## 10 Abstract

11 Secondary organic aerosol (SOA) represents a significant fraction of the tropospheric aerosol  
12 and its precursors are volatile organic compounds (VOC). Anthropogenic VOCs (AVOC) dominate the  
13 VOC budget in many urban areas with 1,3,5-trimethylbenzene (TMB) being among the most reactive  
14 aromatic AVOCs. TMB formed highly oxygenated organic molecules (HOM) in NO<sub>x</sub> free environment,  
15 which could contribute to new particle formation (NPF) depending on oxidation conditions were  
16 elevated OH oxidation enhanced particle formation. The experiments were performed in an oxidation  
17 flow reactor, the Go:PAM unit, under controlled OH oxidation conditions. By addition of NO<sub>x</sub> to the  
18 system we investigated the effect of NO<sub>x</sub> on particle formation and on the product distribution. We show  
19 that the formation of HOM and especially HOM accretion products, strongly varies with NO<sub>x</sub> conditions.  
20 We observe a suppression of HOM and particle formation with increasing NO<sub>x</sub>/ΔTMB and an increase  
21 in the formation of organonitrates (ON) mostly at the expense of HOM accretion products. We propose  
22 reaction mechanisms/pathways that explain the formation and observed product distributions with  
23 respect to oxidation conditions. We hypothesize that, based on our findings from TMB oxidation studies,  
24 aromatic AVOCs may not contribute significantly to NPF under typical NO<sub>x</sub> /AVOC conditions found  
25 in urban atmospheres.

## 26 1 Introduction

27 Volatile organic compounds (VOC) are ubiquitous in the atmosphere and major precursors for  
28 secondary organic aerosol (SOA). SOA represents a dominant fraction of the tropospheric aerosol  
29 (Hallquist et al., 2009;Shrivastava et al., 2017;Gentner et al., 2017) and affects climate  
30 (Intergovernmental Panel on Climate, 2014) and health (WHO, 2016). Consequently research interest  
31 in SOA formation and properties is ranging from remote atmospheres (Ehn et al., 2012;Ehn et al.,  
32 2014;Kristensen et al., 2016) to densely populated and polluted environments (Chan and Yao, 2008;Hu  
33 et al., 2015;Guo et al., 2014;Hallquist et al., 2016). Following the study by Ehn et al. (Ehn et al., 2012),  
34 highly oxygenated organic molecules (HOM) with low volatilities, formed from the oxidation of  
35 biogenic volatile organic compounds (BVOCs), have attracted much research interest (Crouse et al.,  
36 2013;Ehn et al., 2014;Jokinen et al., 2014;Jokinen et al., 2015;Mentel et al., 2015;Yan et al.,  
37 2016;Berndt et al., 2016;Bianchi et al., 2019). These compounds have been shown to contribute to new  
38 particle formation (NPF) and to SOA growth (Ehn et al., 2014;Bianchi et al., 2016;Kirby et al.,  
39 2016;Trostl et al., 2016;McFiggans et al., 2019), making them an important factor in the formation of  
40 atmospheric SOA. These oxidation products can be either described as HOM based on their high oxygen  
41 number (O<sub>n</sub> > 6) (Bianchi et al., 2019) or as extremely low volatile organic compounds (ELVOC) based  
42 on their volatility (Donahue et al., 2012;Trostl et al., 2016). In this study, we will refer to oxidation  
43 products as HOM, because not all of the measured compounds may fulfill the criteria for ELVOC (Trostl

44 et al., 2016;Kurtén et al., 2016). Gas phase autoxidation of alkylperoxy radicals (RO<sub>2</sub>) has been proposed  
 45 as the formation mechanism for HOM (Crounse et al., 2013;Ehn et al., 2014;Jokinen et al., 2014). After  
 46 the initial reaction of an oxidant with the VOC and subsequent addition of O<sub>2</sub> to the alkylradical (R), the  
 47 produced RO<sub>2</sub> isomerizes via intra molecular H abstraction (H-shift). During this process a  
 48 hydroperoxide group and a new R is formed. Additional O<sub>2</sub> addition and H-shift sequences can introduce  
 49 large amounts of oxygen to the molecule and subsequently lower the vapour pressure. The chemistry of  
 50 aromatic compounds is somewhat different compared to other VOCs as they can lose their aromaticity  
 51 during the initial OH attack while they can retain the ring structure. Moreover, reaction products are  
 52 more reactive than the parent compound. The produced RO<sub>2</sub> form an oxygen bridge, a bicyclic and  
 53 potentially a tricyclic alkylradical (Molteni et al., 2018;Wang et al., 2017) before further oxidation  
 54 processes open the ring structure. For 1,3,5-trimethylbenzene (TMB), emitted from combustion sources  
 55 in the urban environment, Molteni et al. (2018) proposed a generalized reaction scheme for HOM  
 56 formation after OH addition. According to their scheme, first generation alkylperoxy radicals with the  
 57 general formula of C<sub>9</sub>H<sub>13</sub>O<sub>5-11</sub> were formed from the initial OH attack and subsequent H shift and O<sub>2</sub>  
 58 addition sequences. A postulated second OH attack would result in propagating peroxy radical chains  
 59 yielding radicals with the general formulas C<sub>9</sub>H<sub>15</sub>O<sub>7-11</sub>.

60 Generally, the termination reaction of RO<sub>2</sub> (with a general  $m/z = x$ ) with HO<sub>2</sub>, leads to the  
 61 formation of hydro peroxides ( $m/z = x + 1$ ) while termination reactions with other RO<sub>2</sub> can lead to the  
 62 formation of a carbonyl ( $m/z = x - 17$ ), a hydroxy group ( $m/z = x - 15$ ) or dimers ( $m/z = 2x - 32$ ) (Mentel  
 63 et al., 2015;Jokinen et al., 2014;Rissanen et al., 2014). The propagation reaction of RO<sub>2</sub> with another  
 64 RO<sub>2</sub> or NO also results in the formation of RO ( $m/z = x - 16$ ). The RO can undergo internal H shift leading  
 65 to the formation of a hydroxy group and subsequent a new peroxy radical which can continue the  
 66 autoxidation sequences. The alkoxy step shifts of the observed  $m/z$  by 16 leads to overlap of different  
 67 termination product sequences. During extensive oxidation the first generation products are subject to  
 68 secondary chemistry increasing the numbers of products. Molteni et al. (Molteni et al., 2018) found  
 69 several closed shell monomer products with the general formula C<sub>9</sub>H<sub>12-16</sub>O<sub>5-11</sub> from the oxidation of  
 70 TMB with OH. The formation of dimers with different number of H atoms in their study was explained  
 71 by reactions of two first generation RO<sub>2</sub> radicals (C<sub>18</sub>H<sub>26</sub>O<sub>5-10</sub>), one first and one second generation RO<sub>2</sub>  
 72 (C<sub>18</sub>H<sub>28</sub>O<sub>9-12</sub>) or two second generation RO<sub>2</sub> resulting in the dimer C<sub>18</sub>H<sub>30</sub>O<sub>11</sub>. Although dimers have in  
 73 general lower O:C ratios than monomers, they are expected to be less volatile due to higher molecular  
 74 weight and more functional groups making them candidates to participate in nucleation processes  
 75 (Kirkby et al., 2016).

76 Organonitrates (ON) are formed as soon as sufficient NO<sub>x</sub> is present in the atmosphere. ON are  
 77 highly important for the reactive nitrogen budget wherein the formation of highly functionalized organic  
 78 nitrates can contribute significantly to secondary organic aerosol (Lee et al., 2016;Bianchi et al., 2017).  
 79 In this study we refer to compounds that only consist of H, C and O as HOM monomers or HOM dimers  
 80 and to N containing compounds as ONs.

81 NO<sub>x</sub> influences the oxidation of organics directly by changing oxidant levels (reducing or  
 82 increasing OH, depending on the NO<sub>x</sub> regime) and indirectly by influencing RO<sub>2</sub> chemistry. In high NO<sub>x</sub>  
 83 environment such as urban areas the reaction of NO with RO<sub>2</sub> radicals can compete with the autoxidation  
 84 mechanism (reaction 1 and 2) and thus potentially inhibit HOM while favouring some ON formation  
 85 (reaction 1 with a yield of up to 0.3).

