16
17 **Abstract**

18 China is experiencing increasingly serious ambient ozone pollution, including the economically
19 developed Pearl River Delta (PRD) region. However, the underlying reasons for ozone increase remain
20 largely unclear, leading to perplexity in formulating effective ozone control strategies. In this study, by
21 developing a statistical analysis framework combining meteorological adjustment and source
22 apportionment, we examine quantitatively the impacts of meteorology and precursor emissions from
23 within and outside the PRD on the evolution of ozone during the past decade. We found that
24 meteorological condition has mitigated ozone increase, and its variation can account for at most 15% of
25 annual ozone concentration in the PRD. Precursor emission from outside the PRD ('non-local') makes
26 the largest contribution to ambient ozone in the PRD and shows a consistently increasing trend, while
27 that from within the PRD ('local') shows a significant spatial heterogeneity and plays a more important
28 role during ozone episodes over southwestern. Under general conditions, the impact on northeastern is
29 positive but decreasing, and on southwestern is negative but increasing. During ozone episodes, the
30 impact on northeastern is negative and decreasing, while on southwestern is positive but decreasing.
31 Central and western PRD is the only area with increasing local ozone contribution. The spatial
32 heterogeneity in both local ozone contribution and its trend under general conditions and ozone episodes
33 are well interpreted by a conceptual diagram collectively taking into consideration ozone precursor
34 emissions and their changing trends, ozone formation regimes, and the monsoonal and micro-scale
35 synoptic conditions over different sub-regions of the PRD. In particular, we conclude that the
36 inappropriate NO_x/VOC control ratio within the PRD over the past years is most likely responsible for
37 the ozone increase over southwestern, both under general conditions and during ozone episodes. By
38 investigating the ozone evolution influenced by emission changes within and outside PRD during the
39 past decade, this study highlights the importance of establishing a dichotomous ozone control strategy to
40 tackle with general conditions and pollution events separately. NO_x emission control should be further
41 strengthened to alleviate peak ozone level during episodes. Detailed investigation is needed to retrieve
42 appropriate NO_x/VOC ratios for different emission and meteorological conditions, so as to maximize the
43 ozone reduction efficiency in the PRD.

48 **1. Introduction**

49 Thanks to a series of stringent air pollution control measures, most types of air pollutants, including SO₂,
50 NO_x, CO, PM₁₀ and PM_{2.5}, exhibited decreasing concentrations in the past six years (2013-2018) in China,
51 with the only exception of ozone (Souri et al., 2017; Koukouli et al., 2018; Lin et al., 2018; Lu et al.,
52 2018; Wang et al., 2018; Zhang et al., 2018). During 2015-2018, ozone concentrations in the three major
53 city clusters, Beijing-Tianjin-Hebei, Yangtze River Delta, and Pearl River Delta (PRD), had increased by
54 20%, 4%, and 14%, respectively (Report on the State of the Environment in China,
55 <http://english.mee.gov.cn/Resources/Reports/soe/>). Although with comparable median ozone
56 concentrations, the magnitude and frequency of high-ozone events are much higher in China than those
57 in Japan, South Korea, Europe, and the United States (Lu et al., 2018). Ozone would become one of the
58 major air pollution control targets in China in the near future to protect public health.

59

60 Ozone control is far more difficult than particulate matter (PM) control, according to the experiences in
61 Los Angeles and Mexico City (Madronich, 2014). The difficulties of ozone control lie in two major
62 aspects. First, ozone can be contributed by both local formation and non-local transport, and their relative
63 importance is largely driven by meteorological conditions and precursor emission characteristics (Elminir,
64 2005; Beaver and Palazoglu, 2009; Kovač-Andrić et al., 2009). Moreover, ozone is a secondary pollutant
65 with non-linear relationship with its precursors, NO_x and volatile organic compounds (VOCs) (Stevenson
66 et al., 2013; Thompson et al., 2014). Synergistic control with desirable VOC-to-NO_x reduction ratio is
67 required for ozone reduction. However, such a ratio is hard to determine and practically implement due
68 to our limited understanding on VOC emissions, especially those fugitive (Ou et al., 2016). The
69 appropriate VOCs-to-NO_x reduction ratio may also vary greatly under different meteorological
70 conditions. Therefore, from an ozone control point of view, it is fundamental to quantitatively understand
71 the roles of meteorology and precursor emissions in shaping local and non-local ozone contributions, and
72 their evolution during a long time scale in response to meteorology and emission changes.

73

74 Meteorology could either strengthen or dampen the efforts of precursor emission control on ozone
75 reduction (Elminir, 2005; Beaver and Palazoglu, 2009; Kovač-Andrić et al., 2009). Hence, in order to
76 investigate the effectiveness of precursor control during a long period, it is a common practice to
77 homogenize meteorological conditions. In numerical simulation studies, this is implemented by a set of
78 scenarios in different meteorological and emission conditions (Gilliland et al., 2008; Godowitch et al.,
79 2008; Wu et al., 2008; Foley et al., 2015). Differences in ozone levels between scenarios with the same
80 meteorological conditions (emissions) are attributed to emission (meteorology) changes. Statistical
81 models are also widely applied to establish relationship between ozone and meteorological variables so
82 as to remove the meteorological impact, which is usually called meteorological adjustment (Lu and
83 Chang, 2005; Zheng et al., 2007; Foley et al., 2015). After meteorological adjustment, ozone changes are
84 solely attributed to emission changes.

