32 **Abstract**

33 Air pollution in West Africa has yet to be well characterized and was one of the principal
34 motivations of the “Air Pollution and Health” work package in the DACCIWA (Dynamics-
35 Aerosol-Chemistry-Cloud Interactions in West Africa) program. Intensive measurement
36 campaigns were performed in two West African capitals (Abidjan in Côte d’Ivoire and Cotonou
37 in Benin), in order to examine the size distribution of particulate matter (PM) and their chemical
38 composition (Elemental Carbon (EC), Organic Carbon (OC), Water-soluble organic carbon
39 (WSOC), Water-soluble inorganic ions (WSI) and trace metals). In this study, we characterize
40 PM from different sites in Abidjan which are representative of Domestic Fires (ADF), Traffic
41 (AT) and Waste Burning (AWB), as well as a Traffic site (CT) in Cotonou. These sites,
42 impacted by a large volumes of pollution, are representative of the main combustion sources in
43 south West Africa during the dry and wet seasons. To this end, intensive campaigns were run
44 in Abidjan and Cotonou in July (2015 and 2016) and January (2016 and 2017).

45 Results show a well-marked seasonality and inter-annual variability and spatial
46 variabilities with PM₁₀ levels higher than the WHO guidelines of 25 $\mu\text{g}/\text{m}^3$. The average mass
47 concentrations during the wet season were 90, 104.1, 69.1 and 517.3 $\mu\text{g}\cdot\text{m}^{-3}$ at the AT, CT,
48 AWB and ADF sites, respectively. The largest value at the ADF site is due to the contribution
49 of food smoking and roasting activities. In the dry season, concentrations increase to 141.3,
50 269.7 and 175.3 $\mu\text{g}\cdot\text{m}^{-3}$ at the AT, CT and AWB sites respectively, whereas at the ADF site,
51 concentrations decrease to 375.7 $\mu\text{g}\cdot\text{m}^{-3}$.

52 The chemical aerosol mass closure shows that dust contributed to 25-65% of PM at both
53 the AT, CT and AWB sites, and 10-30% at the ADF site with a clear seasonal cycle. A large
54 variability in Particulate Organic Matter (POM) is observed, ranging from 37-68% at ADF, 20-
55 42% at AT, 10-34% at AWB and 15-22% at CT. The contribution of WSI to bulk PM (lower
56 than 20%) is 2-3 times larger in the wet season than the dry, except at the ADF site where no
57 season variation is observed. The most dominant species in the WSI fraction at ADF are
58 chloride (18-36% of the total ions), potassium (8-22%) and calcium (13-25%), while at the rest
59 of the sites, nitrate (21-36%), chloride (6-30%) and sulfate (9-20%) are dominant. At all sites,
60 the proportion of EC is twice as high in the dry season as in the wet season. Carbonaceous
61 aerosol (sum of EC and POM) and dust particles are the two major contributors to the coarse,

62 fine, and ultrafine particle fractions with carbonaceous aerosol predominant in Abidjan, while
63 dust is predominant in Cotonou.

64 The highest carbonaceous aerosol contribution is observed at ADF (up to 75% of total
65 PM), while at the other sites its contribution ranges between 18 and 35%. WSOC levels are the
66 highest at the ADF site with more important values during the wet season. The concentrations
67 of WSOC at the Abidjan traffic site are higher than those recorded at the Cotonou traffic site in
68 the wet seasons, but lower in dry periods. Element trace characterization is also determined,
69 showing predominance of Al, Na and Ca followed by Fe, K and Mg.

70 Our study highlights the contribution of different traffic emissions in two major West
71 African cities to atmospheric aerosol composition. It also highlights the role of domestic fires
72 and waste combustion sources. It constitutes an original database that characterizes urban air
73 pollution from specific African combustion sources.

74 **Keywords:** DACCIWA, atmospheric pollution, size distribution, chemical composition,
75 traffic, waste burning, domestic fire, biomass burning.

76

77 1. Introduction

78 The impact of anthropogenic pollution on health has been demonstrated by numerous
79 studies in Europe and North America which have contributed to the implementation of emission
80 reduction policies. By contrast, air pollution in Africa is far from being well characterized,
81 although it is suspected to be responsible for negative health outcomes (World Health Organization, 2016). This is a major
82 problem since Africa is an intense emitter of pollution including biomass burning domestic
83 fires, car traffic and growing oil and mining industries. It also has one of the fastest growing
84 populations in the world. Indeed, it has been shown that massive urbanization and rapid
85 economic growth could be responsible for tripling anthropogenic emissions in Africa between
86 2000 and 2030 (Lioussé et al., 2014). This results in a major degradation of air quality and an
87 impact on the health of exposed populations. Only a few studies on this subject have been
88 conducted in Africa (Val et al., 2013; Dieme et al., 2012; Kouassi et al., 2010).