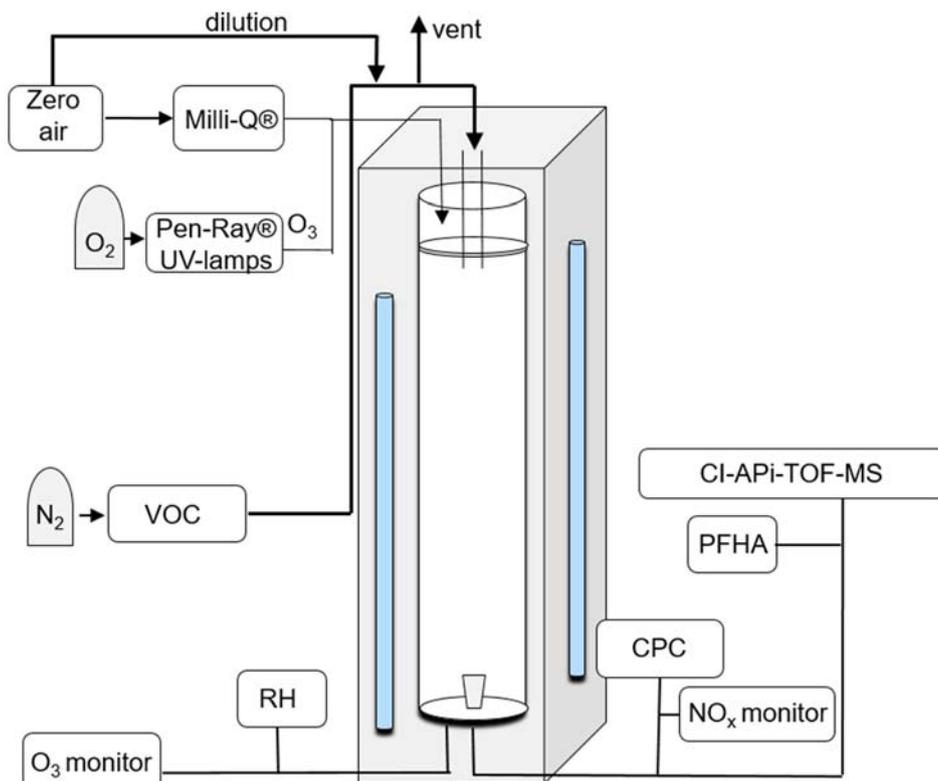

88 Although ON may have high O:C they differ from HOM as they contain at least one nitrogen atom.  
 89 While HOM formation from BVOCs has been intensively studied, only few studies have been conducted  
 90 focusing on the formation of HOM from anthropogenic aromatic volatile organic compounds (AVOCs)

91 (Molteni et al., 2018; Wang et al., 2017). However, these studies indicate that AVOCs have a strong  
92 potential to form HOM under NO<sub>x</sub> free conditions and proposed that they may play a crucial role in NPF  
93 and particle growth of SOA in urban areas. Regarding SOA yields a number of smog chamber studies  
94 have been conducted in order to investigate the oxidation of TMB with OH radical under different NO<sub>x</sub>  
95 and aerosol seed conditions (Paulsen et al., 2005; Rodigast et al., 2017; Wyche et al., 2009; Huang et al.,  
96 2015; Sato et al., 2012). They reported that under higher NO<sub>x</sub>:VOC conditions, SOA yield is reduced  
97 compared to medium or lower NO<sub>x</sub>:VOC conditions. The NO<sub>x</sub>:VOC, in almost all studies, was < 1, apart  
98 from one experiment (Wyche et al., 2009), with NO<sub>x</sub>:VOC = 1.9 in which the SOA yield was 0.29,  
99 compared to yields up to 7.47 under lower NO<sub>x</sub> conditions.

100 In this study we investigate the oxidation of TMB in a laminar flow reactor, while different NO<sub>x</sub>  
101 and OH conditions were applied. A nitrate chemical ionization atmospheric pressure interface time of  
102 flight mass spectrometer (CI-APi-TOF-MS) (Junninen et al., 2010; Jokinen et al., 2012) was used to  
103 monitor the oxidation product distribution. We show the formation of HOM and nitrate containing  
104 compounds with and without NO<sub>x</sub> added to the reaction system. Possible mechanisms leading to the  
105 formation of ON and suppression of particle formation are discussed.

## 106 2 Materials and Methods

107 The measured HOM were generated using the laminar flow Gothenburg Potential Aerosol Mass  
108 reactor (Go:PAM), initially described by Watne et al. (Watne et al., 2018). The Go:PAM is a 100 cm  
109 long, 9.6 cm wide quartz glass cylinder which is irradiated over a length of 84 cm by two 30 W Phillips  
110 TUV lamps (254 nm); a schematic is shown in Figure 1. The OH radicals are produced inside Go:PAM  
111 by photolysing O<sub>3</sub> in the presence of water vapour. The O<sub>3</sub> is generated outside Go:PAM by photolyzing  
112 pure O<sub>2</sub> (UVP Pen-Ray® Mercury Lamps, 185 nm) and distributed in 3 L min<sup>-1</sup> particle free and  
113 humidified air (Milli – Q) over the reactor cross section. The VOC was introduced through a  
114 gravimetrically characterized diffusion source (see Figure S2) centrally at the top of the reactor with a  
115 flow of 8 L min<sup>-1</sup> while NO was introduced via a NO gas cylinder. Flows were adjusted for a median  
116 residence time of 34 s in Go:PAM. A funnel shaped device is subsampling the centre part of the laminar  
117 flow to minimize wall effects on the sample. A condensation particle counter (CPC, 3775 TSI) was used  
118 to measure the number particle concentration in the sample flow. O<sub>3</sub> was monitored by a model 202  
119 monitor (2B Technologies), relative humidity by a Vaisala HMP60 probe and NO<sub>x</sub> by a model 42i  
120 monitor (Thermo Scientific) over the course of the experiments. The OH exposure, over the residence  
121 time in the reactor, for NO<sub>x</sub> free conditions without added TMB was measured using SO<sub>2</sub> titration  
122 (Teledyne T100) as described by Kang et al. (Kang et al., 2007). Gas phase oxidation products were  
123 measured with an Atmospheric Pressure interface High Resolution Time of Flight Mass Spectrometer  
124 (APi-TOF-MS, Aerodyne Research Inc. & Tofwerk AG) (Junninen et al., 2010; Jokinen et al., 2012) in  
125 connection with a A70 CI-inlet (Airmodus Ltd) (Eisele and Tanner, 1993). The CI inlet is a laminar  
126 flow inlet operated with a sheath flow of 20 L min<sup>-1</sup> containing NO<sub>3</sub><sup>-</sup> ions which are generated by  
127 ionizing HNO<sub>3</sub> using an <sup>241</sup>Am foil upstream in the inlet design. The sample stream from Go:PAM is  
128 introduced in the centre of the sheath flow at a rate of 8 L min<sup>-1</sup>. The NO<sub>3</sub><sup>-</sup> ions are electrostatically  
129 pushed into the sample flow and form stable adducts with sample molecules as described by Ehn et al.  
130 (2012). The reaction time of oxidation products and NO<sub>3</sub><sup>-</sup> is a few hundred ms before being subsampled  
131 into the TOF-MS at 0.8 L min<sup>-1</sup> by a critical orifice. Differential pumping decreased the pressure from  
132 103 mbar in the CI source to 10<sup>-6</sup> mbar in the TOF extraction region where HOM are detected as  
133 negatively charged clusters with NO<sub>3</sub><sup>-</sup>.

134  
 135 **Figure 1: Schematics of the experimental setup with Go:PAM chamber connected to CI- API-**  
 136 **TOF-MS.**

137 A kinetic box model was used to simulate the chemistry in the Go:PAM reactor. The core of the  
 138 model were first described by Watne et al. (Watne et al., 2018). The model consists of 32 species and  
 139 68 reactions now including TMB chemistry partly from the MCM v3.3.1 (Jenkin et al., 2003) as well as  
 140 proposed mechanisms and rate coefficients for NO<sub>2</sub> chemistry (Atkinson et al., 1992; Finlayson-Pitts,  
 141 1999) and highly oxygenated compounds (Ehn et al., 2014; Berndt et al., 2018; Zhao et al., 2018) (see  
 142 SI Table S2). The photon flux used in the simulations was tuned to match measured decay of O<sub>3</sub> while  
 143 an OH sink was added to match the observed OH exposure in the background experiment, i.e. without  
 144 the addition of TMB. The model was run for all experiments with and without NO<sub>x</sub>. Primarily, the  
 145 modelled output on OH exposure for each experiments was used to interpret the results and for  
 146 calculating the consumed TMB. However, broadly the modelling output was also used to understand  
 147 the effects of changing experimental conditions on monomer, dimer and organonitrate (ON) production.  
 148 The experiments without NO<sub>x</sub> were named 1-4 denoting the increase in OH exposure and experiments  
 149 with NO<sub>x</sub> were denoted according to their NO<sub>x</sub>/ ΔTMB and high (H) and low (L) OH exposure as seen  
 150 in Table 1.