85

86 Both local and non-local emission changes contribute to ambient ozone levels in a particular region.
87 From an ozone control point of view, it is also essential to quantitatively differentiate local and non-local
88 contributions. Source apportionment module coupled in chemical transport models, e.g. the Ozone

89 Source Apportionment Technology (OSAT) in the Comprehensive Air-quality Model with extensions
90 (CAMx) and the Integrated Source Apportionment Method (ISAM) in the Community Multiscale Air
91 Quality (CMAQ), are widely used to attribute ambient ozone concentrations at a particular place into
92 different (local and non-local) source regions and categories (Li et al., 2013; Kwok et al., 2015). As
93 numerical simulation is suffered from uncertainties in emission inventories and largely constrained in
94 time span due to computing resources, statistical models, e.g. lowest-as-background method (Nielsen-
95 Gammon et al., 2005; Xue et al., 2014) and Empirical Orthogonal Function (EOF) (Langford et al., 2009;
96 Berlin et al., 2013), are preferentially adopted when the long-term monitoring data is available. They
97 apportion local and non-local contributions by examining variability and co-variability of ozone
98 concentrations at multiple monitoring sites. However, without meteorological adjustment, source
99 apportionment by both methods reflects only the absolute contribution from local and non-local sources
100 / processes and cannot directly link with local and non-local emissions of ozone precursors. Therefore,
101 combined application of meteorological adjustment and source apportionment are indispensable in
102 investigating the effect of local and non-local emission changes on long-term ambient ozone variations.
103 Such combined application has not been reported in previous studies.

104

105 In this study, PRD is used as a research target area. After restraining its annual $PM_{2.5}$ concentration below
106 $35\mu g m^{-3}$ (China's National Ambient Air Quality Standard for annual $PM_{2.5}$) for four consecutive years
107 (2015-2018), PRD is the first major city cluster in China to transfer its main air pollution control target
108 onto ozone. By utilizing continuous ozone monitoring at multiple stations across the PRD since 2007,
109 we investigate the impacts of meteorology and local ('within PRD') and non-local ('outside PRD')
110 emission changes on the long-term trend of ambient ozone by using the framework of meteorological
111 adjustment followed by local and non-local contribution differentiation. Ozone contributions from
112 meteorology and local and non-local emissions are quantitatively demonstrated in 2016 and 2017 the
113 recent two years with significant ozone increase. We further develop a conceptual diagram depicting
114 the impact of emission control within the PRD to the ambient ozone, both under general conditions and
115 during ozone pollution episodes. Evaluation on the effectiveness of ozone precursor control measures
116 within and outside the PRD during the past decade would shed light on future control efforts that
117 hopefully shorten the ozone abatement paths experienced in Europe and the United States.

118

119 **2. Data and Method**

120 **2.1 Ozone and meteorological data set**

121 Hourly ozone monitoring data at fifteen monitoring stations across the PRD from 2007 to 2017 are used
122 to calculate maximum daily 8-hour average (MDA8) in this study. Missing data are filled taking the
123 yearly, monthly, weekly and hourly mean into account, otherwise it is replaced by the ozone data at the
124 nearest monitoring station (Zheng et al., 2007). Geographical distribution of the monitoring stations is
125 illustrated in Fig. 1, and the latitudes / longitudes and the types of functional areas where the stations are
126 located are provided in Table 1.

127

128 The meteorological data during the same period, including daily maximum 2m temperature (T , °C), daily
129 minimum relative humidity (RH, %), total net surface solar radiation (SSR, J/M^2), and 10m mean wind
130 direction and speed (u and v , the absolute values show wind speed (m/s), while positive and negative
131 signs of u and v indicate westerly, southerly and easterly, northerly wind direction, respectively), are
132 retrieved from the European Center for Medium-range Weather Forecast (ECMWF) simulations for

133 meteorological adjustment. Temporal and spatial resolution is 3-hour and $0.125^\circ \times 0.125^\circ$, respectively.
 134 Meteorological condition at the ozone monitoring station is represented by the simulation data at the
 135 closest point to the station, as illustrated in Fig. 1. In this study, we composed an ozone and
 136 meteorological dataset with 4018 days at fifteen stations.

137

138 2.2 Meteorological adjustment

139 In this study, a statistical analysis framework combining meteorological adjustment and source
 140 apportionment is developed to identify ozone changes attributable to meteorology and local and non-
 141 local emissions. Long-term trends of ozone changes by meteorological conditions and local and non-
 142 local emissions are subsequently evaluated by trend analysis. In this study, ‘local’ emissions refer to those
 143 from within the PRD, while ‘non-local’ emissions refer to those from outside the PRD. A conceptual
 144 diagram highlighting major calculation procedures of the statistical analysis framework is shown in Fig.
 145 2.

146

147 In meteorological adjustment, Kolmogorov-Zurbenko (KZ) filter is firstly used to separate the raw ozone
 148 and meteorological data into long-term, seasonal and short-term data (Rao and Zurbenko, 1994a; Rao
 149 and Zurbenko, 1994b). KZ filter can be expressed as

$$150 \quad X(t) = LT(t) + SE(t) + ST(t) \quad (1)$$

151 Where $X(t)$ is the raw time series data, $LT(t)$ reflects the long-term trend in the time scale of years, $SE(t)$
 152 is the seasonal variation in the time scale of months, and $ST(t)$ refers to short-term component in the time
 153 scale of days.

154 The KZ filter repeats the iterations of a moving average to remove the high-pass signal defined by

$$155 \quad Y_i = \frac{1}{m} \sum_{j=-k}^k A_{i+j} \quad (2)$$

156 where k is the number of values included on each side, the window length $m=2k+1$, i is interval time, j
 157 is window variables, and Y is the input time-series. Thus the output of the i^{th} pass becomes the input for
 158 the $i+1^{\text{th}}$ pass, and so on. Different scales of motion are obtained by changing the window length and the
 159 number of the iterations (Milanchus et al., 1998; Eskridge et al., 1997). The filter periods of less than N
 160 days can be calculated with window length m and the number of iterations p , as

$$161 \quad m \times p^{1/2} \leq N \quad (3)$$

162 So a $KZ(15, 5)$ filter with the window length of 15 with 5 iterations remove cycles of 33 days. The ozone
 163 and meteorological time series by $KZ(15, 5)$ refer to their baseline variations which are the sum of long-
 164 term $LT(t)$ and seasonal components $SE(t)$.

$$165 \quad BL(t) = KZ_{(15,5)} = LT(t) + SE(t) = KZ_{(36, 53)} + SE(t) \quad (4)$$