89 Because of its high atmospheric particulate concentrations already measured to be of
90 the same order as in Asian megacities, as well above international standards of the WHO
91 (World Organization Health) (WHO, 2014), and due to the complex mixture of pollutants from
92 various origins, West Africa is an "unique laboratory" to study urban pollution. Previous studies

93 conducted under the framework of the AMMA (Analyses Multidisciplinaires de la Mousson
94 Africaine) and POLCA (POLlution des Capitales Africaines) programs, have revealed very
95 high pollution concentration levels in Cotonou (Benin), Bamako (Mali), Dakar (Senegal) and
96 Yaoundé (Cameroun) during the dry season, suggesting that the population may be affected by
97 negative health outcomes. For example, Val et al. (2013) showed that the inflammatory impact
98 of combustion aerosol depends on the type of emission sources and determined the predominant
99 role of particulate organic matter. Moreover, fine and ultrafine aerosol fractions, as well as
100 specific compositions including trace metals and organic compounds, have been shown to
101 induce biological effects due to their ability to reach the distal lung (Cassee et al., 2013). Such
102 reasons highlight the need to better understand the size-speciation of aerosol chemical
103 composition for the main African anthropogenic sources during the different seasons. In this
104 context, the DACCIWA (Dynamics-Aerosol-Chemistry-Cloud Interactions in West Africa)
105 program, dedicated a specific work package to “Air Pollution and Health” dealing with
106 pollutant characterization related to health issues through toxicological studies and
107 inflammatory risk modeling. The strategy was to measure aerosol chemical composition in two
108 typical traffic-sampling sites, one in Abidjan (Côte d’Ivoire) and another one in Cotonou
109 (Benin), which differ in terms of fleets, type of fuel used and quality of roads.

110 In Cotonou, the majority of the population uses motorbikes for transportation, whereas in
111 Abidjan the vehicle fleet is dominated by diesel engines. Measurements were also performed
112 at domestic fire and waste burning sites, both located in Abidjan. Intensive campaigns have
113 been organized during both the dry and wet seasons of January 2016 and 2017 in Abidjan and
114 Cotonou. In this paper, we present the aerosol chemical results for these cities and the different
115 studied combustion sources: (i) PM size distribution and mass concentrations and (ii) PM
116 chemical composition including carbonaceous aerosol, water-soluble organic carbon, water-
117 soluble inorganic ions, dust and trace elements for coarse, fine, ultrafine particles will be
118 detailed for all sites.

119

120 **2. Experimental method**

121 **2.1. Experimental sites**

122 Four measurement campaigns have been performed in July 2015 (07/20-26 period-wet
123 season) and January 2016 (01/7-15 period-dry season), July 2016 (07/4-13 period-wet season),

124 and January 2017 (01/5-14 period-dry season) at Abidjan (Côte d'Ivoire) and Cotonou (Benin)
125 at the four different source sites: ADF for Abidjan Domestic Fires, AWB for Abidjan Waste
126 Burning, AT for Abidjan Traffic (Figure 1) and CT for Cotonou Traffic site (Figure 2).

127 The ADF site is situated in Yopougon Bracody district near a market (5° 19' 44" North, 4° 06'
128 21" West) (Figure 1). This geographical area is highly populated with various small commercial
129 activities such as a fish and meat-smoking by women which gives rise to air pollution. There
130 are also many formal and informal settlements, which mainly use wood and charcoal as a source
131 of fuel for private and professional activities. Other sources of concern contributing to the mix
132 of pollutant emissions in the area include transportation-related emissions, biomass burning,
133 garbage bins or small landfills, and various other fugitive sources.

134 The Abidjan traffic site, (AT) is located in Adjamé, on the roof of « 220 pharmacie logement
135 building » (5° 21' 14" N, 4° 01' 04" W), 10 m above ground level, and roughly 10 m away from
136 the main road. This site, close to the Adjamé market and to a bus station, is thus highly affected
137 by traffic (Gbaka, bus, taxi, woro-woro, personal cars...). The Abidjan waste Burning site
138 (AWB) (5° 21' 12" N, 3° 56' 16" W) is located at Akouédo in the district of Cocody, on the roof
139 of « Talafigué », a building 15 m above ground level. This site is close to the big waste burning
140 area of Abidjan established in 1965, which covers an area of 153 ha.