### 151 3 Results and Discussions

152 Table 1 summarises eight experiments where TMB has been oxidised by various amounts of  
 153 OH using the Go:PAM unit. Generally, a high OH production, induced either by increased light exposure  
 154 (two lamps) or elevated ozone concentration, resulted in new particles (e.g. exp 3 and 4) while addition  
 155 of NO<sub>x</sub> reduced or suppressed the particle formation. The results from the kinetic model show that the  
 156 amount of reacted TMB ranges from 5 – 30 ppb, depending on OH exposure (SI Figure S1). An overview  
 157 of the oxidation product distribution measured with the CI- API-TOF-MS for different conditions is

158 shown in Figure 3 and 4. The compounds were detected as nitrate clusters at  $m/z = \text{mass}_{\text{compound}} + 62$ .  
 159 The spectra in Figure 3 and 4 show significant ion signals from oxygenated hydrocarbons retaining the  
 160 9 carbons from the original TMB with either even H numbers (closed shell) or odd H numbers (open  
 161 shell) with limited amount of products from fragmentation, i.e. ions with less than nine C.  $C_9$  compounds  
 162 with an O/C ratio of 6/9 or higher were classified as HOM monomers with the general formula  
 163  $C_9H_{12-16}O_{6-11}$  in the mass range 280 – 360  $m/z$ . Oxygenated hydrocarbons found in the range 460 – 560  
 164  $m/z$  containing 18 C were classified as dimers with chemical formulas  $C_{18}H_{24-30}O_{10-16}$ . The monomer  
 165 with the highest intensity detected was  $C_9H_{14}O_7$   $m/z$  296. The highest intensities among the dimers were  
 166  $C_{18}H_{26}O_{10}$ ,  $C_{18}H_{28}O_{11}$  and  $C_{18}H_{28}O_{12}$  at  $m/z$  464,  $m/z$  482 and  $m/z$  498, respectively. In addition to HOM  
 167 monomers and dimers, nitrogen containing compounds were found as  $C_9$  compounds with one or two N  
 168 or  $C_{18}$  compounds with one N. The nitrogen containing compounds were of the general formulas  
 169  $C_9H_{12-18}NO_{6-13}$ ,  $C_9H_{12-18}N_2O_{8-15}$  and  $C_{18}H_{18-24}NO_{6-10}$ . The dominating ON were  $C_9H_{13}NO_8$  at  $m/z$  325,  
 170  $C_9H_{15}NO_{10}$  at  $m/z$  359 and  $C_9H_{14}N_2O_{10}$  at  $m/z$  372 respectively. In the experiments where  $NO_x$  was  
 171 added, the formation of ON compounds was increasing with the  $NO_x$  concentration. In parallel, the  
 172 levels of HOM monomers and dimers were reduced with  $NO_x$  concentration, where dimers were  
 173 stronger affected than monomers. Even if the fragmentation products were limited some fragmentation  
 174 leading to less than 9 carbons could be observed. The most prominent fragments were assigned  
 175 molecular formulas  $C_4H_7NO_7$  at  $m/z$  243,  $C_4H_6O_{12}$  at  $m/z$  246,  $C_5H_6O_{12}$  at  $m/z$  258 and  $C_6H_9NO_7$  at  $m/z$   
 176 269. Some compounds with C numbers of 15 and 17 were detected in the range 270 – 560  $m/z$  but their  
 177 contribution to the total signal was negligible (Figure 3).

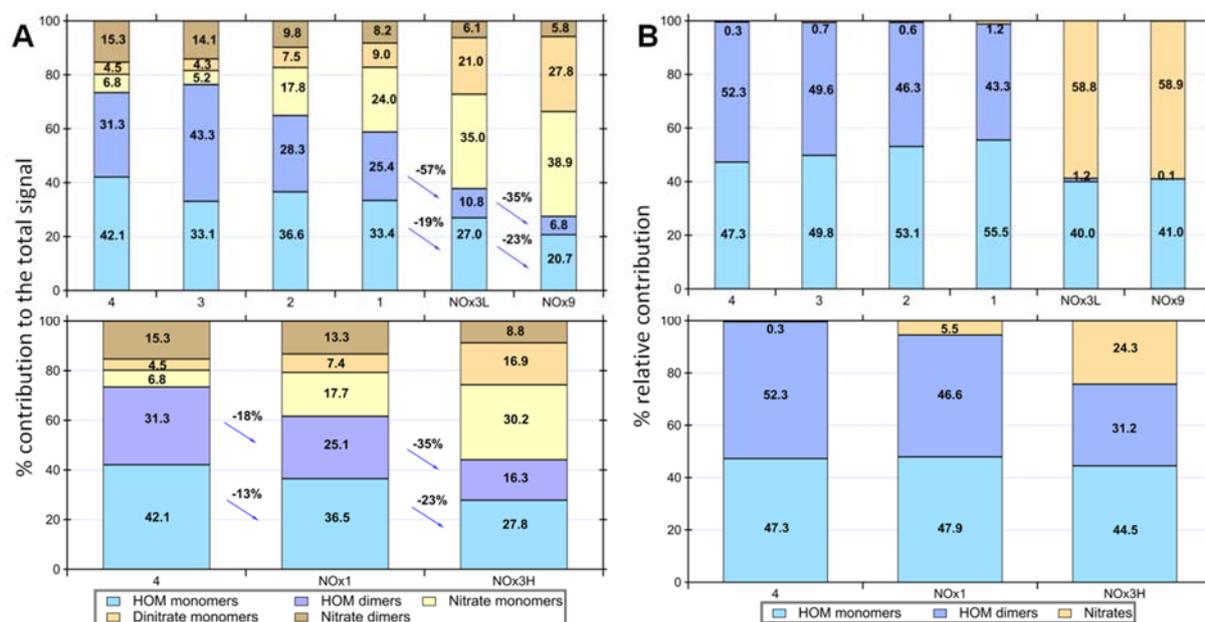

178

179 **Table 1: Experimental conditions for experiments with 30 ppb TMB. Ozone and initial  $NO_x$**   
 180 **concentration at time 0 are given in ppb and explicitly modelled OH exposure in molecules  $s\text{ cm}^{-3}$**   
 181  **$^3$ . TMB reacted ( $\Delta$  TMB) in ppb after a reaction time of 34 s and particle number concentration**  
 182 **given in  $\# \text{ cm}^{-3}$  after reaching steady state in Go:PAM. RH in all experiments was 38%.**

#	$[O_3]_0$	$[NO_x]_0$	OH exposure	$\Delta$ TMB	$NO_x / \Delta TMB$	Particle number	Contribution of top 10 species (%)
1	~19	5	$3.5 \times 10^9$	5.4	0.9	-	28.6
2	~19	5	$7.1 \times 10^9$	9.9	0.5	-	29.8
3	~100	3	$3.8 \times 10^{10}$	26	0.1	$60 \pm 14$	38.6
4	~100	3	$2.1 \times 10^{11}$	30	0.1	$1610 \pm 217$	35.9
NOx9	~9	82	$6.3 \times 10^9$	9	9.1	-	52.4

NOx3H	~100	79	$3.1 \times 10^{10}$	25	3.2	-	34.2
NOx1	~100	35	$9.1 \times 10^{10}$	30	1.2	$170 \pm 50$	30.5