166 The long-term trend is separated from the raw data by $KZ(365, 3)$ with the periods $>632d$, and then the
 167 seasonal and the short-term component $ST(t)$ can be derived by

$$168 \quad SE(t) = KZ_{(15,5)} - KZ_{(36, 53)} \quad (5)$$

$$169 \quad ST(t) = X(t) - BL(t) = X(t) - KZ_{(15,5)} \quad (6)$$

170 After KZ filtering, meteorological adjustment is conducted by stepwise regression between ozone
 171 concentration and meteorological factors such as T, RH and SSR (Flaum et al., 1996; Wise and Comrie,
 172 2005; Papanastasiou et al., 2012).

$$173 \quad A_{BL}(t) = a_{BL} + \sum b_{BLi} \cdot M_{BLi} + \epsilon_{BL}(t) \quad (7)$$

$$174 \quad A_{ST}(t) = a_{ST} + \sum b_{STi} \cdot M_{STi} + \epsilon_{ST}(t) \quad (8)$$

$$175 \quad \epsilon(t) = \epsilon_{BL}(t) + \epsilon_{ST}(t) \quad (9)$$

$$A_{ad}(t) = \epsilon(t) + \sum b_{BLi} \cdot \bar{M}_{BLi} + \sum b_{STi} \cdot \bar{M}_{STi} + a_{BL} + a_{ST} \quad (10)$$

Formula 7 and 8 are the multivariate regression models between baseline and short-term ozone and meteorological factors, respectively. $A_{ST}(t)$ and $A_{BL}(t)$ are the baseline and short-term components of ozone and M_{BL} and M_{ST} are the baseline and short-term components of meteorological factors. The parameters a and b are the fitted parameters and i is time points (days). $\epsilon(t)$ is the residual term. The average meteorological condition \bar{M} of the same calendar date throughout 11 years is used as the base condition for that date, and the meteorological adjustment is conducted against the base condition. By doing so, the inter-annual variation of meteorology is removed while the annual variation is largely reserved. With the homogenized annual variation of meteorological conditions, $A_{ad}(t)$ in formula 10 represents the meteorologically adjusted ozone variations, and the difference between $X(t)$ and $A_{ad}(t)$ reflects the meteorological impact. It is noted that, by using the average meteorological condition as the base condition, the average ozone concentration during the 11 years keeps unchanged.

2.3 Source apportionment of ozone contributions from local and non-local emissions

In this study, EOF and absolute principal component scores (APCS) are applied to apportion meteorologically adjusted ozone concentration into local and non-local emission sources. EOF transforms a large number of variables into a new set of uncorrelated, orthogonal principal components (PCs). The few new variables contains the most information of the original variables, and the new variables represent different processes contributing to ambient ozone levels. Here we present a brief description of EOF and APCS. Detailed information regarding the method can be found in Langford et al. (2009) and Berlin et al. (2013).

EOF analysis is performed on the correlation matrix from the meteorologically adjusted ozone data set (4018 days \times 15 stations), without further rotation of the PCs. The first step is to normalize the ozone data (Thurston and Spengler, 1985; Guo et al., 2004).

$$Z_{ik} = (C_{ik} - C_i)/S_i \quad (11)$$

where C_{ik} is the concentration of ozone in sample k of the station i , C_i is the arithmetic mean value of ozone in station i and S_i is the standard deviation.

$$Z_{ik} = L_{ip} \cdot P_{pk} \quad (12)$$

L_{ip} is loadings of EOF without rotation and P_{pk} is scores.

Since the factor scores are normalized with the mean to be zero, true zero is calculated through introducing an artificial sample with the zero concentration. Then the APCS are estimated by subtracting the artificial sample from the true samples.

$$(Z_0)_i = \frac{(0 - C_i)}{S_i} = -C_i/S_i \quad (13)$$

$$(APCS)_{pi} = P_{pi} - P_{0pi} \quad (14)$$

The regression between APCS and ozone concentration estimates source contributions to C_i by

$$C_i = (b_0)_i + \sum APCS_p \cdot b_{pi} \quad (15)$$

where $(b_0)_i$ is the constant term at station i , b_{pi} is the coefficient of the source p , and $\sum APCS_p$ is the scaled value of the factor p . Multiplication of $\sum APCS_p$ and b_{pi} calculates the contribution from source p to ozone concentration. Local and non-local sources are determined according to the temporal and spatial distribution characteristics of source contributions across the PRD.

3. Results and Discussion

219 **3.1 Long-term trend of meteorological impact on ozone concentration**

220 Fig. 3a shows the long-term trends of ambient ozone, meteorologically adjusted ozone, and the
221 meteorological impact in the PRD during 2007-2017. Ambient ozone concentration in the PRD increased
222 from $76 \mu\text{g m}^{-3}$ in 2007 to $89 \mu\text{g m}^{-3}$ in 2017, corresponding to an annual increase rate of $1.2 \mu\text{g m}^{-3}$.
223 Previous studies also evidenced ozone increase in the PRD (e.g. Li et al., 2014) and we here demonstrate
224 that such an increase has been continuing for more than a decade. After meteorological adjustment, ozone
225 concentration increases from $68 \mu\text{g m}^{-3}$ in 2007 to $90 \mu\text{g m}^{-3}$ in 2017, corresponding to an annual increase
226 rate of $2.0 \mu\text{g m}^{-3}$. Higher increase rate of meteorologically adjusted ozone implies that if the
227 meteorological condition keeps unchanged throughout the 11 years, ambient ozone concentration would
228 increase more significantly. As shown in Fig. 3a, meteorological conditions are generally favorable for
229 ozone pollution during 2007-2011, responsible for at most $6 \mu\text{g m}^{-3}$ of ozone increase. During 2012-2017,
230 meteorological condition became unfavorable for ozone pollution, leading to at most $6 \mu\text{g m}^{-3}$ of ozone
231 reduction. Comparing between the most favorable (2007) and unfavorable (2016) year, meteorological
232 condition change ozone concentration by $12 \mu\text{g m}^{-3}$ at most, roughly corresponding to 15% of annual
233 ozone concentration.

