Abstract.

With the increased concerns on the shipping emitted air pollutants, the feasible technology for the surveillance is in high demand. Here we presented the shore-based Multi-Axis Differential Optical Absorption Spectroscopy (MAX-DOAS) measurements of emitted SO₂ and NO₂ from ships under different traffic conditions in China's ship emission control area (ECA) of Shanghai and Shenzhen, China. These three typical measurement sites are used to represent emission scenarios of ship docked at berth, navigation in the inland waterway and inbound/outbound in the deep water port. With 2-dimensional scanning, the observation shows that the hotspots of SO₂ and NO₂ can be quickly and easily located from multiple berth. Although the MAX-DOAS measurements can not distinguish the single ship plume in the busy shipping lanes of inland waterway area, it certifies that the variations of SO₂ and NO₂ levels are mainly impacted by the ship traffic density and atmospheric dispersion conditions. In the open water area with low density of vessels, the MAX-DOAS measurements can capture the pulse signal of ship emitted SO₂ and NO₂ very well, and characterize the peaks altitude and insistent duration of the individual ship plumes. Combined with the ship information of activity data, rated power of engine and fuel sulfur content, it was found that SO₂/NO₂ ratio in single plume is usually low (<1.5) for inbound vessel due to the usage of auxiliary engine with less power and clean fuel of low sulfur content. Meanwhile, the unexpected high SO₂/NO₂ ratio implies the fuel usage with sulfur content exceeding limit of regulations. Therefore, the observed SO₂/NO₂ ratio in the plume of single ship can be used as the index for the compliance of fuel sulfur content, and then tag the suspicious ship for further enforcement. Combined the ship emission estimated by actual operation parameters and logical sulfur content, the shore-based MAX-DOAS measurement will provide the fast and more accurate way for the surveillance of ship emissions.

1 Introduction

Sulphur dioxide (SO₂) and nitrogen dioxide (NO₂) are the important air pollutants, and also recognized as the main pollutants of ship emissions (Corbett et al., 1999; Endresen et al., 2003; Eyring et al., 2010; Matthias et al., 2010). Both of them can

engage in the atmospheric chemical reactions to produce aerosols and acid rain, and further have negative effects on the air quality, climate system, and human health, as well as acidification of terrestrial and marine ecosystem (Berglen et al., 2004; Seinfeld and Pandis, 2006; Singh, 1987). Moreover, NO₂ is also the key substance to form photochemical smog (Dimitriadis, 1972). With the rapid growth of the transportation volume, air pollution has become the most challenging environmental issue in the shipping industry, such as the emissions of SO₂, NO_x, particles and greenhouse gases (Eyring et al., 2005; Becagli et al., 2012; Coggon et al., 2012; Diesch et al., 2013; Lauer et al., 2007). Eyring et al. (2010) reported that ships contribute 15% of global NO_x emissions and 4-9% of SO₂, respectively. In the view of spatial distribution, global hotspots with high SO₂ and NO₂ emissions were identified to be the regions in Eastern and Southern China Seas, the sea areas in the south-eastern and southern Asia, the Red Sea, the Mediterranean, North Atlantic near the European coast, and along the western coast of North America, etc. (Johansson et al., 2017). In China, ship emitted pollutants play important roles in the air quality, human health and climate (Lai et al., 2013; Liu et al., 2016; Yang et al., 2007). It not only affects the air quality in coastal areas, but even influences the inland areas hundreds kilometers away from the emission sources (Lv et al., 2018). The port city is the most affected by ship pollution, followed by cities along the river. As an example, ship emitted SO₂ and NO_x occupied for 12.4% and 11.6% of total emissions of the whole city of Shanghai in 2012, respectively, while there could be 64% of primary PM_{2.5} contributed by ships in Shanghai Port transported to inland region (Fan et al., 2016; Zhao et al., 2013).

In order to reduce the negative impacts of ship emissions, the European Union and the United States have implemented regulations in an effort to decrease ship emissions (Kattner et al., 2015), among which the fuel quality regulation has been proven to be the most effective measures for addressing the issue of sulphur oxides (SO_x) and particulate matter (PM) emissions in many countries. Besides, the International Maritime Organization (IMO, 2009) also has set up multiple emission control zone (ECA) worldwide. It stipulates that all ships shall use fuel oil with a sulfur content not more than 0.5% (mass fraction) during the berthing of all ports within the ECA by 2020. The regulations also set limits for pollutant emissions such as NO_x and CO₂ in the exhaust gas. Since January 1st, 2017, ships berth at the core ports of three designated Domestic Emission Control Area (DECA) in Pearl River Delta (PRD), the Yangtze River Delta (YRD) and the Bohai Rim (Beijing-Tianjin-Hebei area) of China should use fuel with sulphur content less than or equal to 0.5% (MOT, 2015). As a consequence, it is obviously that the reliable and practical monitoring system are highly demanded for the implementation of ECA regulations.

The common options to monitor ship emissions can be classified into two categories: estimates based on activity data or written documentation; and measurements of on-board fuel sample and exhaust gas made on board the ship. Basically, the continuous online monitoring of fuel and exhaust gas on-board is the highly effective and accurate supervision means, but less operability in practice. For the regulatory party, fuel sampling and document inspection are currently the common measures and the sulfur content in the fuel is usually fast detecting after the ship is docked. Besides, other technical methods has been developed to determine both SO₂ and NO_x emissions, such as a new type of ship exhaust gas detection technology that mounts a portable sniffer/instrument on board a ship or on a helicopter (Beecken et al., 2015; Berg et al., 2012; Murphy et al., 2009; Villa et al.,

2016). Alternatively, shore-based remote sensing is another effective way to measure the ship plume and further estimate the sulfur content, when ships pass the lanes or dock at berth.

70 Remote sensing technique shows the advantages of fast detection, easy operation and high automation. Besides the passive “sniffing” method with in-situ instrumentation, optical remote sensing technique can detect the variation of the light properties after interaction with the exhaust plume and corresponding SO₂ and NO₂ emission in the plume, such as differential optical absorption spectroscopy (DOAS), light detection and ranging (LIDAR), and the ultraviolet camera (UV-CAM) technique (Balzani et al., 2014; Seyler et al., 2017). LIDAR system can be used to retrieve a 2-dimensional concentration distribution by scanning through the ship plume, and to obtain the ship emissions combining the wind and concentration profiles. McLaren et al. (2012) employed active long-path DOAS technique to measure NO₂-to-SO₂ ratios in ship plumes and speculate on its relationship with the sulfur content of fuels. UV camera has been successfully applied to measure the SO₂ concentrations and emission rates of moving and stationary ship plumes (Prata, 2014).