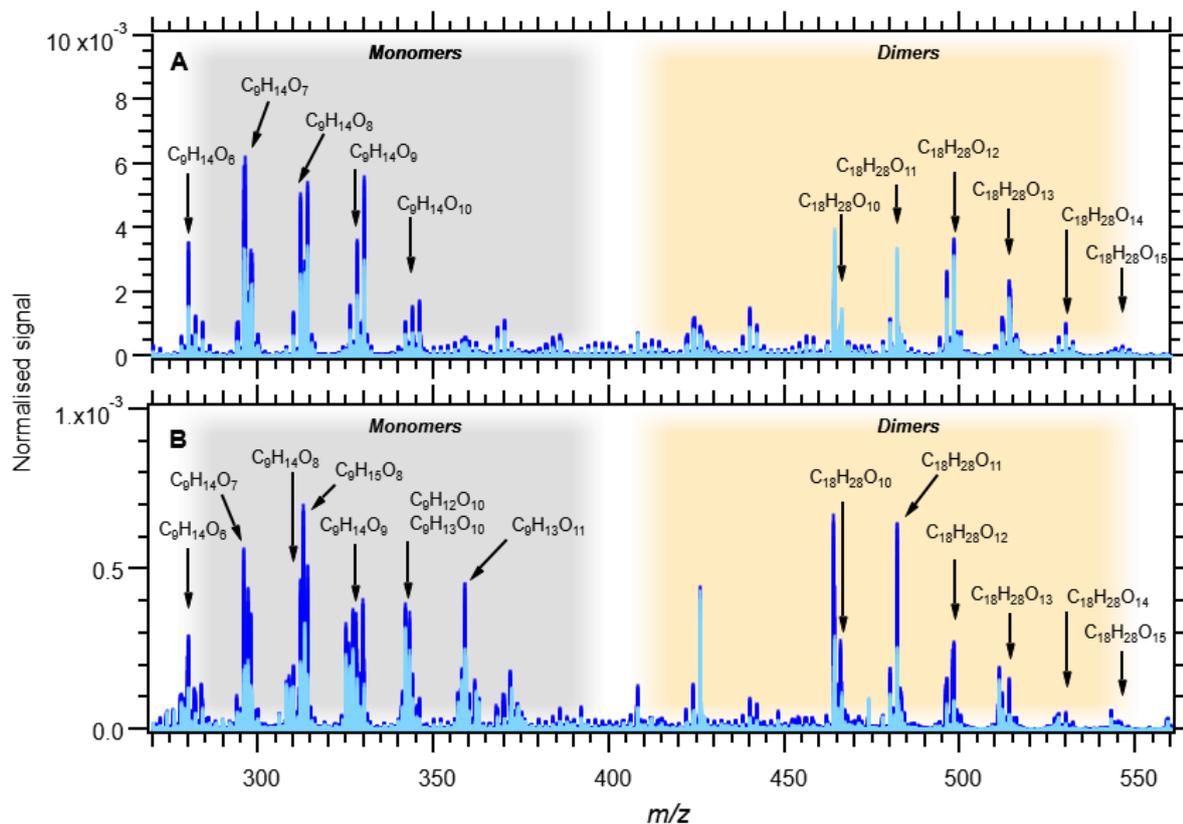

183

184 The relative contribution of the different compound classes to the total assigned signal are shown in  
 185 Figure 2. It is apparent that HOM monomers and dimers dominate in the experiments with low  $NO_x$ .  
 186 The contribution of the monomers to the total oxidation product signal ranges from 20.7- 42.1% and  
 187 dimers make 6.8 – 43.3 % of the total, depending on experimental conditions. Dimer contributions are  
 188 highest at high OH exposure (exp 3 and 4 with estimated OH exposure of  $3.8 \times 10^{10}$  and  $2.1 \times 10^{11}$   
 189 molecules  $s\text{ cm}^{-3}$ , respectively) and decrease with increasing  $NO_x$ . Nitrated compounds dominated the  
 190 spectra with contributions up to ~75% in the experiments with highest amount of  $NO_x$ . Surprisingly,  
 191 some nitrated compounds were also found in the experiments without added  $NO_x$  which may stem from  
 192 background NO contamination (~3-5ppb).

193  
 194 **Figure 2: A) Overview of different compound groups to the total explained signal. Top panel**  
 195 **illustrates the influence of a decrease of OH exposure (exp 4 - exp 1) and further decrease after**  
 196 **adding NO<sub>x</sub> in exp NO<sub>x</sub>3L – exp NO<sub>x</sub>9. Dimers show a larger relative reduction than monomers**

 200 **dimers and their relative contributions**

201 Recently, Molteni et al. (2018) assigned 17 compounds making up 80% of the total detected signal for  
 202 HOM oxidation products from the reaction of TMB with OH. Their compound with the highest fraction  
 203 of the signal (24.2%) was the dimer C<sub>18</sub>H<sub>26</sub>O<sub>8</sub>. This compound was not detected in our study. We did  
 204 neither detected deprotonated compounds in the mass range 270 – 560 *m/z* nor HOM monomers with  
 205 17 H nor compounds with O/C<0.55 which were found by Molteni et al. (2018). However, we do find  
 206 10 of the previously reported 17 monomers and dimers in our spectra. The oxidation product  
 207 distributions in our experiments are in general term more diverse, i.e. we found more compounds with  
 208 smaller yields compared to Molteni et al. (2018). In our experiments the highest 20 compounds together  
 209 explain 46 – 63 % of the total signal with the individual highest oxidation products contributing only  
 210 between 4.4 and 16%. These differences can be the result of different experimental conditions and set  
 211 up. In our study the residence time is almost double compared to Molteni et al., leading to the formation  
 212 of more oxidized compounds, especially more oxidized dimers, which have been reported in this study.  
 213 In addition we produce OH radicals through irradiation at 254 nm in the full length of the flow reactor  
 214 enhancing the effects of secondary chemistry. Despite these differences there is a general agreement on  
 215 the conclusions for the NO<sub>x</sub> free conditions with the Molteni et al. study where one rapidly form HOM  
 216 of very low volatility, that can initiate NPF.

**Figure 3: Mass spectra of all experiments without NO<sub>x</sub>: 1, 2, 3, and 4. Panel A shows experiments 3 (light blue) and 4 (blue) with OH exposure of  $2.87 \times 10^{11}$  and  $3.47 \times 10^{11}$  molecules s cm<sup>-3</sup> respectively. Panel B shows experiment 1 (light blue) and 2 (blue) with of  $3.47 \times 10^{10}$  and  $7.62 \times 10^{10}$  molecules s cm<sup>-3</sup> respectively. The signal at m/z 426 is associated with the used mass calibrant PFHA. Note the ten times lower Normalised Signal scale in B.**

217 The amount of TMB reacted after 34 s in the experiments ranges from 30 ppb (almost all) in experiment  
 218 4 to 5 ppb in experiments 1 and NO<sub>x</sub>9 (comp. Table 1 and Figure S1). The signal intensities of the HOM  
 219 monomers are increasing with increasing OH exposure. Dimer compounds also increase with increasing  
 220 OH and reach their highest levels in exp 3, resulting in the highest ratio of dimer to monomer (see Figure  
 221 2). Faster conversion of TMB will result in higher initial RO<sub>2</sub> levels enabling faster RO<sub>2</sub> + RO<sub>2</sub> (self-)  
 222 reaction. The concentration profile of RO<sub>2</sub> in exp 1 and 2 is lower and more evenly spread out over the  
 223 length of Go:PAM (Figure S1) and the influence of the RO<sub>2</sub> + RO<sub>2</sub> reaction will be less in these  
 224 experiments compared to exp 3 and 4. Enhanced OH exposure does not only affect the monomer/dimer  
 225 ratio but also the total amount of compounds measured. Observed compounds were 10 times higher in  
 226 the high OH exposure exp 3, 4, compared to exp 1, 2. This was also valid for the experiments with added  
 227 NO<sub>x</sub> (NO<sub>x</sub>1 and NO<sub>x</sub>3<sub>H</sub> vs NO<sub>x</sub>3<sub>L</sub> and NO<sub>x</sub>9). Under high OH exposure (exp 4) the major HOM  
 228 monomer is C<sub>9</sub>H<sub>14</sub>O<sub>7</sub> with a contribution of 5.5 % to the total explained signal, followed by C<sub>9</sub>H<sub>16</sub>O<sub>9</sub>  
 229 and C<sub>9</sub>H<sub>14</sub>O<sub>8</sub>, contributing 4.6 and 4.5 % respectively.