234

235 It should be noted that meteorological adjustment does not change the overall increasing trend of ozone
236 concentration, indicating that emission change is the primary driving factor for the long-term ozone trend.
237 However, as shown in Fig. 3a, the fluctuation of ozone concentration is suppressed by meteorological
238 adjustment, indicating that meteorology plays an important role in the inter-annual fluctuation of ozone
239 concentration, especially during 2011-2015 when ozone changes due to emissions are minor. This is
240 largely caused by emission changes within and outside the PRD. Emissions inventory in the PRD (Fig.
241 S1) shows that increase in VOCs emission started to mitigate in 2011, while NO_x emissions showed
242 significant reduction starting from 2013. As PRD is generally in a VOC-limited ozone formation regime,
243 reduction in the magnitude of VOCs emission increase is likely responsible for the minor changes in
244 ozone during 2011-2015. During some specific period, meteorology plays a greater role in governing
245 ozone changes than emissions, such as during 2016-2017 as will be discussed in section 3.4. As shown
246 in Fig. 3b, variations of ozone before (black lines) and after (blue lines) meteorological adjustment
247 demonstrated that meteorological adjustment significantly reduces the magnitude of ozone spikes,
248 indicating that meteorological condition is one of the most important driving factors for ozone episodes
249 in the PRD. Therefore, ozone precursor emission control should be strengthened during adverse weather
250 condition to lower peak ozone levels.

251

252 Fig. 3c shows the impacts from different meteorological factors (T, RH, SSR, u and v) on ozone
253 concentration. Overall, SSR is the most crucial factor and their variation follows well with that of the
254 total meteorological impact. Contribution from the other four factors are comparable and relatively
255 insignificant. As expected, higher SSR, higher T and lower RH are favorable for ozone production.

256

257 **3.2 Spatial distribution of meteorological impact**

258 We further examine the spatial distribution of meteorological impact. Fig. 4a shows the spatial
259 distribution of averaged ozone concentration in the PRD and the annual ozone concentration changes
260 before and after meteorological adjustment. Although northeastern PRD has the overall highest ozone
261 concentrations, central and western PRD shows the most rapid ozone increase during the 11 years (black
262 bars), and such increases are further substantiated if meteorological impact is removed (green bars).

263 There are two sub-regions in the PRD with overall decreased ozone concentrations, one in the northeast
264 (TH and JGW) and the other in the southwest (ZML and TJ). The ozone decrease is largely mitigated or
265 at ZML even reversed after meteorological adjustment. The different mechanisms leading to the ozone
266 increase in these two sub-regions are explained by a conceptual diagram in section 3.6.

267

268 The spatial distribution of meteorological impact in each year during 2007-2017 is illustrated in Fig. 4b.
269 It is noted that when the meteorological condition favors ozone pollution in the PRD, it increases more
270 in the central and western area. On the contrary, when it decrease ozone concentration in the PRD, central
271 and western PRD is also the region with larger decrease in most years. Therefore, central and western
272 PRD is a meteorology-sensitive region for ozone pollution. Generally, area with higher pollutant
273 emission is more sensitive to changes in meteorological condition (Seo et al., 2014). Various studies have
274 shown that central and western PRD is the area with the most intense VOCs and NO_x emissions over the
275 PRD (e.g. Zheng et al., 2009a), therefore is more sensitive to meteorological condition. Formulation of
276 ozone control strategy in this region needs to consider meteorological impact.

277 **3.3 Identification of ozone changes resulted from local and non-local emissions**

278 Long-term variation of meteorologically adjusted ozone reflects the impacts from precursor (VOCs and
279 NO_x) emission changes. As ozone can be contributed by both local production and long-range transport,
280 it is important to quantitatively separate them from an emission control point of view. Considering PRD's
281 monsoonal synoptic condition and that most local emissions are concentrated in the central and western
282 PRD area, local ('within PRD') emissions tend to pose contrasting impacts to different sub-regions in
283 different seasons while the impacts from non-local ('outside PRD') emissions in a relatively larger scale
284 tend to be spatially similar over the PRD. We use this philosophy to examine the PCs derived from EOF
285 analysis.

286

287 According to the Kaiser's rule (Wilks, 2006), three PCs are retained in EOF analysis, explaining 53%,
288 16% and 7% of total variance, respectively. Fig. 5a shows the interpolated PC loadings in the PRD, and
289 Fig. 5b shows the long-term variation of PC scores during the 11 years. PC1 shows relatively consistent
290 spatial distribution across PRD, with its loadings ranging from 0.47 at TH to 0.84 at JJZ. Further
291 examination on the relationship between PC scores and wind direction discovered that the score of PC1
292 is higher during high ozone concentration in the PRD, and is associated with northeasterly wind (Fig.
293 6a). Situated along the southeastern coast of China, PRD has two main prevailing winds, northeasterly
294 mainly during winter and spring and southwesterly mainly during summer and fall. Northeasterly wind
295 tends to bring emissions from inland to the PRD, while southwesterly wind originated from the ocean is
296 relatively clean. All the above evidences support the notion that PC1 is associated with non-local impact
297 from continental long-range transport. Higher impact in the central PRD may be caused by the rough
298 land use and micro-scale circulation in this urbanized region that increases the residence time of non-
299 local ozone. The score of PC1 (Fig. 5b) is almost consistently increasing during the 11 years, indicating
300 increased ozone contribution from long-range transport. It should be noted that meteorological
301 adjustment is conducted against the base condition which is the average meteorological condition of the
302 same calendar date throughout 11 years. Therefore, meteorological adjustment removes the inter-annual
303 variation of meteorological condition, while still preserves seasonal variation and make it consistent in
304 all years. Therefore, the monsoonal characteristics (northerly or northeasterly winds in winter and
305 southerly and southwesterly winds in summer) still remain and act as an important justification for PC
306 determination.