80 DOAS technique allows to identify and quantify the absorption of variety of species showing characteristic absorption features in the wavelength range (Platt and Stutz, 2008). It has been widely used for trace gases measurements in several decades, especially very mature for NO₂ and SO₂ (Edner et al., 1993; Mellqvist and Rosén, 1996; Platt et al., 1979). As an expanded apparatus, the multi-axis differential optical absorption spectroscopy (MAX-DOAS) measurements are high sensitivity to aerosols and trace gases in the lower troposphere by observing scattered sunlight under different viewing angles closed to the horizontal and the zenith directions (Hönninger et al., 2004; Ma et al., 2013; Sinreich et al., 2005; Wang et al., 2014). Due to its portability, MAX-DOAS instrument can be carried on the ship to observe the vertical column densities (VCDs) of NO₂ and SO₂ along the cruise, during which high levels of pollutants were found close to the busy port and dense lanes (Hong et al., 2018; Schreier et al., 2015; Takashima et al., 2012; Tan et al., 2018). In addition, MAX-DOAS has been successfully employed for monitoring shipping emissions directly. Premuda et al. (2011) used the ground-based MAX-DOAS measurements to evaluate the NO₂ and SO₂ levels in ship plume discharged from the single ship in the Giudecca Strait of the Venetian Lagoon. Seyler et al. (2017) have utilized MAX-DOAS to perform long-term measurements of NO₂ and SO₂ from shipping emissions in the German Bight, and evaluated the reduction in SO₂ levels after implement stricter sulfur limits in shipping fuel.

In this study, the shore-based MAX-DOAS measurements were employed to measure the NO₂ and SO₂ in ship plumes for different ship traffic environments of Shanghai and Shenzhen, China. Combined with the photos taken by the camera of instrument and AIS (Automatic Identification System) information, it is verified that emissions of ships at berth, passing through the inland waterway and open sea areas can be successfully detected. The measurements can also provide the fuel sulfur content information of individual ship by comparing the emitted NO₂ and SO₂ in the plume. With the fuel sample analysis and ship activity data, it suggests that the shore-based MAX-DOAS method shows the feasibility and reliability of surveillance for ship emitted SO₂ and NO₂ and further allows to know compliance of fuel sulfur content.

2 Measurements and method

2.1 MAX-DOAS measurements for ship emissions

105 The algorithm of DOAS is basically based on Lambert-Beer law, which describes the extinction of radiation through the atmosphere (Platt and Stutz, 2008). MAX-DOAS instruments observe scattered sunlight from various viewing directions and stored in the form of spectrum (e.g. Hönninger et al., 2004; Sinreich et al., 2005). The spectral analysis generates the measured SCD (slant column densities), defined as the integral of the trace gas concentration along the entire optical path including the SCDs in the troposphere and the stratosphere. (e.g. Platt and Stutz, 2008, Wagner, et al., 2010).

110 The stratospheric absorption has been assumed as the same level in all spectra taken within one scan cycle, so we generally choose the spectrum with small trace gas absorption as the reference, such as the spectrum measured in zenith direction. The slope column concentration of the trace gas measured at each lower elevation angle (α) is represented by DSCD (differential SCD), which is the gas information of the measured slant column densities minus background densities in the reference spectrum.

115
$$\begin{aligned} \text{DSCD}(\alpha) &= \text{SCD}(\alpha) - \text{SCD}(\text{ref}) \\ &= \text{SCD}(\alpha)_{\text{trop}} + \text{SCD}_{\text{strat}} - \text{SCD}(\text{ref})_{\text{trop}} - \text{SCD}_{\text{strat}} \\ &= \text{SCD}(\alpha)_{\text{trop}} - \text{SCD}(\text{ref})_{\text{trop}} \end{aligned} \quad (1)$$

For ship emissions measurements, the DSCDs of pollutants at low elevation angles should express the change of integrated concentrations along the light path after contamination by the exhaust plume, which collects scattered sunlight passing through ship plumes. Figure 1 depicts the schematic diagram of ground-based MAX-DOAS measurements of ship emissions. The telescope is pointed towards the ship lanes or the direction of ship passed through. Consequently, the measured spectra at low elevation angle will be impacted the plumes of ship emissions.

120

125

2.2 Instrument setup and sites

In this study, the MAX-DOAS instrument has been designed and assembled by the authors (Zhang et al., 2018a). It mainly consists of a receiving telescope, a spectrometer (Ocean Optics, QE65 Pro), and a computer to control the measurements. Driven by the two-dimensional stepper motor system, the telescope can collect the scattered sunlight from different elevation angles in vertical and azimuth angles in horizontal. The scattered light is converged by the lens to the fiber bundle connected to the spectrometer. The receiving sunlight is dispersed by a grating, detected by a CCD detector and recorded by the spectrometer covering the wavelength range from 300 to 480 nm with a resolution about 0.5 nm Full Width at Half Maximum (FWHM). As a new designed feature, a camera has been configured on the MAX-DOAS apparatus, which moves coaxially with the receiving telescope and can record the scene and sky conditions same as the views of telescope. The scanning of telescope can be set in the sequence of several elevation angles from close to horizontal and 90° and then move to next azimuth angle for another vertical scanning sequence. Due to the different ship traffic conditions, the types of ship passing in inland waterway and seaside ports are different in size and tonnage. Therefore, the configuration of observing geometric angles were adjusted dependent on the conditions of ships, as referred in Table 1.

140 The MAX-DOAS measurements of ship emissions were performed in two typical port cities of Shanghai and Shenzhen in China. As shown in Fig. 2(a), sea areas in surrounding Shanghai and Shenzhen city are located in the ECA of Yangtze River

Delta and Pearl River Delta. In Shanghai, two different ship traffic scenarios were considered, i.e. ships at berth in Waigaoqiao container port area (31.36° N, 121.58° E, Fig. 2(b)), and ships passing through inland waterway of the downstream of Huangpu River at Wusong area (31.37° N, 121.50° E, Fig. 2(c)). In Shenzhen, the measurements were carried out in the deep water port of Yantian (114.29° E, 22.56° N, Fig. 2(d)). More details about the environments and operation configurations of measurement were listed in Table 1.

Table 1. Measurements details and operative configurations of MAX-DOAS.

Sites	Locations and periods	Operations*	Environment types
Waigaoqiao, Shanghai	31.36° N, 121.58° E 28/08/2017	AZ: 26° to 34°; ELE: 3°, 4°, 5°, 6°, 7°; Spectrum temporal resolution: 15-30 s; Completed scanning cycle: 15 min.	Viewing to: berths; Ships: container ship.
Wusong, Shanghai	31.37° N, 121.50° E 30/12/2017-18/05/2018	AZ: 85°; ELE: 0°, 1°, 2°, 3°, 4°, 5°, 6°, 8°, 65°; Spectrum temporal resolution: 40 s; Completed scanning cycle: 7 min.	Viewing to: inland waterway with high traffic volume; Ships: a wide variety of ships and small in size
Yantian, Shenzhen	114.29° E, 22.56° N 23/05/2018-30/06/2018	AZ: 75°; ELE: 2°, 3°, 5°, 7°, 10°, 15°, 30°, 90°; Spectrum temporal resolution: 60 s; Completed scanning cycle: 9 min.	Viewing to: open sea areas with Smaller traffic volume; Ships: container ship as the main part

*AZ: azimuth angle in horizontal direction; ELE: elevation angle in vertical direction.