230 At the lowest OH exposure (exp 1) the major signals comprise the monomer C<sub>9</sub>H<sub>12</sub>O<sub>10</sub> and the dimers  
 231 C<sub>18</sub>H<sub>26</sub>O<sub>10</sub> and C<sub>18</sub>H<sub>28</sub>O<sub>11</sub>, contributing 4.4, 4.0 and 3.4 % to the total. These dimer compounds,  
 232 C<sub>18</sub>H<sub>26</sub>O<sub>10</sub> and C<sub>18</sub>H<sub>28</sub>O<sub>11</sub>, are the highest signals in exp 2 and 3. Two open shell species were found  
 233 among the larger signals in exp 1 and 2 (see Figure 3): C<sub>9</sub>H<sub>15</sub>O<sub>8</sub> and C<sub>9</sub>H<sub>15</sub>O<sub>7</sub>.

234 The number of H atoms is a characteristic for HOM monomers and dimers. An overview of  
 235 different oxidation product generations is given in Table 2. We observe HOM monomers with 12-16 H

236 and all compounds with an even number of H are closed shell products. Compounds with an uneven  
 237 number of H are open shell molecules (radicals). Following the proposed termination scheme by Mentel  
 238 et al. (2015) compounds with 12 H can be identified as first generation monomers (terminated from  
 239 C<sub>9</sub>H<sub>13</sub>O<sub>x</sub> radicals, reaction 3) and compounds with 16 H as second generation monomers (terminated  
 240 from C<sub>9</sub>H<sub>15</sub>O<sub>x</sub> radicals, reaction 4). C<sub>9</sub>H<sub>14</sub>O<sub>x</sub> can be either first or second generation products and  
 241 originate from either C<sub>9</sub>H<sub>13</sub>O<sub>x</sub> or C<sub>9</sub>H<sub>15</sub>O<sub>x</sub> (reactions 5 and 6).

246 The RO<sub>2</sub> radicals C<sub>9</sub>H<sub>13,15</sub>O<sub>x</sub> can form dimers likely via the reaction

248 Such reaction is possible between any HOM-RO<sub>2</sub>, first or second generation (and other C<sub>9</sub> peroxy  
 249 radicals with sufficient high abundance). Two first generation HOM-RO<sub>2</sub> will result in C<sub>18</sub>H<sub>26</sub>O<sub>x</sub> dimers  
 250 (reaction 8) while one first and one second generation HOM-RO<sub>2</sub> produce a C<sub>18</sub>H<sub>28</sub>O<sub>x</sub> (reaction 9) and  
 251 dimerization of two second generation HOM-RO<sub>2</sub> will result in dimers of the formula C<sub>18</sub>H<sub>30</sub>O<sub>x</sub> (reaction  
 252 10).

256 A closer examination of the contribution of different HOM generations in Table 2 shows that  
 257 first generation monomers with 12 H are showing the highest contribution in experiments with low OH  
 258 exposure (exp 1, 2) while monomers with 14 H gain importance with higher OH exposure. The second  
 259 generation monomers with 16 H dominate in experiments with the highest OH exposure (exp 3, 4). The  
 260 dimer population with 28 H has a larger fraction of the total signal at higher OH exposures compared to  
 261 dimers with 26 H. Dimer population with 30 H is generally lower than other dimers but has the highest  
 262 fraction in exp 4. The overall dimer fraction of up to 43% in this study (Figure 2) is similar to the dimer  
 263 fraction of 40% reported by Molteni et al. (2018). However, the relative contributions of monomer and  
 264 dimer generations differ. We find higher contributions of H<sub>12</sub> monomers (up to 11%) and a higher  
 265 contribution of H<sub>28</sub> dimer (up to 12%) under our experimental conditions. The contribution of H<sub>14</sub>  
 266 monomers and H<sub>26</sub> dimers is significantly less compared to Molteni et al. (2018).

267 Increasing OH exposure promotes second OH attacks on oxidation products leading to the  
 268 observed reduction of first generation products (C<sub>9</sub>H<sub>12</sub>O<sub>x</sub>) as well as increase of second generation  
 269 products (C<sub>9</sub>H<sub>14</sub>O<sub>x</sub> and C<sub>9</sub>H<sub>16</sub>O<sub>x</sub>). The C<sub>9</sub>H<sub>14</sub>O<sub>x</sub> products have mainly characteristics of second  
 270 generation products, as their contribution is enhanced in the experiments with higher OH exposures  
 271 (Table S1), in which there is an enhanced possibility for secondary chemistry initiated by reaction of  
 272 OH with the first generation products. The increased oxidation degree can also explain the formation of  
 273 dimers (C<sub>18</sub>H<sub>28</sub>O<sub>x</sub>) from first and second generation RO<sub>2</sub> (C<sub>9</sub>H<sub>13</sub>O<sub>x</sub> and C<sub>9</sub>H<sub>15</sub>O<sub>x</sub>) at higher OH exposure  
 274 and the increase in second generation dimers. Open shell species are observed as first generation RO<sub>2</sub>  
 275 (C<sub>9</sub>H<sub>13</sub>O<sub>x</sub>) and have a higher contribution lower at OH exposures. Second generation RO<sub>2</sub> (C<sub>9</sub>H<sub>15</sub>O<sub>x</sub>)  
 276 have the highest contribution in exp 3. At the highest OH exposures in exp 4, the contribution of C<sub>9</sub>H<sub>15</sub>O<sub>x</sub>  
 277 radicals, one of the top ten contributors to the signal (Table S1), is reduced, while the contribution of  
 278 the second generation products (C<sub>9</sub>H<sub>14</sub>O<sub>x</sub> and C<sub>9</sub>H<sub>16</sub>O<sub>x</sub>) and dimers increased.

279

280 **Table 2: Contribution of oxidation product families to the total signal between 270 – 560 m/z**

Compound family	1	2	3	4	NO <sub>x</sub> 9	NO <sub>x</sub> 3 <sub>L</sub>	NO <sub>x</sub> 3 <sub>H</sub>	NO <sub>x</sub> 1
C <sub>9</sub> H <sub>12</sub> O <sub>x</sub>	11.3	7.8	3.5	5.4	8.5	9.3	5.9	5.4
C <sub>9</sub> H <sub>13</sub> O <sub>x</sub>	5.7	4.5	3.3	2.1	6.0	7.0	5.6	4.2
C <sub>9</sub> H <sub>14</sub> O <sub>x</sub>	8.3	10.8	9.9	17.4	4.3	6.6	8.0	13.0
C <sub>9</sub> H <sub>15</sub> O <sub>x</sub>	5.6	7.2	9.4	4.1	2.4	3.3	4.6	4.7
C <sub>9</sub> H <sub>16</sub> O <sub>x</sub>	4.8	8.0	7.7	14.5	1.5	2.5	4.8	10.3
C <sub>18</sub> H <sub>26</sub> O <sub>x</sub>	8.5	9.1	8.5	9.3	0.8	2.0	2.7	6.0
C <sub>18</sub> H <sub>28</sub> O <sub>x</sub>	7.1	9.9	9.3	11.0	0.4	1.2	2.6	6.9

C <sub>9</sub> H <sub>13</sub> NO <sub>x</sub>	6.2	4.7	0.6	0.6	26.8	17.1	10.1	4.8
C <sub>9</sub> H <sub>15</sub> NO <sub>x</sub>	6.4	5.6	0.7	0.9	3.7	10.3	14.5	8.5
C <sub>9</sub> H <sub>14</sub> N <sub>2</sub> O <sub>x</sub>	2.1	1.7	1.0	1.1	18.7	11.8	7.5	1.9