307

308 In comparison, PC2 and PC3 loadings show significant spatial variations. PC2 loadings have an obvious
309 north-south gradient with different signs, indicating that the impact of PC2 on northern and southern
310 PRD are reversed at all times. Further examination on their relationship with wind direction, as shown
311 in Fig. 6b and 6c, indicates that during high ozone periods, PC2 score tends to be positive with southerly
312 winds and negative with northerly winds. With southerly winds, northern PRD receives the highest
313 impact from PC2, leading to increased ozone concentration. On the contrary, southern PRD receives the
314 highest impact (negative score and negative loading) with northerly winds. This reflects exactly the
315 impact from emissions within the PRD posed by the north-south components of the prevailing winds.
316 Similarly, PC3 is associated with the impact from local emissions by the west-east components of the
317 prevailing winds. Therefore, PC2 and PC3 collectively reflect the impact of local emissions on ozone
318 formation. PC2 and PC3 scores show a bimodal pattern that are higher in 2007 and 2011-2014 (Fig. 5b).
319 This suggests that local emissions pose higher ozone contribution to northern and eastern PRD during
320 2007 and 2011-2014 and to southern and western PRD during 2008-2010 and 2015-2017.

321

322 The PC loadings and scores may reflect the spatial distributions and temporal variations of the PCs,
323 respectively. However, as they are normalized values, APCS calculation is conducted to quantify the
324 absolute ozone contributions from local and non-local emission sources. As explained earlier, the impacts
325 from non-local ozone by long-range transport tend to be spatially more consistent within the PRD, while
326 those from local ozone is more spatially inconsistent. With such a philosophy, we select Tianhu (TH) in
327 the north, Luhu (LH) in the central, and Donghu (DH) in the south of PRD to study the long-term trend
328 of ozone contributed by local and non-local emission sources in different areas, as shown in Fig. 7. Ozone
329 contributions from local and non-local at the other stations is provided in Fig. S2. A first glance on this
330 figure reveals identical and consistently increasing non-local trends at all three stations. Actually, ozone
331 level in most areas of China was increasing during the past years, which inevitably led to increased non-
332 local contribution to ozone over the PRD (Lu et al., 2018) Non-local emission contributions at DH reach
333 $90\sim 115\ \mu\text{g m}^{-3}$, more than doubling those of $44\sim 56\ \mu\text{g m}^{-3}$ at TH. As explained previously, such a spatial
334 heterogeneity is mainly caused by longer residence time of non-local ozone in the urbanized area. In
335 comparison, local emission contributions show differences in both magnitude and trend over three
336 stations. Local emission contribution on ozone ranges from $15\sim 30\ \mu\text{g m}^{-3}$ at TH, $1\sim 6\ \mu\text{g m}^{-3}$ at LH, and
337 $-30\sim -15\ \mu\text{g m}^{-3}$ at DH. As a net effect of ozone production and loss, the positive or negative sign of local
338 emission contribution reflects the relative strengths of ozone production by HO_x and RO_x cycles and
339 ozone loss by NO titration and deposition. As non-local emission contributions dominate over the local
340 counterpart at all stations, its consistently increasing trend determines the meteorologically adjusted
341 ozone trend over the 11 years.

342

343 We further plot the spatial distribution of ozone contribution from local and non-local emissions and its
344 long-term changes over the PRD, as shown in Fig. 8. Local emissions give positive contribution to
345 northeastern, with the largest contribution of $31\ \mu\text{g m}^{-3}$ at JGW, and negative contribution to southwestern,
346 with the largest contribution of $-23\ \mu\text{g m}^{-3}$ at DH. Furthermore, apart from reversed ozone contribution
347 from local emissions, northeastern and southwestern PRD also exhibit reversed trends in changes of
348 ozone contribution from local emissions during the 11 years, as illustrated in the bars of Fig. 8. The most
349 significant increase trend is found over southwestern, with the largest increase rate of $0.6\ \mu\text{g m}^{-3}\ \text{year}^{-1}$
350 at DH, while the most significant decrease trend is found over northeastern, with the largest decrease rate

351 of $0.8 \mu\text{g m}^{-3} \text{ year}^{-1}$ at JGW. The underlying mechanism resulting in the opposite trends in both local
352 ozone contribution and its long-term changes between northeastern and southwestern are explained with
353 a conceptual diagram in section 3.6. In comparison, the ozone contributions from non-local emissions
354 are relatively consistent over the PRD, and non-local emission poses increasing influence on ozone for
355 the entire region.

356

357 **3.4 Identification of driving factors for ozone changes in 2016 and 2017**

358 With meteorological adjustment and source apportionment, the contributions from meteorology and local
359 and non-local emissions to the ambient ozone changes can be quantitatively analyzed for all years at all
360 stations. Due to the limitation of space, we here select the recent two years, 2016 and 2017, and
361 demonstrate this capability by analyzing the relative importance of meteorology and local and non-local
362 emissions to the ozone changes during these two years, 2016 and 2017. Significant ozone level increases
363 are revealed at most stations during the two years, with the average concentration rising from $81 \mu\text{g m}^{-3}$
364 in 2016 to $87 \mu\text{g m}^{-3}$ in 2017 for PRD. It is found that meteorology, local emission and non-local emission
365 contribute to around $3.5 \mu\text{g m}^{-3}$, $-0.1 \mu\text{g m}^{-3}$ and $2.0 \mu\text{g m}^{-3}$ of ozone increase, respectively. Overall,
366 meteorology plays a greater role in elevating ozone levels during these two years.

367

368 Contributions from meteorology and local and non-local emissions are further analyzed at each
369 monitoring station, as listed in Table 2. Under general conditions, in comparison with local and non-local
370 emissions, meteorology gives the highest contributions to ozone changes at all stations except for CZ
371 and DH, the two southwestern-most stations. In addition, local emissions gives higher contributions than
372 non-local ones at CZ, DH, JJZ, ZML and TJ, the cluster of stations in the southwestern PRD. Therefore,
373 the ozone increase over southwestern PRD during these two years is most attributable to local emission
374 changes, while the ozone increase in other parts of the PRD is firstly driven by meteorological condition
375 changes, followed by non-local emission changes. This suggests that in order to reduce ozone levels in
376 the southwestern PRD, strengthening local VOCs emission control should be of the top priority, so as to
377 prevent ozone titration from decreasing further.