The YRD and PRD Domestic Emission Control Area (DECA) in China and locations of the MAX-DOAS measurements in coastal cities of Shanghai and Shenzhen: Waigaoqiao Port and Wusong Wharf in Shanghai, and Yantian Port in Shenzhen. The viewing direction of instrument azimuth angle is indicated by a red arrow.

155

2.3 DOAS spectral analysis

Based on the DOAS principle, the measured scattered sun-light spectra are analyzed using the QDOAS spectral fitting software, which is developed by BIRA-IASB (<http://uv-vis.aeronomie.be/software/QDOAS/>). The fitting wavelength intervals of SO₂ and NO₂ are 307.5-320 nm and 405-430 nm, respectively. Trace gases with absorptions in relevant fitting windows and Ring spectrum were included. The details of spectral fitting configuration are listed in Table 2. Wavelength calibration was performed by using high-resolution solar reference spectrum (Chance and Kurucz, 2010). The offset and the signal of the dark current were measured every night and extracted automatically from the measured spectra before spectral analysis.

160

Consequently, the DSCDs of SO₂ and NO₂ were yielded by taken the measured spectrum at 90° as the Fraunhofer reference spectrum.

165

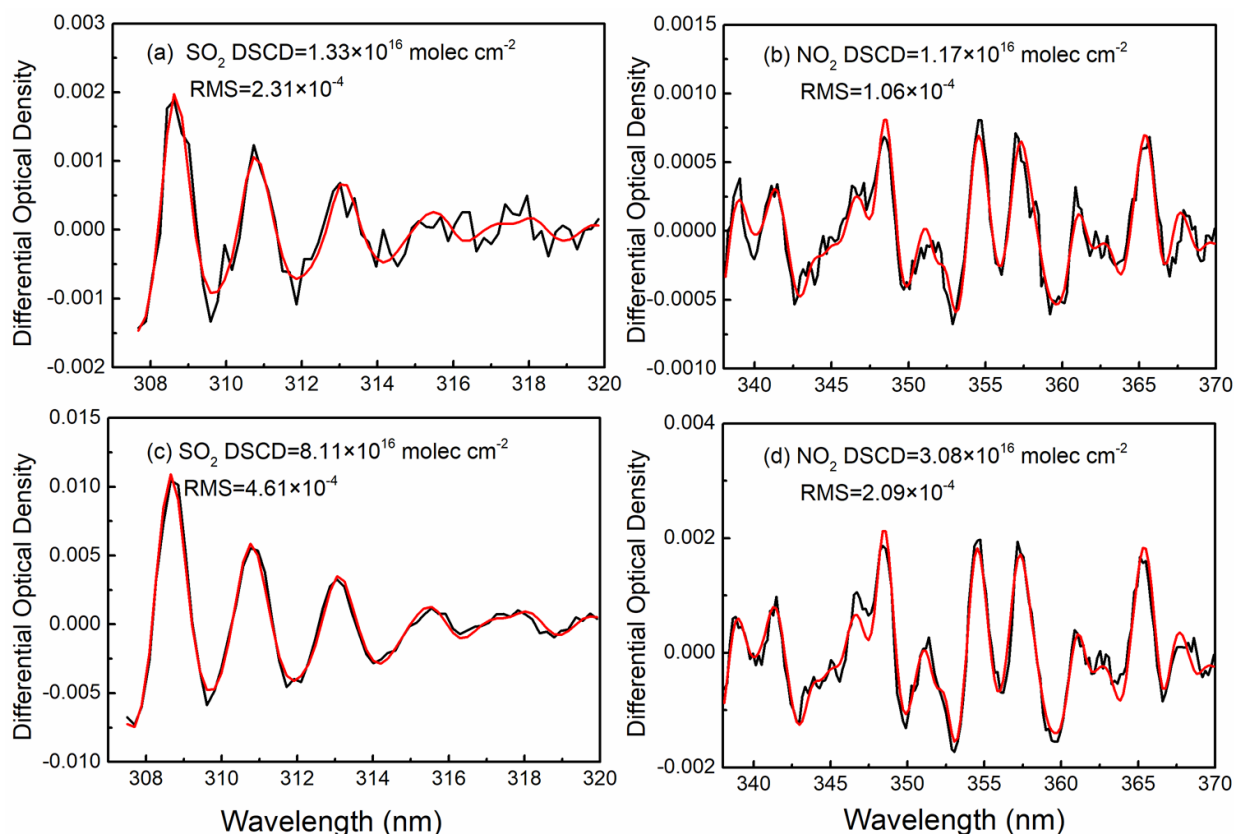

Table 2. Configuration of spectral fitting for SO₂ and NO₂

Parameters	SO ₂	NO ₂
Fitting window	307.5–320 nm	338–370 nm
NO ₂	298 K (Vandaele et al., 1998)	
SO ₂	293 K (Bogumil et al., 2003)	/
O ₄	--	293 K (Thalman and Volkamer, 2013)
O ₃	223 K & 243 K (Serdyuchenko et al., 2014)	223 K (Serdyuchenko et al., 2014)
BrO	/	293 K (Fleischmann et al., 2004)
CH ₂ O	298K (Meller and Moortgat, 2000)	
Ring	Calculated by QDOAS	
Polynomial Degree	3	5
Intensity Offset	Constant	

Figure 3 shows the typical spectral fitting of measured spectra with and without ship plume contamination. The obvious absorbing structures of SO₂, NO₂ and fairly low residuals can be observed in both conditions of polluted spectrum (collected at elevation angle of 7° at 11:04 LT on 26 June, 2018) and clean spectrum (collected at elevation angle of 5° at 09:53 LT on 22 June, 2018). By contrast, the retrieved SO₂ and NO₂ DSCDs of 8.11×10¹⁶ and 3.08×10¹⁶ molec cm⁻² in polluted case are significantly higher than those in clean condition of 2.31×10¹⁶ and 1.06×10¹⁶ molec cm⁻². It demonstrates the high sensitivity of measurements to ship plumes and the good performance of the spectral fitting. In this study, a threshold of residual < 1×10⁻³ is used for screen out the unqualified NO₂ and SO₂ DSCDs, and 94.57% of NO₂ fitting results and 76.26% of SO₂ fitting results remains in further discussion. The uncertainties for the spectral analysis of SO₂ were higher because of the weak scatter sunlight intensity and lower signal-to-noise at the short wavelengths.