141 The Cotonou Traffic (CT) (6° 22' 19" N, 2° 26' 5.143" E) site is located in Cotonou, on the
142 «Sogema» building roof, 4m above ground level. This site is close to the Dantokpa market and
143 also to the biggest crossroad of Cotonou (intersection of 4 main roads). This site is highly
144 influenced by traffic activities. It is important to note that vehicle fleet and fuels are different
145 in Cotonou than in Abidjan since (1) there are many two-wheel vehicles in Cotonou, (2) in
146 Cotonou, gasoline is of poor quality due to the illegal fuel transport from Nigeria (Figure 3) and
147 (3) the roads are in worse condition in Cotonou than in Abidjan.

148 2.2. Measurements

149 The collection of aerosol filter samples was performed with three cascade impactors,
150 operating in parallel for 3 hours over three days for each intensive campaign to allow size-
151 speciated characterization of the aerosol chemical composition. The first 4-stage impactor
152 included 4 quartz fiber filters (QMA, Whatman), for carbonaceous aerosol (EC, OC and WSOC
153 analysis), with three filters of 47mm size for the upper stages and 1 of 70 mm for the lower
154 stage. The second 3-stage cascade impactor was equipped with three Teflon filters (Zefluor,
155 Pall Corporation®) of 25 mm size and was dedicated for aerosol mass, water-soluble ions

156 species and trace elements. Finally, the third 4-stage cascade impactor dedicated to
157 toxicological analyses and whose results are not used in this paper, was mounted with four 47
158 mm diameter filters and a 70 mm filter in Nuclepore polycarbonate filters quality (porosity 1
159 μm).

160 Note that filters were provided in each case to allow a UF ($<0.7 \mu\text{m}$), F [(0.5–1.2)
161 μm] and C (>2.5 –
162 $1 \mu\text{m}$) classification. Chemical characterization included aerosol mass, EC, OC, Water Soluble
Organic Carbon, Water Soluble Ionic species and trace elements.

163 **2.3. Analyses**

164 **2.3.1. Gravimetric analyses**

165 Aerosol mass concentrations are obtained using a high-precision balance (SARTORIUS
166 MC21S) in Toulouse, France, at Laboratoire d'Aérodologie, placed under a controlled
167 temperature and humidity atmosphere (Person and Tymen, 2005). Before weighing, the filters
168 are kept about for 24 hours in the weighing room at an ambient relative humidity of $30 \pm 15\%$.
169 The filters are weighed before and after sampling. Result of a gravimetric measurement consists
170 of the average of 2 to 4 weighings whose differences do not exceed $5 \mu\text{g}$. The standard error on
171 a gravimetric measurement is therefore less than $10 \mu\text{g}$, typically representing less than 5% of
172 the particles mass.

173 **2.3.2. Carbonaceous aerosols**

174 Carbonaceous aerosol is obtained from a thermal analysis with a two-step method
175 adapted from Cachier et al. (1989). Two aliquots of the same filter are separately analyzed.

176 One portion is directly analyzed for its total carbon content (TC). The other portion is
177 first submitted to a pre-combustion step (2 h at 340°C under pure oxygen) in order to eliminate
178 OC, and then analyzed for its BC content. Organic carbon (OC) concentrations are calculated
179 as the differences between TC and BC. Note that the aerosol carbon content is quantified by a
180 non-dispersive infrared (NDIR) detector with G4 ICARUS instrument with a detection limit of
181 the order of $2 \mu\text{gC}/\text{cm}^2$. Uncertainty is of the order of 5% for TC, whereas in the range of 5–
182 20%, for BC and OC, depending on the sites.