378

379 **3.5 Impact of meteorology and emission changes during ozone episodes**

380 In this section, we examine the impacts of meteorology and local and non-local emission changes to
381 ambient ozone level during ozone episodes. Ozone episodes are defined as days with MDA8 ozone
382 concentration greater than $160 \mu\text{g m}^{-3}$ at five stations or more across the PRD. During 14 years, there are
383 in total 442 days identified as ozone episodes. The number of ozone episodes are much smaller than that
384 during general conditions, therefore the results below might be associated with larger uncertainties than
385 that during general conditions.

386

387 Ozone levels during episodes are the highest in the central PRD, mainly Guangzhou and Foshan, as
388 shown in Fig. S3. Fig. S4 shows the long-term trends of ambient ozone, meteorologically adjusted ozone,
389 and the meteorological impact in the PRD during ozone episodes in 2007-2017. Ambient ozone
390 concentration during episodes increases from $150 \mu\text{g m}^{-3}$ in 2007 to $161 \mu\text{g m}^{-3}$ in 2017, corresponding
391 to an annual increase rate of $1.0 \mu\text{g m}^{-3}$. It is noteworthy that meteorological adjustment does not alter
392 ozone concentration much, with the largest change of $3 \mu\text{g m}^{-3}$ only. This implies that, although with
393 significant variation under general conditions, meteorology does not vary significantly during ozone
394 episodes across all years. Changes in precursor emissions are therefore the driving factor for long-term

395 ozone variations during ozone episodes. A slightly different picture is discovered in 2017 during which
396 meteorology is the major culprit for ozone increase. Without meteorological impact, ozone level during
397 episodes should be lower than that in 2016.

398

399 We further differentiate ozone changes into those by local and non-local emissions using EOF/APCS
400 approach. Four principal components are discovered, and they are assigned to local or non-local
401 emissions by their spatial variations, as shown in Fig. S3. Fig. 9 illustrates the long-term trend of ozone
402 contribution by local and non-local emissions during ozone episodes at TH, LH and DH stations. At TH
403 and LH, non-local emissions give dominant contribution to ozone, while local emissions pose negative
404 impacts, while contributions from local and non-local emissions are comparable at DH. Different from
405 general conditions during which non-local contribution shows a consistently increasing trend, non-local
406 contribution fluctuates greatly during ozone episodes and presents a bimodal picture. Starting from 2014,
407 ozone contribution from non-local emissions has leveled off and decreased gradually. This may be related
408 to the VOCs and NO_x emissions in the non-PRD area in Guangdong (Fig. S1) and further upwind area,
409 and deserves further study.

410

411 Local emission contribution to ozone during episodes differs greatly in different areas. As shown in Fig.
412 10a, local emissions give positive contribution to southwestern, with the largest average contribution of
413 78 $\mu\text{g m}^{-3}$ at DH. They pose negative contribution to northeastern, with the largest contribution of -36 $\mu\text{g m}^{-3}$
414 at TH and HG. Such a spatial distribution is contrary to that during general conditions, as illustrated
415 in Fig. 8a. Stations over central PRD show increasing trend, with the largest increase rate of 1.9 $\mu\text{g m}^{-3}$
416 year⁻¹ at HG, while stations surrounding central and western PRD show decreasing trend, while the
417 largest decrease rate of 3.5 $\mu\text{g m}^{-3}$ year⁻¹ at JGW. In comparison, ozone contributions from non-local
418 emissions are relatively consistent over the PRD, with the hotspot shifted from central and western PRD
419 under general conditions (Fig. 8b) to central and eastern PRD during ozone episodes (Fig. 10b). The
420 entire PRD experienced increasing ozone contribution from non-local emission. Comparing with non-
421 local emission, ozone contribution from local emission and its trend show significant spatial
422 heterogeneity. We develop a conceptual diagram to explain in detail the underlying mechanisms resulting
423 in the distinct spatial distribution of local ozone contribution and its trend between general conditions
424 and ozone episodes, as elaborated in section 3.6.

425

426 **3.6 A conceptual diagram describing impact of local emission changes to ozone in the Pearl River** 427 **Delta**

428 As discussed in section 3.3 and 3.5, the spatial pattern of ozone contribution from local ('within PRD')
429 emissions and its long-term changes in the PRD under general condition and during ozone episodes
430 present different pictures. Under general condition, local emissions give positive and decreasing
431 contribution to ozone over northeastern PRD, and negative and increasing contribution over southwestern
432 (Fig. 8a). In contrast, during ozone episodes, local emissions give negative and decreasing contribution
433 over northeastern, and positive and decreasing contribution over southwestern. Central and western PRD
434 is the only region having slight increasing local ozone contribution during episodes (Fig. 10a). In this
435 section, we aim to provide detailed explanation on such phenomena by developing a conceptual diagram
436 collectively taking into account ozone precursor emissions and their changing trends, ozone formation
437 regimes, and the monsoonal and micro-scale synoptic conditions over different sub-regions of the PRD.

438

439 **3.6.1 General condition**

440 PRD has distinct VOCs and NO_x emission characteristics across its different sub-regions, leading to
441 different prevailing ozone formation regimes (OFR) over the PRD. Central PRD, essentially western and
442 southern Guangzhou, Foshan and western Dongguan, is the area with the most significant economic and
443 industrial activities. Central PRD is associated with significant amount of VOCs and NO_x emissions
444 (Zheng et al., 2009b, Zhong et al., 2018), and is mostly in a VOC-limited OFR (Ye et al., 2016). The
445 polluted air mass can be transported to different areas of the PRD under different prevailing winds, and
446 largely determines the ozone behaviors over those areas. In the past years, NO_x emissions are decreasing
447 due to stringent control measures, while VOCs emissions are increasing, as shown in Fig. S1.