170

175

180 **Figure 3. Typical DOAS spectral fitting for SO₂ and NO₂. (a) and (b) show the clean condition of spectrum collected at an elevation angle of 7° at 11:04 LT on 26 June, 2018, while (c) and (d) are the ship plumes polluted case of spectrum measured at an elevation angle of 5° at 09:53 LT on 22 June, 2018. Black lines show the measured atmospheric spectrum and the red line shows the reference absorption cross-section.**

3 Results and discussion

3.1 Identifying the emissions of ship at berth

185 The measurement site at Waigaoqiao Container Terminal is located on the south bank of the Yangtze River, and close to the confluence of Yangtze River and Huangpu River. The Terminal has a total quay length more than one kilometer, and its three container berths are able to accommodate the fifth and sixth generation container ships. The special location determines that it is the important traffic route for ships to enter or leave the Yangtze River, Shanghai Port, and Waigaoqiao wharf. In order to detect the emissions ship at berths, the MAX-DOAS instrument is placed on a fifth floor at the building of Pudong MSB
190 (Maritime Safety Bureau). The distance between the instrument and berth is about 1.4 km. Since no other constructions obscured, multiple berth can be seen directly in the viewing of the MAX-DOAS instrument. Considering the size and chimney

height of berthed ships, the MAX-DOAS telescope was set to scan vertically in sequence of 3° , 4° , 5° , 6° , and 7° (indicated with angle α in Fig. 4). In horizontal, telescope ranged from 26° to 34° (the viewing angle from north in clockwise) and yielded a range of angle β , which can covers about 195 m quay length. After completing one full scanning in both vertical and horizontal, a 2-D distributions of DSCDs in front view of the instrument can be generated. To avoid the interference of pollutants absorptions in the reference spectrum, the spectrum measured at azimuth angle of 10° was considered as the reference spectrum in the background area without the direct ship emissions pollution.

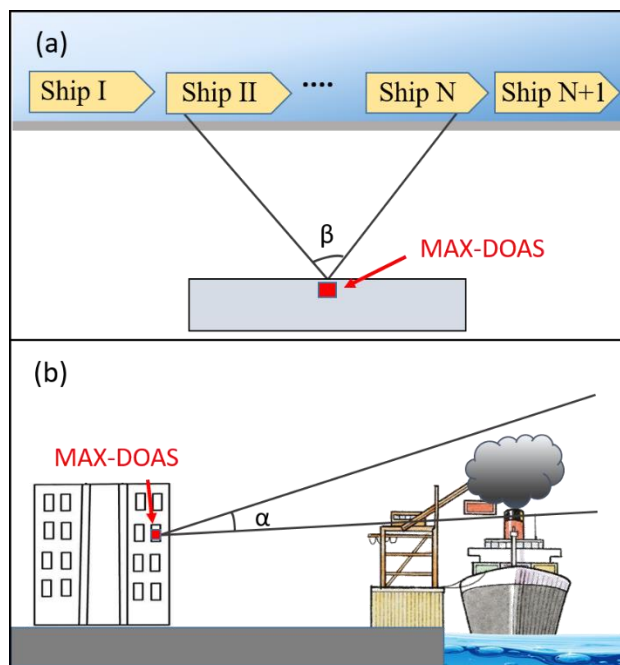

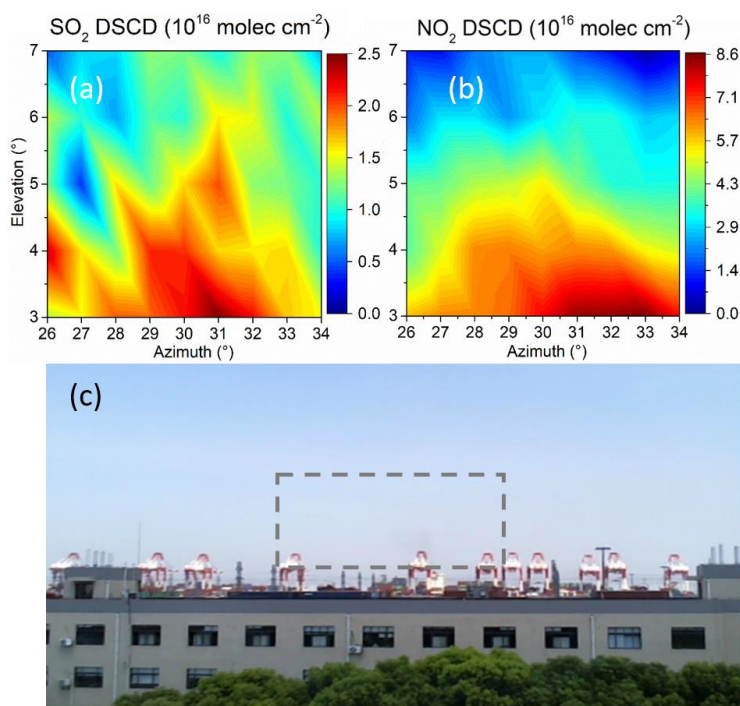

Figure 4. The observational geometry of MAX-DOAS for identifying the emissions of ship at berth in Waigaoqiao port, Shanghai:
200 (a) top view and (b) side view.

Fig. 5(a) and (b) shows the spatial distributions of SO_2 and NO_2 DSCDs in horizontal and vertical during a complete scanning sequence, respectively. Large spatial gradients can be observed for both SO_2 and NO_2 levels, while the pollutants concentrations are in general higher at lower elevation angles and declined with the increases of height. The highest SO_2 , i.e. DSCDs up to 2.5×10^{16} molec cm^{-2} , appeared in horizontal azimuth of 31° and elevation of 3° and attenuated in the direction toward left-upward. Similarly, hot-spots of NO_2 with DSCDs of $7.0 \sim 8.0 \times 10^{16}$ molec cm^{-2} are centered between 31° and 33° in horizontal at elevation of 3° , and decreases in periphery. It should be noted that the hot-spots of SO_2 and NO_2 distribution are shifted to the left accordingly while the height is raised. It is implied that the plumes containing SO_2 and NO_2 emitted at the bottom in the observational field of view, dispersed and diluted in left-up ward, and the weather recorded that the wind at this test site mainly came from the south. Combined with the real scene shown in Fig. 5(c), the rectangle encircled by dash line indicates the range of MAX-DOAS telescope scanning. It can be seen that there are smoke clusters discharged by ship at the
210

right part of the picture, which is correspond to the azimuth angle between 31° and 33° . And under the action of the wind, the plume spreads to the left of the observational view.