183 **2.3.3 Water Soluble Organic Carbon analysis**

184 WSOC measurements are performed using a total organic carbon analyzer (Sievers M9).
185 A detailed description of this technique is reported in Favez et al. (2008). Briefly, in this

186 instrument, the full oxidation of organic carbon into CO₂ is obtained by coupling chemical
187 oxidation (with ammonium persulphate) and UV light. CO₂ is then quantified by conductivity.
188 Analyses are conducted on 20 ml of solution extracts. For ultrafine samples, solutions to be
189 analyzed are obtained using a total filter surface of 3cm² (6x0.5 cm² punches symmetrically
190 taken out of each QMA filter), whereas, for coarse and fine sizes, due to the geometry of the
191 spots formed at the surface of the filters, samples are divided into equivalent parts (1/2 or 1/4
192 of filters, rest of carbonaceous analysis). The extraction protocol consists in 16h soaking under
193 soft shaking in an Erlen-Meyer containing 20mL of ultra-pure water. Prior to WSOC analysis,
194 water extracts are filtered through Teflon (PTFE) filters (0.2µm pore size diameter) in order to
195 remove any suspended particle. Measurement uncertainty, given by the manufacturer, is of the
196 order of 7%. The overall calculated blank value is of the order of 2.27 ± 0.33 µgC/cm², which
197 represents 16.4± 8.5% of the mean WSOC content. For each sample, duplicate analyses showed
198 a good reproducibility.

199 **2.3.4 Water-soluble ionic species**

200 Water-soluble ionic species (Na⁺, NH₄⁺, K⁺, Mg²⁺, Ca⁺⁺, S₄²⁻, NO₃⁻, Cl⁻) are analyzed using
201 ion chromatography (IC) analyzer, following the analytical protocol described in Adon et al.
202 (2010). Briefly, the aerosol water-soluble fraction is first extracted from half Teflon filter (the
203 other part is used for trace element analysis), with a 10 min sonication in plastic vials including
204 6 ml or 10 ml of purified water (with a controlled resistivity of 18.2MΩ). Then such vials are
205 submitted to ionic chromatography analysis or stored at +4°C if not analyzed immediately.
206 Cations are analyzed with Dionex DX-100 and anions with Dionex DX-500 with a detection
207 limit of 1 to 6 ppb depending on ionic species. Uncertainties in the range of 1-50% is found
208 depending on ionic species.

209 **2.3.5 Trace elements**

210 Half sampled Teflon filters are mineralized by acid digestion with a 10 ml concentrated
211 HNO₃ and 0.5 ml HF solution (Lamaison, 2006) using a closed vessel microwave accelerated
212 reaction system (MARS 5, CEM Corporation) at high pressure (700 psi) (Celo et al. 2010). The
213 digestion is realized in 3 steps: a rise in temperature at 130°C in 3min and holding for 1 min,
214 then, a second rise at 160°C in 1 min and holding for 30 seconds and finally a third rise to
215 180°C in 1 min and holding for 3min. After a 12 h cooling period, the solutions are evaporated
216 at 80°C, and concentrated in 7 ml of 2% concentrated HNO₃ solution, before analysis by ICP-
217 MS. This protocol is developed and performed at the Laboratory of Environmental Geosciences

218 of Toulouse. ICP-MS analyses are performed with a 7500 ce Agilent Technologies instrument
219 equipped with a collision cell, and using In and Re as internal standards. Quality control and
220 measurement performance are checked using NIST SRM 1648 ‘‘Urban Particulate Matter’’.
221 The detection limit is less than 10 ppt. For all the samples, the final blank values and detection
222 limit on filters are taken into account for final concentrations calculations. 13 trace metals are
223 considered in this work: Al, Ti, Cr, Mn, Fe, Ni, Cu, Zn, Ba, La, Th, Pb, and Cd.

224 **2.3.6 Dust calculation**

225 Many methods can be used to quantify the dust concentrations in our samples.

226 (1) Sciare et al. (2005) methodology consists in using soluble calcium data obtained with
227 Ionic Chromatography (IC) to estimate Dust mass following the relationship:

228 $\text{Dust} = 10.96 \pm 1.00 [\text{nss-Ca}^{2+}]$, where $\text{nss-Ca}^{2+} (=1.02*\text{Ca}^{2+}-0.038*\text{Na}^+)$ refers to non-sea-salt
229 calcium concentration.

230 (2) Pettijohn (1975) and Besombes et al. (2001) propose the following equation:

231 $\text{Dust} = 2.20[\text{Al}] + 2.49[\text{Si}] + 1.63[\text{Ca}] + 1.42[\text{Fe}] + 1.94[\text{Ti}]$

232 (3) Terzi et al. (2010) used this one:

233 $\text{Dust} = 1.89[\text{Al}] + 1.21[\text{K}] + 1.95[\text{Ca}] + 1.66[\text{Mg}] + 1.7 [\text{Ti}] + 2.14[\text{Si}] + 1.42[\text{Fe}]$.