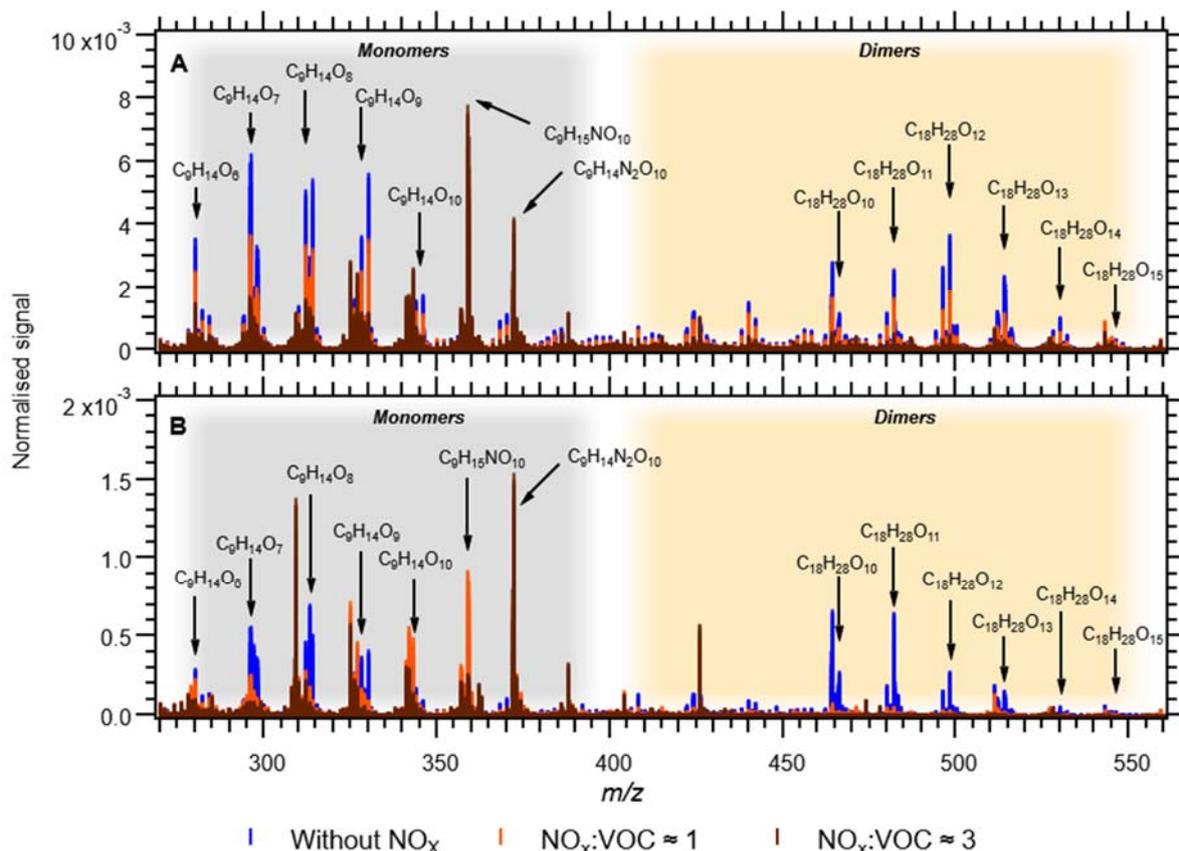

281  
 282 In this study the contribution of C<sub>18</sub>H<sub>28</sub>O<sub>x</sub> shows that both first and second generation HOM-  
 283 RO<sub>2</sub> were dimerising. The kinetics of dimer formation, if produced from RO<sub>2</sub> self-reaction, depends on  
 284 the square of [HOM-RO<sub>2</sub>] and their relative importance will increase with the RO<sub>2</sub> concentration.  
 285 Increased local RO<sub>2</sub> concentrations (in the first part of Go:PAM) would explain the increase of dimers  
 286 with increasing OH exposure.

287 Substantial particle formation was observed in exp 4, under the highest OH exposure. Although  
 288 the amount of reacted TMB in exp 3 and 4 is similar (26 and 30 ppb respectively), significant particle  
 289 formation was not observed under the conditions of exp 3. The rate at which new particle formation  
 290 (nucleation) occurs is related to the chemical composition and concentration of the nucleating species  
 291 (McGraw and Zhang, 2008). After reaching the critical nucleus, particle growth becomes spontaneous  
 292 in the presence of condensable vapour. Apparently, the local concentration of nucleating species or  
 293 condensable vapour was not high enough in exp 3 to yield large numbers of particles, compared to exp  
 294 4. According to recent studies (Ehn et al., 2014; Trostl et al., 2016; Mohr et al., 2017; McFiggans et al.,  
 295 2019) dimers play an important role in new particle formation. Mohr et al. (2017) found decreased levels  
 296 of gas phase dimers in ambient air during NPF events, which is in line with our observations of lower  
 297 dimer levels in the presence of particles in exp 4, compared to exp 3. A large enough concentration of  
 298 low volatility dimers obviously helps forming critical nuclei that then grow by condensation. Note that  
 299 the newly formed particles will provide an additional sink for dimers and thus reduce their presence as  
 300 observable gas phase products at the end of the flow reactor.

301  
 302 **Influence of NO<sub>x</sub>**

303 In the experiments NO<sub>x</sub>1, NO<sub>x</sub>3<sub>H</sub>, NO<sub>x</sub>3<sub>L</sub> and NO<sub>x</sub>9, the NO<sub>x</sub> levels were increased (Table 1).  
 304 As already has been described NO<sub>x</sub> was introduced to the Go:PAM as NO. After the addition of ozone,  
 305 the ozone concentration decreases from 100 ppb to ~80 ppb at the experiment with lower NO<sub>x</sub> levels  
 306 and to ~50 ppb at the experiment with higher NO<sub>x</sub> levels, as it reacts with NO producing NO<sub>2</sub>. For both  
 307 high and low NO<sub>x</sub> conditions there is NO left after the initial reaction with ozone (see grey areas of  
 308 Figure S3). The presence of NO<sub>x</sub> gave nitrogen containing C<sub>9</sub> compounds with one or two N atoms and  
 309 C<sub>18</sub> compounds with only one N atom, in addition to HOM monomers and HOM dimers. These  
 310 compounds are expected to be nitrates or peroxy nitrates, as it is highly unlikely to form nitro-aromatic  
 311 compounds from TMB (Sato et al., 2012). N-containing compounds were the dominating species in  
 312 experiments with NO<sub>x</sub> (see Figure 2), except for the experiment NO<sub>x</sub>1 with the smallest amount of NO<sub>x</sub>

313 added and a high OH exposure (NO<sub>x</sub>1). The amount of nitrated compounds increased with the amount  
 314 of added NO<sub>x</sub> at the expense of HOM monomers and HOM dimers as illustrated by the arrows in Figure  
 315 2. The effect of the added NO<sub>x</sub> is attenuated at higher OH exposure. E.g., the nitrated monomers are  
 316 reduced from 35.0 and 38.9% at low OH exposure down to 17.7 and 30.2% at high OH exposure. Under  
 317 elevated NO<sub>x</sub> conditions nitrated species were found among the 10 compounds with the highest  
 318 contribution to the respective total signal, (see the top-ten lists Table S1 and Figure 4).  
 319

320  
 321 **Figure 4: Comparison of mass spectra of HOM and nitrates.** Panel A shows experiment 4 (blue),  
 322 NO<sub>x</sub>1 (orange) and experiment NO<sub>x</sub>3<sub>H</sub> (brown). Panel B shows experiments 2 (blue), NO<sub>x</sub>3<sub>L</sub>  
 323 (orange) and NO<sub>x</sub>9 (brown).

324 For the two experiments with low OH exposure where the nitrated species dominated, seven out  
 325 of the top ten species were nitrated with the highest signal arising from the di-nitrated compound  
 326 (C<sub>9</sub>H<sub>14</sub>N<sub>2</sub>O<sub>10</sub>). In these two experiments the top-ten compounds contributed the most to the observed  
 327 signal (42.3 and 52.4%); most likely owing to the high fraction of nitrated species acting as radical chain  
 328 termination products. Under highest NO<sub>x</sub> conditions, the high OH exposure experiment (NO<sub>x</sub>3<sub>H</sub>) has  
 329 six nitrated compounds in the top-ten list with the di-nitrated C<sub>9</sub>H<sub>14</sub>N<sub>2</sub>O<sub>10</sub> on the second rank. In  
 330 experiment NO<sub>x</sub>1 only one nitrated species (C<sub>9</sub>H<sub>15</sub>NO<sub>10</sub>) is found in the top-ten list despite the elevated  
 331 NO<sub>x</sub> conditions.