215

Figure 5. Distributions of measured DSCDs of (a) SO₂ and NO₂ (b) from emissions of ship at berth during 12:04~12:20 in 28 August, 2017 and (c) live photo captured by camera of MAX-DOAS instrument. The dash line rectangle indicates the observational view of MAX-DOAS.

220 Since a full 2-D scanning sequence in horizontal and vertical directions took about 15 minutes, more than a dozen cycles in total can be performed during the afternoon. In view of the identified emission source position above, the DSCDs of NO₂ and SO₂ observed at elevation 4° and azimuth angle between 31° - 33° were selected to display the temporal pattern of emissions at berth. In general, the level of NO₂ DSCDs is much higher than SO₂, because there are considerable NO_x emission of in port trucks between the berth and the instrument, whereas there no other obvious emission source of SO₂. In order to show the variations of DSCDs with less interference due to light path change, we used the mathematic method to remove the slowly change from the trend line of NO₂ and SO₂ DSCDs, and kept the residual of background subtraction in the Fig. 6. Afterwards, four significant increases of SO₂ levels can be observed during this afternoon, accompanied with NO₂ enhancements at approximately same moment, which can be verified by the real scene photos showing evidently the emitted plumes from the expected exhausting position.

230

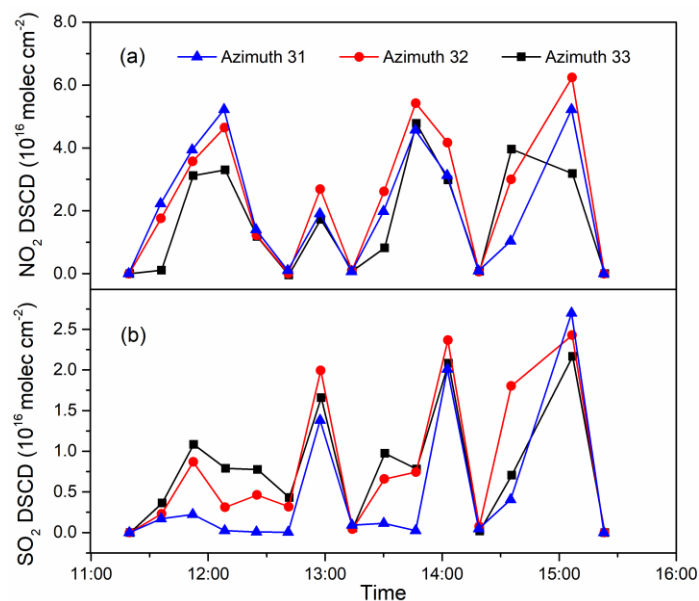

Figure 6. Time series of DSCD of (a) NO_2 and (b) SO_2 measured at 4° elevation angle in three azimuths on August 28, 2017.

Therefore, it can be concluded that the concentration of NO_2 and SO_2 gases contained in the plume emitted by the container
235 ships and the corresponding discharge position at berth were identified and monitored remotely by the 2-D MAX-DOAS
observation. This application of 2-D MAX-DOAS is similar to the Imagine DOAS (IDOAS) technique, which is also used to
map the 2-dimensional spatial distribution of polluted gases, such as the distribution of SO_2 in plumes of the industrial point
sources (General et al., 2014; Pikelnaya et al., 2013). It suggests that the 2-D DOAS technique has the potential to measure
the polluted gases mapping from the ships.

240

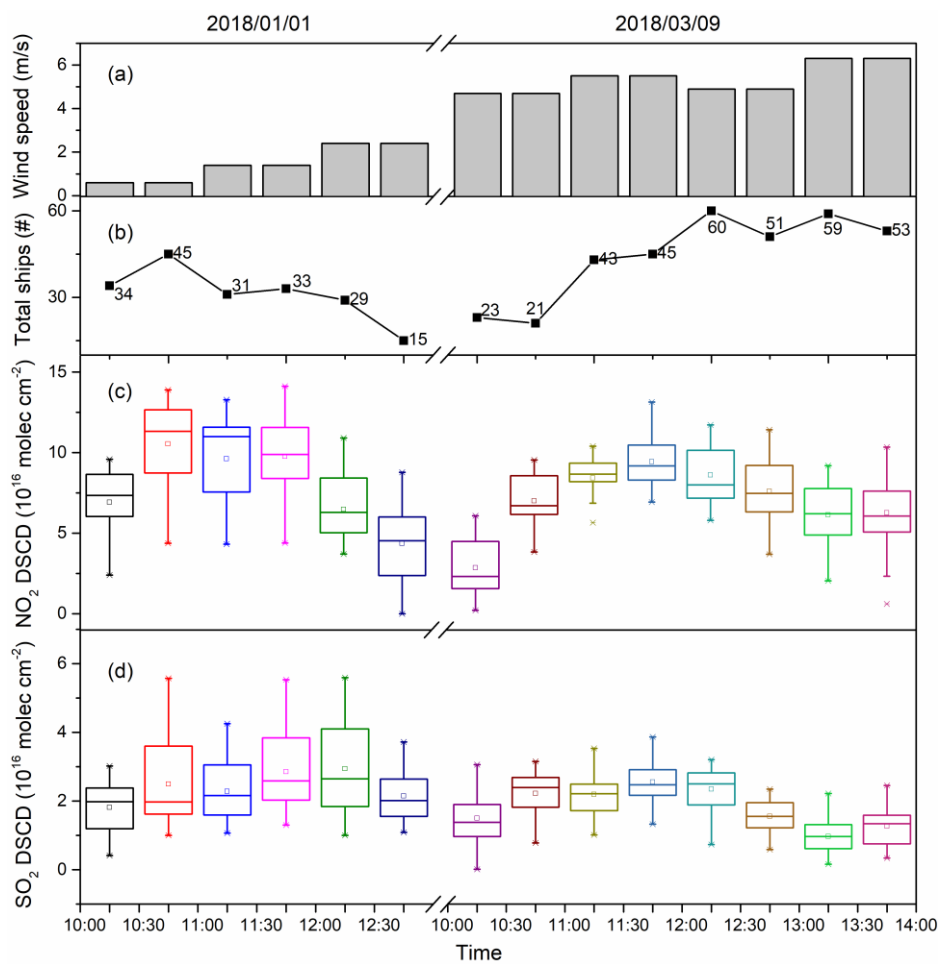

3.2 Ship emissions at inland waterway

Besides ocean-going ship emissions, inland waterway vessels also contributed significantly to the ship emissions (Kurtenbach
et al., 2016; Pillot et al., 2016; Zhang et al., 2017). To consider this situation, the MAX-DOAS instrument was installed at the
outside windowsill on the third floor of Wusong MSB Building ($121^\circ 29' \text{ E}$, $31^\circ 22' \text{ N}$) from December 30, 2017 to May 18,
245 2018. The measurement site is located in the downstream of Huangpu River and closed to the confluence into the Yangtze
River. It is only channel to the upstream of Huangpu River, and also some other non-container terminals are located nearby,
which mainly handles boxes serving in domestic trading. As a consequence, a large number of ships entering and leaving the
wharf area every day, and the lanes in the downstream of Huangpu River suffers from dense ship traffic. By checking the
synchronized photos taken by the camera attached to the instrument, it is found that the types of vessels passing through are
250 in a wide variety, such as medium and small sized container ships, passenger vessels, bulker and cargo ships. In addition, the
traffic volume in the area is quite high, even up to hundreds of ships per hour. As shown in Fig. 2(c), the view direction of