234 In our study, all these elements needed for (2) and (3) have been determined except Silica (Si).
235 Consequently, we used different relationships available in the literature to determine mean Si
236 values ($\text{SiO}_2 = 3*\text{Al}_2\text{O}_3$ mass ratios (Alastuey et al., 2005), $\text{Si} = 4.0*\text{Al}$ (Zhang et al., 2003) and
237 $\text{Si} = 2.03*\text{Al}$ (Chiapello et al., 1997)).

238 (4) Guieu et al (2002) relationships are based on Al or Fe:

239 $[\text{Al}] (\%) = 7.09 \pm 0.79[\text{dust}]$

240 $[\text{Fe}] (\%) = 4.45 \pm 0.49[\text{dust}]$

241 (5) Guinot et al. (2007) approach is based on a chemical closure method based on
242 reconstructed aerosol mass from EC, OC, WSI, Ca^{2+} concentrations and weighed aerosol mass.
243 Briefly, Ca^{2+} -to-dust conversion factor (f) is obtained by arbitrary fixing OC-to-POM
244 conversion factor (k) to 1.8 and by performing a linear regression between Ca^{2+} concentration
245 and the missing mass (difference between the reconstructed and weighed mass). The slope of
246 this regression represents the factor f. Based on this methodology, f ranges from 0.015 to 0.15
247 in the wet season and from 0.006 to 0.07 in the dry season in our sites. Note that at all of our
248 sites, the correlation between Ca^{2+} and missing mass is sufficiently good ($r^2=0.9$) to support the
249 consistency of this simple approach for the evaluation of dust. These f values are included in

250 the range of values provided in the literature (He et al. 2001; Sun et al. 2004; Guinot et al.
251 2007).

252 The results of dust masses estimated from the six methodologies described above are
253 summarized in the Table 1 for WS2016 and DS2017. Indeed, Ca, Al, and Fe concentrations
254 measured by ICP-MS are only obtained in WS 2016 and DS 2017 due to experimental
255 problems, whereas Ca^{2+} concentrations measured by IC are available for all campaigns. As a
256 result, the dust obtained from Ca^{2+} measured by IC (Sciare et al., 2005 and Guinot et al., 2007)
257 is lower than that obtained from Al and Fe by Guieu et al. (2002), by Pettijohn (1975) and by
258 Terzi et al. (2010). In addition, dust obtained from Al is generally higher than that of Fe.

259 Such comparison seems to be in agreement with methodological aspects. Indeed, Al, Fe, Ca
260 obtained by ICP-MS include both soluble and insoluble particles whereas Ca^{2+} measured by IC
261 only include soluble particles. Comparison of Ca^{2+} measured by ICP-MS (not shown here) is
262 effectively higher than that of the CI, by a factor of 1.7, 1.8, 2.2 and 1.1 in dry season, at the
263 ADF, AWB, AT, and CT sites respectively. By contrast, this factor is constant (1.3) in the wet
264 season for all the sites.

265 In our study, due to the lack of trace element data for the WS2015 and the DS2016, dust
266 estimations will be performed from Sciare et al. (2005) methodology. This is the most direct
267 one, taking into account available chemical data. The one of Guinot et al. (2007) will be used
268 for aerosol chemical closure.

269 **2.3.7 Aerosol chemical closure methodology**

270 As mentioned previously, aerosol chemical closure is performed following the Guinot
271 et al. (2007) methodology. Aerosol is separated into four components: EC, POM, water-soluble
272 ionic species and Dust. EC is directly given by thermal analysis as shown earlier. WSI is the
273 sum of all ionic species obtained by ionic chromatography. Particulate organic matter (POM)
274 values are obtained from our OC concentrations with a POM/OC ratio in the range of 1.2 to 2.1
275 whereas dust is derived from Ca^{2+} and linear regression between reconstructed and weighed
276 aerosol masses.

277

278 **2.4 Meteorological conditions**

279 Figure 4 shows meteorological data, provided by the NOAA Integrated Surface database
280 (ISD; see [https:// www.ncdc.noaa.gov/isd](https://www.ncdc.noaa.gov/isd), last access and the ASECNA (Agence pour la
281 Sécurité de la Navigation Aérienne en Afrique et à Madagascar).