332 Dimer formation is drastically reduced in the presence of elevated NO<sub>x</sub>. The NO<sub>x</sub> effect on NPF  
 333 was clear and high NO<sub>x</sub>/ΔTMB suppresses NPF from TMB oxidation, a trend that was also observed by  
 334 Wildt et al. (2014) and Lehtipalo et al. (2018) for NPF from monoterpene oxidation. Whenever the  
 335 products were dominated by ON (NO<sub>x</sub>3<sub>L</sub>, NO<sub>x</sub>9 and NO<sub>x</sub>3<sub>H</sub>) particle formation was not observed.  
 336 Reduced particle formation was observed in NO<sub>x</sub>1 compared to exp 1 which had a higher contribution  
 337 of HOM. Owing to the importance of dimers for NPF, as reported by Lehtipalo et al. (2018), we suggest

338 that the reaction of RO<sub>2</sub> + NO resulting in ON is responsible for the observed reduced particle formation,  
 339 because it competes with the dimer formation from RO<sub>2</sub> + RO<sub>2</sub>, This reaction is also reducing the  
 340 contribution of HOM monomers and dimers with increasing NO<sub>x</sub>/ΔTMB and decreasing OH exposure  
 341 from a total of 61% in exp NOx1 (OH exposure=9.1×10<sup>10</sup> molecules s cm<sup>-3</sup>) to 27.5% in NOx9 (OH  
 342 exposure=6.3×10<sup>9</sup> molecules s cm<sup>-3</sup>). The reaction RO<sub>2</sub> + NO reduce the amount of HOM monomers  
 343 and dimers in competing with autoxidation and termination by RO<sub>2</sub>+RO<sub>2</sub> or RO<sub>2</sub>+HO<sub>2</sub>. The yield of ON  
 344 from NO+RO<sub>2</sub> might be significant (e.g. up to 0.3) based on the measurable increase of ON and the  
 345 decrease of NO<sub>x</sub> in the system (Figure S3).

346 The contribution of HOM monomer generations follows the general trend observed in  
 347 experiments without NO<sub>x</sub>. The first generation HOM have higher contribution at low OH exposures in  
 348 NOx3<sub>L</sub> and NOx9 and the contribution of second generation HOM is higher the higher the OH exposure  
 349 is. Similarly, the contribution of C<sub>9</sub>H<sub>14</sub>O<sub>x</sub> is increasing with increasing OH exposure. Analogously to the  
 350 families of HOM, different families of nitrates can be defined. Table 2 gives an overview of the nitrate  
 351 families and how they contribute to the total signal in the experiments. At lowest OH exposures we find  
 352 the highest contributions of first generation nitrates (C<sub>9</sub>H<sub>13</sub>NO<sub>x</sub>) as well as di-nitrates (C<sub>9</sub>H<sub>14</sub>N<sub>2</sub>O<sub>x</sub>). The  
 353 contribution of second generation nitrates (C<sub>9</sub>H<sub>15</sub>NO<sub>x</sub>) is increasing with increasing OH exposure and is  
 354 highest in NOx3<sub>H</sub>.

355 For the formation of observed first generation nitrates C<sub>9</sub>H<sub>13</sub>NO<sub>6-12</sub> (C<sub>9</sub>H<sub>13</sub>NO<sub>x</sub> in Table 2) we  
 356 propose the reaction of a first generation (HOM-)RO<sub>2</sub> with NO following the pathway:

358 The precursor C<sub>9</sub>H<sub>13</sub>O<sub>5</sub> is formed after one autoxidation step and its termination reaction with NO results  
 359 in C<sub>9</sub>H<sub>13</sub>NO<sub>6</sub> which has only minor contribution. C<sub>9</sub>H<sub>13</sub>NO<sub>7&8</sub>, with higher contribution in exp NOx3<sub>L</sub>  
 360 and NOx9 can be formed from the radicals C<sub>9</sub>H<sub>13</sub>O<sub>6</sub> and C<sub>9</sub>H<sub>13</sub>O<sub>7</sub> respectively. The even oxygen number  
 361 in C<sub>9</sub>H<sub>13</sub>O<sub>6</sub> indicates that the compound should have undergone a transformation to RO (via reaction  
 362 with RO<sub>2</sub> or NO) and subsequent H-shift and further O<sub>2</sub> addition (Vereecken and Peeters, 2010; Mentel  
 363 et al., 2015). A proposed detailed reaction mechanism is depicted in the Figure 5.

364 Second generation nitrates (C<sub>9</sub>H<sub>15</sub>NO<sub>8-12</sub>) can be formed after an additional OH attack (and introduction  
 365 of an additional H) on a first generation (HOM) monomer, which explains the increase of these  
 366 compounds with increasing OH exposure. The termination of the RO<sub>2</sub> radical chain with NO (reaction  
 367 12) will then lead to the formation of the second generation nitrate. The formation of RO<sub>2</sub> precursor  
 368 species with 7-8 O numbers, i.e. C<sub>9</sub>H<sub>15</sub>O<sub>7-8</sub> likely stem from compounds terminated earlier in the radical  
 369 chain process (C<sub>9</sub>H<sub>14</sub>O<sub>4-5</sub>), which do not fall in the typical HOM class (O:C ≥ 6:9). The reaction of a first  
 370 generation nitrate with OH, followed by autoxidation could also possibly produce C<sub>9</sub>H<sub>15</sub>NO<sub>8-12</sub> by  
 371 terminating via peroxy (reaction 13) or hydroperoxy pathway (reaction 14).

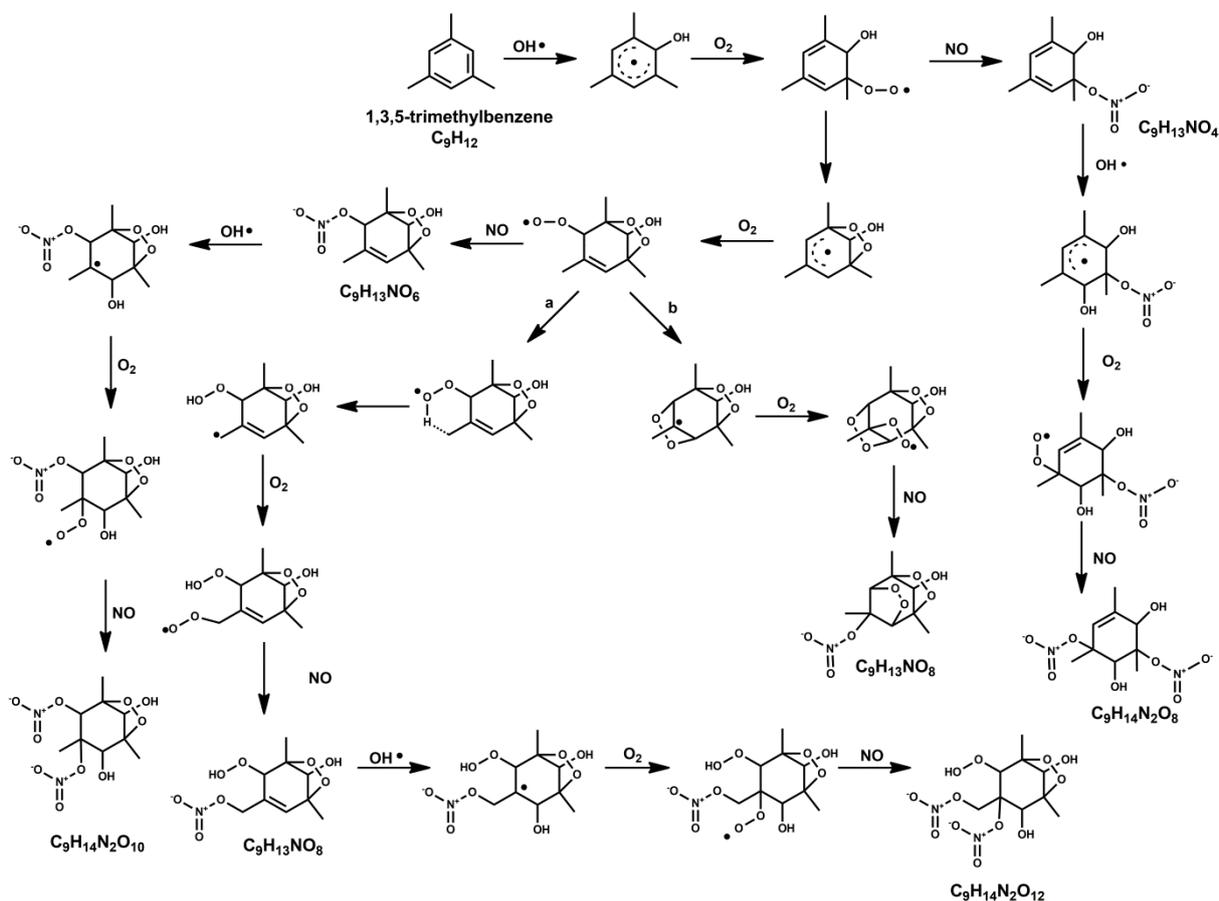

375 For the formation of the most abundant di-nitrates of the formula C<sub>9</sub>H<sub>14</sub>N<sub>2</sub>O<sub>8-12</sub> (reaction 15), OH has to  
 376 attack a nitrated compound C<sub>9</sub>H<sub>13</sub>NO<sub>6-10</sub> and the RO<sub>2</sub> radical chain has to be terminated with NO (Figure  
 377 5).