448

449 Northeastern PRD is mainly a rural area with plenty of vegetation coverage. Significant VOC emissions
450 from biogenic sources make it primarily in a NO_x-limited OFR, especially in summer (Ye et al., 2016).
451 In summer and fall, southwesterly winds originated from the South China Sea prevail, bringing the NO_x-
452 laden air mass from central PRD to the downwind NO_x-limited northeastern and increasing ozone levels
453 over TH, XP and JGW stations. However, NO_x/VOC ratio in the air mass is decreasing during the past
454 years due to emission control measures that are preferentially targeting on NO_x emissions. Lowered
455 NO_x/VOC ratio would inhibit ozone production in the NO_x-limited northeastern, leading to a downward
456 ozone trend. In contrast, southwestern PRD shows relatively higher NO_x/VOC emission ratios, and is
457 mostly in a VOC-limited OFR (Ye et al., 2016). The OFR would shift to be more VOC-limited in winter
458 due to the suppressed biogenic VOC emissions and reduced reaction rate of HO_x and RO_x cycles. In
459 winter and spring, northeasterly winds originated from the Eurasia Continent prevail, bringing the NO_x-
460 laden air mass from the central PRD to the southwestern. The NO_x-laden air mass would react
461 preferentially with ozone in the VOC-limited southwestern, thereby decreasing the ozone levels at CZ,
462 DH and ZML stations. Due to the strengthened NO_x emission control that reduces NO_x/VOC ratio from
463 the central PRD, ozone titration is largely mitigated, leading to an upward ozone trend over southwestern
464 in the past few years. Fig. 11 provides a conceptual diagram on the impact of local emission control on
465 ozone concentrations and their changing trends over the PRD.

466

467 Hence, the combined influences by reduced ozone titration from local emissions and increased ozone
468 import from non-local emissions make southwestern the area having the most rapid ozone increase over
469 the PRD. In order to curb ozone increase in the southwestern, VOC emission control within the PRD
470 must be strengthened to elevate NO_x/VOC ratio into a level that ozone titration would not be further
471 reduced. With decreased influence from local emissions, northeastern shows the least ozone increase.

472

473 **3.6.2 Ozone pollution episodes**

474 Both meteorology and precursor emissions exhibit significant differences during ozone episodes in
475 comparison with general conditions. Ozone episodes typically happen in summer and fall with hot and
476 sunny weather and weakened background wind, which is very often associated with a high pressure ridge
477 or approaching of a tropical cyclone (Huang et al., 2006). Temperature very often rises above 32 degree
478 Celsius with abundant sunshine, leading to more intense biogenic VOC emissions over the PRD.
479 Considering NO_x emissions are insensitive to temperature rise and the high reactivity of biogenic VOCs,
480 the effective NO_x/VOC ratio becomes much lower. As a result, NO_x-limited OFR over northeastern is
481 intensified, and VOC-limited OFR over southwestern shifts to NO_x-limited. VOC-limited area shrinks to
482 merely central PRD and the magnitude is largely weakened (Wang et al., 2011; Jin and Holloway, 2015).

483 Due to significant NO_x emissions, the urban central PRD is probably the last area turning into NO_x-
484 limited due to enhanced biogenic VOC emissions during ozone episodes.

485

486 In addition, the prevailing wind direction changes from northeasterly / southwesterly to easterly, as shown
487 in Fig. S6. With weakened background wind, micro-scale circulations such as land-sea breeze develop
488 around the Pearl River Estuary (PRE), and becomes an effective mechanism in trapping and mixing up
489 pollutants emitted surrounding the PRE (Lo et al., 2006). Micro-scale circulations increase the residence
490 time of pollutants over the PRE and thus expedite chemical reactions to produce ozone. High ozone
491 produced around the PRE is brought to southwestern PRD (a 'sink' region) by the weak easterly wind,
492 thereby increasing ozone levels at DH, ZML and TJ stations. In contrast, with easterly wind, northeastern
493 receives little impact from the central PRD ozone hotspot while instead serves as a 'source' region (ozone
494 import from further east is accounted for as impact from non-local emissions), thereby providing negative
495 contribution at TH, XP, JGW, HG and LH stations.

496

497 With higher biogenic VOC emissions and VOC oxidation rate, the OFR distribution over the PRD during
498 ozone episodes vary from that under general conditions. The preferential NO_x emission reduction due to
499 stringent control would lead to downward trend of local ozone contribution over northeastern due to
500 intensified NO_x-limited OFR, also downward trend over southwestern due to shift from VOC-limited to
501 NO_x-limited OFR (Jin and Holloway, 2015). An upward trend is only discovered over central and western
502 PRD (HG, LH, HJC and ZH) where NO_x emissions are very strong and still persist in VOC-limited OFR.
503 Fig. 12 provides a conceptual diagram on the impact of local emission control on ozone concentrations
504 and their changing trends over the PRD during ozone episodes.

505

506 Hence, even with different formation mechanisms from general conditions, southwestern PRD, mainly
507 Zhongshan, Zhuhai and eastern Jiangmen, is still the area with the most significant impact from local
508 emissions during ozone episodes. However, with less NO_x emissions than central PRD, OFR over
509 southwestern has shifted from VOC-limited to NO_x-limited, leading to reduced local ozone contribution.
510 Comparison of different trends between central and southwestern PRD actually highlights the fact that
511 NO_x emission control is one of the possible means to reduce ozone levels over the PRD, especially during
512 ozone episodes with significantly enhanced biogenic VOCs emissions. Further reduction of NO_x
513 emissions, after bypassing the optimal effective NO_x/VOC ratio leading to the highest ozone
514 concentration, would rapidly pull down peak ozone level and eventually bring it into attainment (Ou et
515 al., 2016). Different OFR characteristics under general condition and during ozone episodes also
516 highlight the importance of formulating dynamic control measures tailored for different emission and
517 meteorological conditions.

518

519 **4. Conclusion and Implication**

520 Ambient ozone level in a particular area is determined by the interaction between meteorology and
521 emission of ozone precursors, VOCs and NO_x. Differentiation of their impacts are important to evaluate
522 the effectiveness of emission control measures in the past and to shed light on directions for future control
523 plans. In this study, we develop a statistical analysis framework to identify ozone changes attributable to
524 meteorology and local and non-local emissions in the PRD. The framework is essentially a combination
525 of meteorological adjustment and source apportionment by EOF. We found that meteorology does not
526 alter the increasing trend of ozone during 2007-2017, but significantly mitigate the magnitude of

527 increasing. Ozone increase solely due to precursor emission changes would have been more significant.