282 Our study area is under the influence of the Convergence Zone of two air masses of a different
283 nature: harmattan (hot and dry continental trade winds) from the north and monsoon (humid
284 maritime trade winds) from the south (Figure 4). Ground contact between these two air masses
285 constitutes the intertropical front (FIT) whose fluctuations during the year determine the
286 seasons in the Gulf of Guinea (Tapsoba, 1997). During the winter (dry season), temperatures
287 are relatively high with maximum around 30°C on the coast. The humidity is low, since the
288 prevailing Harmattan wind blows from the desert, usually bringing dust (Figure 4). The period
289 from June to September, especially in July is the wet season period when daytime temperatures
290 are slightly lower, with maximum around 26/28°C on the coast. The humidity level is high
291 everywhere. Rains may be abundant from April to October but also in March, November, and
292 December on the coast.

293 As depicted in Figure 4 which shows the meteorological conditions during our four campaigns,
294 temperatures are roughly the same at Abidjan and Cotonou, reaching 28°C and 26°C in the dry
295 and wet seasons, respectively. The wind direction is relatively stable in summer and winter,
296 except in January 2016 when there were slight variations. In addition (not shown here), our dry
297 season periods are particularly  with January rainfall lower than 3 mm. Also, precipitation
298 during the wet season of 2015 was roughly  similar to that of the wet season of 2016 in Abidjan
299 and Cotonou.

300 2.5 Backward trajectories

301 Air mass trajectory study is a very important tool to reconstruct the path of an air mass
302 for the days preceding its arrival at the sampling site. The air mass trajectories used in this study
303 are calculated with a model (READY Transport & Dispersion Modeling) developed at the Air
304 resources laboratory. The Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT)
305 modelling system (Draxler and Rolph, 2012) is used for the trajectory analysis. Global Data
306 Assimilation System reanalysis database is used as meteorological input, with a 0.25×0.25
307 degrees horizontal resolution. In our study, the HYSPLIT model is run to compute 120 h back
308 trajectories ending at Abidjan and Cotonou at 1000 m a.g.l. (Figure 5).

309  As expected in January, the air masses mainly came from the north (Figure 5) and some from
310 the south-west, whereas in July the air masses came from the south-west and the south.
311 Therefore, in January, Abidjan and Cotonou are mainly impacted by polluted air masses from
312 surrounding areas and northern countries with possible dust and biomass  burning influences,
313 whereas in July, the impact of cleaner air masses coming from the sea may be observed.

314

315 3. Results and discussion

316 3.1. Aerosol size distribution and mass concentration

317 Figure 6 shows the relative mass distribution of PM for Coarse (C), Fine (F) and Ultra-
318 Fine (UF) particle sizes, with their average by site, for each season and campaign in Abidjan
319 and Cotonou. Bulk concentrations, shown in Figure 6, vary widely from site to site and from
320 year to year. During the wet season, the average total concentrations range from 82.1 to 676.3
321 $\mu\text{g}\cdot\text{m}^{-3}$ in 2015 and 56.3 to 358 $\mu\text{g}\cdot\text{m}^{-3}$ in 2016, with the maximum at the Abidjan Domestic Fire
322 (ADF) site. While during the dry season, values range from 168.2 to 269.4 $\mu\text{g}\cdot\text{m}^{-3}$ in 2016 and
323 from 114.4 to 558.8 $\mu\text{g}\cdot\text{m}^{-3}$ in 2017, with maximum concentration obtained at the Cotonou
324 Traffic (CT) and ADF sites. In terms of size distribution, concentration peaks may be observed
325 for the three aerosol size-fractions, ultra-fine (UF), fine (F) and coarse (C), which are found to
326 exhibit different seasonal patterns. UF particles ($< 0.2 \mu\text{m}$) represent the highest contributor to
327 the bulk mass at the ADF site, by up to 60 % (335.3 $\mu\text{g}\cdot\text{m}^{-3}$) in the dry season 2017. F particles
328 (1-0.2 μm) are the second most important contributor and both combined particle sizes account
329 for more than 70 % of the total mass at the ADF site. Ultra fine and fine fraction are also found
330 to be maximum during the wet season in 2015 and 2016 by up to 47 and 44%, respectively.
331 These results highlight the importance of pollution at the ADF site in Abidjan, which is
332 dominated by particle sizes less than 1 μm that are known to be particularly harmful to health
333 (Kim et al., 2003; Wilson et al., 2002). Val et al. (2013) also indicates that combustion sources
334 such as domestic fire contributes to the high toxicity of F and UF particulate matters of African
335 urban aerosol. When looking at the seasonal variation for a full year i.e. 2016, the bulk mass is
336 twice as high in wet season than in the dry season at the ADF site. This could be related to
337 activities such as women drying fish and meat before selling them who use wood combustion;
338 in wet season the woods are moist and combustion is highly incomplete, producing a large
339 amount of smoke.