379 The precursor species C<sub>9</sub>H<sub>14</sub>NO<sub>7</sub> would be in this case formed from the OH attack on the smallest  
 380 possible nitrate C<sub>9</sub>H<sub>13</sub>NO<sub>4</sub> (formed after one autoxidation step and NO termination).

381 It should be noted that the formation of peroxy nitrates via the reaction  $RO_2 + NO_2 \rightarrow RO_2NO_2$  with  
 382 alkyl and acyl- $RO_2$  (PAN-like) cannot be ruled out as a potential formation mechanisms of nitrates.  
 383 The volatility of the produced ON seems to be too high (compared to dimers) to initiate NPF at the  
 384 present concentrations as seen from the reduction in particle formation potential from exp 4 (HOM  
 385 dominated, particle formation) to  $NOx_1$  (reduction in HOM and increase in ON, reduced particle  
 386 formation) and  $NOx_{3H}$  (ON dominated, no particle formation).

387  
 388 **Figure 5: The proposed radical reaction mechanism for the formation of some of the mono- and**  
 389 **di-nitrates from TMB mentioned in this study. Two separate mechanisms were suggested for the**  
 390 **species with the formula  $C_9H_{13}NO_8$ , which formation pathways are based on (a) (Wang et al., 2017)**  
 391 **and (b) (Molteni et al., 2018).**

392 Figure 2B shows the results for the evolution of HOM monomer, HOM Dimers and organic  
 393 nitrates (ON) as calculated using the kinetic model described in detailed in SI. The model used has a  
 394 very simplified scheme for TMB oxidation and subsequent  $RO_2$  chemistry. We implemented a few rate  
 395 coefficients suggested in the literature in order to demonstrate how those compare with our experimental  
 396 results. Rate coefficients for  $RO_2$  termination reactions from MCM in combination with rate coefficients  
 397 of dimer formation by Berndt et al. (2018) (case 1 and 2 in SI Table S2) led to an overestimation of  
 398 dimer compounds. Better representation of the observations were achieved by applying a) the rate  
 399 coefficients proposed by (Zhao et al., 2018) for dimer formation ( $2.0 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ ) and  
 400  $1.0 \times 10^{-12} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$  for termination and RO formation with branching ratios of 0.4 and 0.6,  
 401 respectively; b) the rate coefficient ( $1.0 \times 10^{-11} \text{ cm}^3 \text{ molecules}^{-1} \text{ s}^{-1}$ ) from Berndt et al. (2018) for  $HOMRO_2$   
 402 +  $NO$  with a branching ratio of 0.3 for ON formation (reaction 56 in Table S2).

403 In Figure 2B, the calculated HOM dimer contribution are the sum of medium (produced from  
 404  $HOM-RO_2+RO_2$ ), and highly oxidised dimers (produced from  $HOM-RO_2 + HOM-RO_2$ ) while the ON

405 includes both organic nitrates (produced from HOM-RO<sub>2</sub>+NO) and peroxy nitrates (produced from  
406 HOM-RO<sub>2</sub>+NO<sub>2</sub>). The increased production of monomers calculated for exp 1 and 2 is in agreement  
407 with experimental results, where we observed a slightly larger contribution from monomers compared  
408 to dimers. Calculated concentrations for dimers are similar in exp 3 and higher in exp 4, compared to  
409 monomers. Secondary chemistry (reaction of OH with the products and possible formation of a second  
410 generation of HOM or nitrates) was not taken into consideration in the model. For the experiment with  
411 NO<sub>x</sub> (Figure 2B) the modeled product distribution follows the general trend of monomer, dimer and  
412 nitrate that we observe in the exp NO<sub>x</sub>3<sub>L</sub> and NO<sub>x</sub>9 with a general higher nitrate production compared  
413 to monomers and dimers. For the NO<sub>x</sub> experiments with high initial ozone, the model can reproduce the  
414 higher HOM monomer and dimer levels in NO<sub>x</sub>1 but slightly overestimates the contribution of dimers.  
415 Particle formation was observed in NO<sub>x</sub>1 which might explain the overestimation owing to missing  
416 condensation sink in the model. Modelling NO<sub>x</sub>3<sub>H</sub> gives an overestimation of monomers and dimers.  
417 In NO<sub>x</sub>3<sub>H</sub> modelled dimers start forming after ~15 sec. Almost all NO is converted to ON or NO<sub>2</sub> at this  
418 point and the reaction HOM-RO<sub>2</sub>+NO does not produce additional ON and the modelled levels of ON  
419 reach a plateau while contribution of HOM dimers can increase. For exp NO<sub>x</sub>1 and NO<sub>x</sub>3<sub>H</sub> the model  
420 is in better agreement with the measurements if only the HOM - dimer formation (from HOM-  
421 RO<sub>2</sub>+HOM-RO<sub>2</sub>) is taken into account, i.e. highly oxidized dimers excluding medium oxidized dimer  
422 (from HOM-RO<sub>2</sub> + RO<sub>2</sub>). Generally, the simplified model was able to support our analysis of the TMB  
423 chemistry as described above. Furthermore, it gave some support to the recently suggested mechanisms  
424 included in case 3 (e.g. (Zhao et al., 2018))  
425

#### 426 **4 Atmospheric implication and Conclusion**

427 We have measured the formation of HOM monomers and dimers from OH initiated oxidation  
428 of TMB. The experiments with highest OH exposures lead to particle formation when NO<sub>x</sub> was not  
429 added. With increasing OH exposure and increased likelihood of a second OH attack, we observe a  
430 higher contribution from second generation oxidation products and dimers in general. The latter is  
431 attributed to the increased RO<sub>2</sub> concentrations from the increased/fast TMB consumption by OH. The  
432 observed products in this study match what would be expected as termination products from previously  
433 proposed reaction mechanisms for HOM formation.

434 The addition of NO<sub>x</sub> to simulate urban condition leads to the formation of ON in addition to  
435 HOM and a reduction in particle formation potential. We observe that the formation of ON is increasing  
436 with increasing NO<sub>x</sub>/ΔTMB, mostly at the expense of dimers. The presence of ONs, formed at the  
437 expense of dimers, can explain the decreased tendency for particle formation. We therefore suggest that  
438 the reaction HOM-RO<sub>2</sub>+NO competes with HOM-RO<sub>2</sub> self-reaction yielding primarily a reduction in  
439 dimer formation, which is responsible for the reduction in particle formation. The experimental designed  
440 using the Go:PAM with concentrations of HO<sub>x</sub> (and RO<sub>x</sub>) higher than ambient would attenuate the  
441 influence of added NO<sub>x</sub>. This will further emphasize the implication of our findings and most likely the  
442 NO<sub>x</sub> effect would be even more important in the urban atmosphere.

443 According to studies by (Molteni et al., 2018) and (Wang et al., 2017) HOM formation from  
444 AVOCs was observed and consequently AVOC-HOM were suggested as potential contributors to  
445 observed NPF in urban atmospheres. In our study, under NO<sub>x</sub> free conditions, we found several of  
446 previous identified HOM even if we did not fully agree with the identity and relative importance of all  
447 HOM. However, the oxidation in polluted environments will happen under elevated NO<sub>x</sub> levels and, as  
448 has been shown here this can lead to formation of ON instead of HOM and subsequently a reduction in  
449 NPF potential. We conclude that for interpretation of NPF from aromatics in urban areas care should be

450 taken and the OH exposure, NO<sub>x</sub> levels and RO<sub>2</sub> concentrations need to be considered in details since  
451 they will largely determine if the HOM-RO<sub>2</sub>+NO can compete with reactions yielding HOM, and  
452 especially HOM dimers.