MAX-DOAS measurements in Wusong area is pointed perpendicularly to the river lanes. The observed signal of pollutants mainly come from the emissions of ships in navigation. The elevations angles were set in scanning sequence of 0°, 1°, 2°, 3°, 4°, 5°, 6°, and 8°. The spectrum measured at 65° was utilized as the reference since the zenith direction is blocked to some extent by the MSB building.

In order to illustrate the impacts of ship traffic volume and meteorological conditions, measurements data of 30-min averaged wind speed, observed NO₂ and SO₂ DSCD on two representative days of January 1, and March 9, 2018 were shown in Fig. 7, as well as the corresponding number of passing ships. It can be seen from Fig. 7(a) that January 1 and March 9 were selected to represent days under stable and unstable atmospheric conditions. The average SO₂ DSCDs changed from 1.8×10¹⁶ to 3.0×10¹⁶ molec cm⁻², while average NO₂ DSCDs varied between 4.0×10¹⁶ and 1.1×10¹⁷ molec cm⁻² on January 1. On March 9, the SO₂ and NO₂ average DSCDs ranged 1.0×10¹⁶ to 2.7×10¹⁶ molec cm⁻² and 2.5×10¹⁶ to 1.0×10¹⁷ molec cm⁻², respectively. According to the ship traffic density shown in Fig. 7(b), the diurnal variations of SO₂ and NO₂ DSCDs are obviously closely related to the flow of the ships (quantitative information). Although the averaged SO₂ and NO₂ DSCDs levels are comparable during these two days, the ship traffic flow on March 9 was overall 50% higher than January 1, which may imply the important role of meteorological conditions. Considering the dense ship lanes, the ship emitted pollutants are easily to be accumulated under the unfavorable condition with lower wind speed less than 2 m·s⁻¹ on January 1. In the contrary, the ship emissions along the lanes can be spread for better diffusion when the averaged wind speed is around on 5 m·s⁻¹ March 9.

270

Figure 7. 30-min averaged wind speed, ship traffic volume, observed NO₂ and SO₂ DSCDs from 10:00 to 13:00 on January 1 and 10:00 to 14:00 on March 9 at Wusong Wharf measurement site. The hollow squares in the middle of the box represent the mean value, and the solid lines in the middle represent the median. The upper and lower edges of the box are 25% and 75% quantiles, respectively.

275

It can be concluded from the continuous five months measurements at Wusong MSB site that the ship traffic volume and meteorological conditions are the two major factors impacting the observed NO₂ and SO₂ levels in this typical inland waterways. For similar diffusion situations, the MAX-DOAS instrument can accurately detect the elevated pollutants concentrations with the increased number of ships. However, due to the busy ship lanes in front of the instrument, the MAX-DOAS instrument usually observes signal of pollutants in the plumes from multiple ships together, and the navigation speed of ships are relatively faster compared to the period of a completed scan measurement. So it is very hard to distinguish the single plume from the mixture. It is another shortcoming of this measurement that the MAX-DOAS measured NO₂ are considerably impacted by surrounding other emission sources, such as main roads and highways nearby.

280

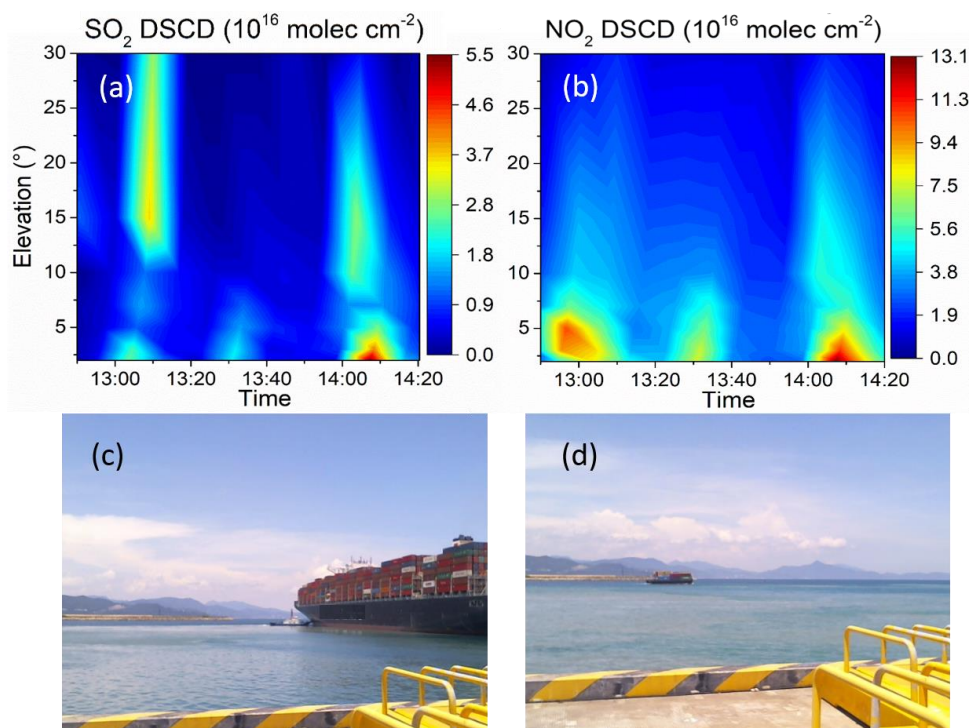

285 Aiming to inspect the compliance of fuel sulfur content, the prospects of the MAX-DOAS application for the complicated inland waterways is used to mark the suspicious ship using fuel with excess sulfur content, by comparing with the theoretical SO₂ emission estimated from the legally fuel sulfur content and ship activity data.