528

529 In comparison with non-local precursor emissions, the impacts of local precursor emissions on ambient
530 ozone present significant spatial and temporal heterogeneity over the PRD. Northeastern and
531 southwestern exhibit different net ozone production and loss characteristics under general conditions and
532 during ozone episodes. In response to the preferential NO_x emission control during the past years, local
533 ozone contribution decreases over northeastern and increases over southwestern under general conditions,
534 while decreases over both northeastern and southwestern but increases over central and western PRD
535 during ozone episodes. Such a complex characteristics can be well interpreted by a conceptual diagram
536 collectively taking into account ozone precursor emissions and their changing trends, ozone formation
537 regimes, and the monsoonal and micro-scale synoptic conditions over different sub-regions of the PRD.
538 In particular, OFR shift during ozone episodes in response to higher biogenic VOC emissions and VOC
539 oxidation rate is the fundamental cause for different trends both spatially and temporally. We conclude
540 that the past control measures preferentially targeted on NO_x are most likely responsible for ozone
541 increase in the PRD, especially over southwestern by reduced ozone titration. However, OFR has started
542 to shift from VOC-limited to NO_x-limited over southwestern, especially during ozone episodes.
543 Therefore, NO_x emission control should be further strengthened to alleviate peak ozone levels.

544

545 By investigating the ozone evolution influenced by emission changes within and outside PRD during the
546 past decade, this study highlights the complexity in ozone pollution control in the PRD. The complexity
547 lies in three aspects. First, ozone control should be location-specific. Northeastern is the area benefited
548 from current control measures in the PRD, and the main focus should be on co-prevention and co-control
549 with further northeastern areas, e.g. Jiangxi and Fujian, to reduce long-range transport; Central and
550 southwestern PRD should pay more efforts on VOCs control to elevate NO_x/VOC ratio into a level that
551 ozone titration would not be further reduced. Second, ozone control should be temporally dynamic and
552 largely dependent upon meteorological conditions. OFR may change greatly under different
553 meteorological conditions which would influence effective control strategy and deserve more in-depth
554 investigation. In particular, precursor emissions surrounding the PRE should be preferentially controlled
555 during ozone episodes as they may contribute greatly to ozone formation when trapped over PRE by the
556 micro-scale circulations. They are responsible for ozone hotspot over southwestern with a drastically
557 increasing trend. Last but not least, under every circumstance, the most desirable NO_x/VOCs ratio for
558 emission control should be investigated in detail. For example, control measures during ozone episodes
559 should preferentially target on NO_x in the context of significantly enhanced biogenic VOCs emissions.
560 Comparison of different trends between central and southwestern PRD provides a perfect highlight on
561 the effect of NO_x control. Further reduction of NO_x emissions, after bypassing the optimal effective
562 NO_x/VOC ratio leading to the highest ozone concentration, would rapidly pull down peak ozone level
563 and eventually bring it into attainment (Ou et al., 2016).

564

565 **Authorship Contribution Statement**

566 ZY and JZ designed the experiments and LY, HL, XL and YB carried them out. PKKL and DC provided
567 ozone monitoring data and contributed to the discussion of the results. LY and ZY drafted the paper, with
568 all co-authors contributing to subsequent enhancements.

569

 808 station and their annual change rate in the Pearl River Delta during ozone episodes. Bars in blue above / in
 809 purple below the station point indicate increasing / decreasing contributions trend. The bar length in the
 810 legend corresponds to an annual increase of $2 \mu\text{g m}^{-3}$. Ozone contributions from local emissions are positive
 811 in the southwestern and negative in the northeastern. Central PRD is the only area with increasing local
 812 ozone contribution trend. Ozone contributions from non-local emissions are positive and increasing region-
 813 wide.

814

815

816

(a)

(b)

817 Fig 11. A conceptual diagram on the impacts of local emissions on (a) ozone concentrations and (b) their
 818 changing trends over the Pearl River Delta. Local NO_x -laden emissions increase ozone level ($\text{O}_3 \uparrow$) in the
 819 downwind northeastern in summer and fall, but the increase is suppressed due to the preferential NO_x
 820 control ($\Delta \text{NO}_x \downarrow$), leading to net ozone decrease ($\Delta \text{O}_3 \downarrow$). In comparison, local emissions decrease ozone
 821 level ($\text{O}_3 \downarrow$) in the downwind southwestern in winter and spring, but the decrease is also mitigated due to
 822 NO_x control ($\Delta \text{NO}_x \downarrow$), leading to net ozone increase ($\Delta \text{O}_3 \uparrow$). Such a phenomenon is essentially governed
 823 by different ozone formation regimes in northeastern (NO_x -limited) and southwestern PRD (VOC-limited).

824

825

(a)

826

827

(b)

828 Fig 12. A conceptual diagram on the impact of local emissions on (a) ozone concentrations and (b) their
 829 changing trends in the Pearl River Delta during ozone pollution episodes. The blue curved angles indicate
 830 micro-scale circulations such as land-sea breeze developed around the Pearl River Estuary (PRE). The
 831 micro-scale circulation leads to a high ozone area around the PRE due to effective mixing and reaction
 832 between VOCs and NO_x. High ozone is transported to southwestern by easterly wind, increasing local ozone
 833 contribution. In comparison, northeastern is a source region of ozone therefore its local contribution is
 834 negative. With higher biogenic VOC emissions and VOC oxidation rate during ozone episodes, most of PRD
 835 is in the NO_x-limited ozone formation regime except for urban central PRD which is still VOC-limited due
 836 to intense NO_x emissions. Therefore, reduced NO_x emissions ($\Delta \text{NO}_x \downarrow$) lead to decreasing ozone level (ΔO_3
 837 \downarrow) over both northeastern and southwestern and increasing ozone level over central PRD ($\Delta \text{O}_3 \uparrow$).

838