340 Bulk aerosol concentrations measured at the Abidjan Waste Burning (AWB) site in summer
341 and winter 2016 are 56.3 and 173.8 $\mu\text{g}\cdot\text{m}^{-3}$, respectively, which suggests less waste burning
342 activities during the wet season. Also, the total concentrations obtained during the wet season
343 of 2015 and 2016 were always lower than during the dry season of 2016 and 2017. It is also
344 observed that at the AWB site, PM mass concentrations are mainly distributed in C mode (30-
345 44%) over the entire period of study excepted during the wet season of 2015, and to a lesser
346 extend in F mode (21-44%).

347 Note that the concentrations obtained at the AWB site ($82.18 \mu\text{g}\cdot\text{m}^{-3}$) are the lowest compared
348 to all sites. This could be explained by the proximity of the site to the studied source (here waste
349 burning source) which is more important than in the other sites.

350 Now, if we focus on traffic sites (Figure 6), the Cotonou traffic site aerosol concentrations are
351 higher by a factor of 1.5 to 2 than those of Abidjan traffic, especially in the dry season. Note
352 that this poor air quality found in Cotonou has recently been reported by Cachon et al. (2014).
353 The higher values found in Cotonou could be due to the more intense traffic in Cotonou than in
354 Abidjan which is associated with the lack of public transportation and the use of highly polluted
355 mopeds (aged over 15 years) (Gounougbe, 1999; Avogbe et al., 2011), despite the effort in the
356 last 10 years to restrict their use. Several studies such as MMEH (2002) have shown that more
357 than 94,000 mopeds and 350,000 second-hand vehicles are in circulation in Cotonou. Other
358 factors contributing to the local pollution include outdoor restaurants using charcoal and
359 motorcycle garages which are more present around the Cotonou site than at the Abidjan site.
360 However, the differences in concentrations between the two traffic sites are less important
361 during the wet season than during the dry season when concentrations are always higher.
362 Therefore, another factor, typical of the dry season should explain the differences between
363 concentrations. One such factor is the influence of long-term imported sources. Indeed, the
364 occurrence of continental air masses is more important in the dry season than in the wet season.
365 Some expected PM components such as dust or biomass burning particles would then appear
366 to be relatively more important in Cotonou than in Abidjan. This will be discussed in more
367 detail later.

368 In terms of PM 2.5, the conclusions are the same. The average mass concentration of PM2.5
369 over the dry season (2016-2017) are 154.30 ± 73.99 , 143.8 ± 41.6 , 134.1 ± 6.7 and 211.1 ± 50.9
370 $\mu\text{g}\cdot\text{m}^{-3}$ and 337.5 ± 23.8 , 44.8 ± 2.9 , 52.3 ± 3.8 and $70.0 \pm 0.8 \mu\text{g}\cdot\text{m}^{-3}$ over the wet season (2015-
371 2016) at the ADF, AWB, AT and CT sites, respectively. The increase in PM2.5 is of the order
372 of 54% at ADF from dry to wet season, whereas a sharp reduction (more than 60%) is obtained
373 at AWB, AT, and CT sites. As shown previously, such differences in PM2.5 concentrations
374 between the sites can be explained by (1) the source specificity with more or less incomplete
375 combustion: wood combustion and two wheel vehicle emission factors are higher than gasoline
376 emission factors (Keita et al., 2018), (2) the proximity between the sites and the sources: the
377 ADF sampling site is much closer to the studied sources than the traffic or waste burning
378 sampling sites (3) the relative influence of transported sources to the studied sites such as dust
379 and biomass burning (4) the occurrence of continental air masses, the decrease of the

380 boundary layer height (as reported by Colette et al., 2007), (6) wet deposition of particles and
381 (7) the meteorological conditions (temperature and relative humidity).

