of GOM (e.g.,  $\text{HgCl}_2$ ,  $\text{HgBr}_2$ ,  $\text{HgSO}_4$ , etc.) could have  
588 different dry deposition velocities. Quantification methods for concentrations of  
589 different GOM species need to be developed to improve the evaluation of the Hg dry  
590 deposition flux, which has much higher uncertainty than the wet, litterfall, and  
591 throughfall deposition fluxes.

592 (2) The resistance model for GOM dry deposition requires better parameterization  
593 considering different GOM species. Moreover, the model should utilize more accurate  
594 GOM concentration data. The KCl denuder-based method for GOM measurements  
595 has significant underestimation caused by high humidity or ozone concentration.

596 (3) The contribution GEM dry deposition has been underestimated previously.  
597 Inter-comparison between different methods for GEM dry deposition measurements  
598 needs to be conducted to determine a unified method for monitoring networks.

599 (4) Cloud, fog or even dew Hg deposition needs careful investigation which  
600 requires more standardized sampling methods. At high-elevation sites cloud/fog Hg  
601 deposition should be included in the total wet deposition.

602

603 *Author contribution.* Dr. Lei Zhang designed the review framework. Dr. Lei Zhang  
604 and Peisheng Zhou did the most literature review work with contributions from  
605 Shuzhen Cao and Dr. Yu Zhao. Dr. Lei Zhang prepared the manuscript with  
606 contributions from all co-authors.

607

608 *Acknowledgements.* This review work was supported by the National Natural Science  
609 Foundation of China (No. 21876077) and the Fundamental Research Funds for the  
610 Central Universities (No. 14380080 and No. 14380092).