3.3 Ocean-going ship emissions

290 Another shipping traffic scenario was also considered for the MAX-DOAS measurements at Yantian Port (114°29' E, 22°56' N), located on the east side of Shenzhen in the Pearl River Delta emission control zone (See Fig. 2). Yantian Port is one of the largest container port, which has 20 large deep-water berths with a quay length of 8,212 meters and water depth alongside of 17.4 meters, which is benefit to the ocean-going vessels with a length of more than 300 m docked. Unlike the measurement sites above, the distinct feature of shipping traffic in Yantian Port is the huge size of inbound and outbound vessels and the
295 much less traffic density. The MAX-DOAS instrument was installed at the shore of the central operation zone of the Yantian Port from May 23, 2018. As can be seen in Fig. 2(d), the view direction of MAX-DOAS was pointed to the lanes in the eastward sea area. Due to lack of other emission sources in the front, the MAX-DOAS observation can easily capture the pollutants in single plume from the individual orderly inbound and outbound ship, as manifested in Fig. 8.

300 Figure 8(a) and (b) presents the altitude dependence of observed SO₂ and NO₂ DSCDs around noontime on May 26, 2019. . During the observational period, there were three apparent peaks of SO₂ and NO₂ DSCDs, i.e. 13:00, 13:30 and 14:10. The increases of both pollutants levels were occurred simultaneously. For the first pulse around 13:00, the higher levels of SO₂ DSCDs are distributed above 10° elevation, whereas the strong signals of NO₂ are concentrated below elevation angle of 5°. This can be explained by the fact that the container ocean-going vessel and tugboat behave differently in emission and operation.
305 Fig. 8(c) proved that there a large container ship is outbound at 12:55 with assistance of two tugs. It is obvious that height of outlet is very high for large container ships, but quite low for the tugboat. Since the tugboat are usually operated in the port area, its fuel usage always obey the regulations of ECA and shows high quality. Thus, stronger SO₂ signal appeared at high altitude due to the container ship emission, while NO₂ hotspots closed to the sea surface contributed by the tugboat emission. During the period around 13:30, both DSCDs of SO₂ and NO₂ were slightly increased and allocated below elevation 7°. According to the live photo in Fig. 8(d), there only a small container ship were passing through about 1 km away in front view of the instrument. Considering the distance between the ship and instrument, the height of exhaust outlet should be related to a lower elevation angle, where the corresponding strong signal of emitted pollutants are expected to be observed. Additionally, obvious SO₂ and NO₂ signals were found around 14:10, during which high SO₂ were distributed among elevation angle 10° to 15°, but strong signals of SO₂ and NO₂ were both found near the sea surface. However, no ship was captured by the live photos.
315 It can be inferred from the AIS information that the observed signal of plume was dispersed from the ship in another lane instead of this in the front view of the instrument.

320 **Figure 8. Measured DSCDs of (a) SO₂ and (b) NO₂ during 12:55~14:20 and live photos taken by the camera at (c) 12:56 and (d) 13:22 on May 26, 2018.**

In general, the characteristics of observed SO₂ and NO₂ DSCDs distributions on height are to some extent related to the ship size, its distance from the instrument and operational status, as well as the atmospheric stability more or less. Based on the example discussion above, the MAX-DOAS measurement in Yantian port can detect the pollutants in single plume from individual ship and provide the information about vertical distribution of pollutants with the conditions of low ship traffic volume. Considering the large discrepancies of SO₂ signals in altitudes, we try to further detailed SO₂ emissions from the measurement and obtain the representative observation elevation. According to the live photos, a large container ship entered the field of view at 9:51 on June 22, 2018, which moved very slowly and emitted a distinct black smoke. Figure 9 shows the distribution of SO₂ DSCDs in plumes at different elevation angles. The SO₂ DSCDs peaked at 8.17×10^{16} molec cm⁻² between elevation angles of 5° and 7°, and decreased with height. It can be found that the DSCDs observed at elevation angle 7° are suitable to stand for the peak concentrations in the plumes considering the chimney height of ship and its horizontal distance from MAX-DOAS instrument.

325
330

Figure 9. A typical distribution of SO₂ DSCDs in the smoke plume of ship on June 22, 2018

335

Thus, the diurnal profiles of SO₂ and NO₂ DSCDs at 7° elevations on June 26, 2018 were further investigated as presented in Fig. 10. With the high temporal resolution measurements of 60 s, there multiple peaks of SO₂ and NO₂, with the highest DSCDs of SO₂ and NO₂ exceeding 6.00×10^{16} molec cm⁻², occurred due to the emissions of the occasional passing ships. By applying the mathematical method, a baseline (the blue dotted line in Fig. 10) can be extracted from the DSCDs trend lines (the black solid line in Fig. 10). The baseline represents the diurnal variations of DSCDs mostly due to the change of light path caused by solar zenith angle and the background emissions. Finally, it can be found that seven synchronous peaks of SO₂ and NO₂ levels higher than 2.00×10^{16} molec cm⁻² in the trend line (the red solid line in Fig. 10). Validated by the live photos of the instrument and the AIS information, these kind of sharp increased concentration of pollutants are originated from the ship plumes passed by. It suggests the high sensitivity of MAX-DOAS measurements to the change of SO₂ and NO₂ contents in the atmosphere. In addition, the increases of pollutants levels lasted from 10 min to half an hour, which is related to the durations of the ship movement in the field of view.

340
345

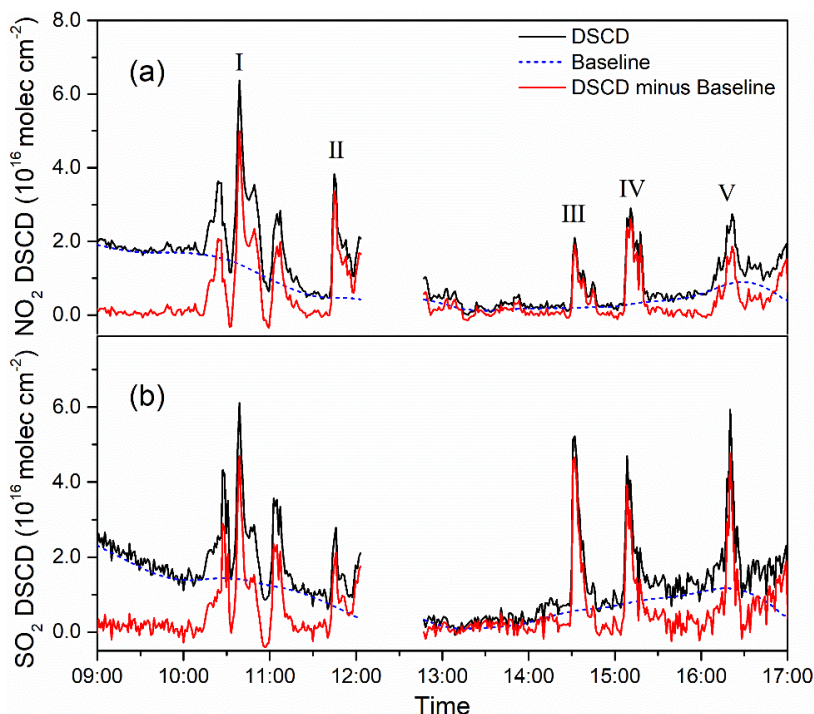

Figure 10. Diurnal variations of DSCDs of (a) NO_2 and (b) SO_2 measured at 7° elevation angle on 26 June 2018.

350

Moreover, it should be noticed that the amplitude of each peak varied differently, which implies that the DSCDs ratio of SO_2 to NO_2 for each peak may reveal the emission information of fuel sulfur content of individual vessels. Thus, the linear regression analysis between SO_2 and NO_2 DSCDs were performed to infer the fuel sulfur content. Figure 11 presents the analysis results of nine different vessels. The strong correlation relationship between SO_2 and NO_2 DSCDs are the obvious evidence of the significant homologies of emission sources between SO_2 and NO_2 . Nevertheless, the slope of different vessels highly changed from 0.59 to 2.81, indicating the diversity of the SO_2 emission intensity in the ship plumes. In general, the SO_2 emission are directly related to the fuel sulfur content and engine operation status of the ships (Zhang et al., 2018b). The outbound vessels usually leave from the shore slowly with the help of tugboat, and then speed up sailing into the sea. It calls the main engine to power the navigation during this process, and the fuel used by the main engine has a higher sulfur content than the auxiliary machine. In contrast, the main engine of vessel is usually shut down during the inbound process. Therefore, the ratio of SO_2/NO_2 DSCDs in the plume emitted by the outbound vessel could be higher than the inbound one.

360

Figure 11. The relationship between SO₂ and NO₂ emitted by several typical vessels.

365

During the MAX-DOAS observation, we have also carried out some fuel sample analysis, investigation on the activity data and engine parameters of these vessels, among which five of them are the vessels in Fig. 10. Therefore, we indicated the different status of these nine vessels in Fig. 12, along with the information about the rated power of engine and fuel sulfur content individually, in which the inbound and outbound shows the rated power of main and auxiliary engine, respectively.

370

The vessel #II is a tugboat operated in the port area, which uses the fuel with lowest sulfur content of 0.001% and shows minimum ratio of SO₂-to-NO₂ in DSCDs. Furthermore, the inbound vessel #I, #VI and #VII (indicated by diamond in Fig. 12) has switched off the main engine when it arrived in the front of the MAX-DOAS instrument, moved under the towing of tugboat and docked by inertia finally. Additionally, the sulfur content of fuel are much lower in auxiliary engine than main engine. So SO₂-to-NO₂ ratios of inbound vessels are much lower than that of outbound vessels.

375

The other vessels, indicated by circle in Fig. 12, are all in outbound. Under the launch of main engine and high sulfur content in fuel, these vessels exhibited relatively higher ratios of SO₂-to-NO₂ over 2.0, except for vessel #IV. Due to the usage of much more cleaner fuel with sulfur content of 1.28%, the vessel #IV presented the lowest ratio of SO₂-to-NO₂ among all the outbound vessels. Compared to vessel #III with similar rated power of engine, it can be observed that the ratio of SO₂-to-NO₂ in plume increased with the growth of fuel sulfur content for vessels. This phenomenon is also applicable to cases of vessel #V and #VIII. It is worth noted that the dot of outbound cargo #IV is deviated from others, which has very low rated power but very high ratio of SO₂-to-NO₂ > 2.0. So it can be recognized as a suspicious ship using fuel with sulfur content exceeding the regular limit.

380

385

Figure 12. The relationship between the ratio of SO_2/NO_2 obtained by linear regression, the fuel sulfur content and engine rated power of all nine vessels. Tugboat, inbound and outbound vessels are represented by pentagram, diamond and circles, respectively.

Basically, the ratios of SO_2 -to- NO_2 in the plume discharged from the inbound vessel and the tugboat are usually lower than
390 1.5 for normal condition, which is much smaller than that of outbound vessels using high rated power engine and sulfur content
fuel. For outbound vessels, the ratios of SO_2 -to- NO_2 are more related to the fuel sulfur content. The irregular observed ratio of
 SO_2 -to- NO_2 can tag the vessel not obeyed to the sulfur content limitation. Therefore, the MAX-DOAS measurement provides
a promising technology for compliance of fuel sulfur content by investigating the ratio of SO_2 -to- NO_2 in the plume and the
more accurate estimation with load factor and emission factor for the actual operation.

395

Conclusion

In this study, we have performed the MAX-DOAS measurements observe the ship emissions of SO_2 and NO_2 in Shanghai and
Shenzhen, China for three different typical ship traffic conditions. At Waigaoqiao container terminal in Shanghai, the SO_2 and
 NO_2 exhausted by ship at berth can be easily identified for the locations and intensity of emission from the 2-dimensional
400 MAX-DOAS observation. At the inland waterway area of Wusong Wharf, it is difficult to determine the single ship emissions
due to the dense traffic volume and complex background environment. The long-term MAX-DOAS measurements shows that
the changes of SO_2 and NO_2 are proportional to ship flow whether in stable and unstable atmospheric conditions. However,
better dispersion under unstable atmospheric condition are favorable for the decrease of pollutants levels. For open sea waters

in Yantian deep water port, the 2-dimensional DSCDs of SO₂ and NO₂ mapped by MAX-DOAS are highly sensitive to the
405 emitted plumes of vessels passing through in front of the shore-based instrument, which shows the significant increase of
pollutants concentrations and 10-30 min duration of the emission signals. Considering the distance and size of the vessels, the
DSCDs observed at elevation angle 7° are the hotspots of the concentration in altitude, and further selected to investigate the
fuel sulfur content. According to the linear regression of SO₂ and NO₂ DSCDs, the ratio of SO₂-to-NO₂ are found to be very
helpful to infer the levels of sulfur emission. Combined the fuel sample analysis and inquiry of the vessel data, the SO₂/NO₂
410 ratio in the plume are usually lower than 1.3 for the inbound vessel and the tugboat, whereas is much smaller than that of other
vessels. The abnormal high ratio of SO₂-to-NO₂ in the plume usually implies the vessel could not be in compliance with the
sulfur content limitation.

In summary, the advantages of optical remote sensing and mature for SO₂ and NO₂ detection are beneficial to MAX-DOAS
415 measurement for the ship emission. These applications at different ship traffic scenarios demonstrated the feasibility of shore-
based MAX-DOAS to observe the emitted SO₂ and NO₂ from vessels docked at berth, navigation in the lanes, inbound and
outbound operations. For the prospects, the combination of MAX-DOAS remote sensing of ship plumes and the estimation on
emissions with theoretical fuel sulfur contents and actual operation data will provide the promising approach for surveillance
in the future.