382 It is interesting to underline that all of these values are well above the annual and daily WHO
383 guidelines of 25 and 10 $\mu\text{g}/\text{m}^3$ respectively, whatever the season and the size; this is a warning
384 signal for pollution levels in African capitals if nothing is done to reduce emissions in the future.
385 Finally, it is interesting to compare our results with other DACCIWA results, including other
386 time sampling. Firstly, Figure 7 presents comparisons between our PM_{2.5} mass concentrations
387 and those obtained by Xu et al. (2019) from personal samplers collected in the same area and
388 at the same dates in 2016 during 11 months from women at the ADF site, students at the AWB site
389 and drivers at the CT site. We note that PM_{2.5} directly measured on women are 2.3 and 0.9
390 times higher than our values obtained at the ADF site in dry and wet seasons, respectively, and
391 3.40 and 4.9 times higher on students than at the AWB site, and 1.6 and 2.1 times higher on
392 drivers than at the CT site.

393 Secondly, Figure 7 presents a comparison between our values and Djossou et al. (2018) weekly
394 measurements at the same sites. It is interesting to note that our values are on average 1.6, 3, 5
395 and 8 times higher than those of Djossou et al. (2018) at the AWB, ADF, AT and CT sites
396 respectively. As it may be seen, the lowest concentrations are observed in Djossou et al. (2018),
397 whereas the highest concentrations are recorded in Xu. et al. (2019). This is valid for all sites,
398 seasons and campaigns. Differences between our values and Djossou values may be explained
399 by the sampling times of the two studies. Indeed, Djossou measurements are weekly, taking
400 into account diurnal activities during all the week, including week-end and nights which have
401 expected lower PM_{2.5} concentrations. Our study includes only maximum pollution conditions
402 for each site. The highest differences occur for the traffic sites. This may be clearly understood
403 since diurnal and weekly variations of traffic sources are the most variable. Comparison
404 between our values and Xu et al. (2019) values is also interesting. Indeed, it is at the ADF site
405 that on-site and women PM_{2.5} concentrations are the closest which shows that this site is the
406 most representative of the pollution exposure to women. The biggest differences are found at
407 the AWB site. As already mentioned, distance from the site to the waste burning source is more
408 important than for other sites, which explains why student concentrations are much higher than
409 on-site concentrations. At the Cotonou traffic site, measurements taken from people are also
410 higher than on site measurements. Such differences can be also explained by additional
411 pollution exposure as people move around. Note that the sampling technique may also play a
412 role in such a comparison.

413 Finally, Table 2 compares our PM_{2.5} results to literature data for different traffic sites in the
414 world including the same daily sampling time. It is interesting to note that our values are
415 situated at the higher end of the range of PM_{2.5} data observed from the other sites.

416 **3.2 Aerosol chemical composition**

417 **3.2.1 Carbonaceous aerosol Concentrations.**

418 **3.2.1.1 EC and OC variation.**

419 In Figure 8, EC values are presented by size and site for each campaign and season: wet
420 season 2015 (WS15), wet season 2016 (WS16), dry season 2016 (DS16) and dry season 2017
421 (DS17). The most striking feature is that the ADF site concentrations are always higher than at
422 the other sites in the wet seasons, whereas only slightly higher or of the same order in the dry
423 seasons. Concentrations at the traffic CT site is slightly higher than at the AT site, whereas the
424 lowest concentrations are found at the AWB site. As for PM mass, these differences are mainly
425 due to the proximity of the site to the sources, where the ADF site is much closer to the sources
426 than the AT and CT sites which are located at the first level of a building at a crossroad, and
427 the AWB site which is the farthest from the source. The strength of each source is another factor
428 which can explain EC concentration variations among the sites. High concentrations at traffic
429 sites may be explained by high EC emission factors observed for vehicles (Keita et al., 2018),
430 whereas differences between wet and dry season concentrations at the ADF sites may be
431 explained by EC emission factor variations: higher EC emission factor values are obtained for
432 moist wood combustion mostly occurring during the wet season than for dry wood combustion,
433 as mentioned previously.

434 Results of the EC size distribution are very consistent among the different sites. Whatever the
435 site and the season, higher EC concentrations are found in C and UF particles compared to F
436 particle with maximum values in UF particle as found in previous studies (Marinoni et al.,
437 2005; Xiu et al., 2015).

438 In terms of seasonal variation, our results are in agreement with long-term EC measurements
439 conducted by Djossou et al. (2018) for the same sites and period. There is no marked seasonal
440 variation for the ADF site with EC peaks in WS 2016 and DS 2017. As mentioned, wet season
441 EC peaks can be explained by the use of moist wood for cooking and smoking fish. For the
442 other sites, higher EC values are observed during the dry season rather than in the wet season

443 due to (1) decreases in EC wet deposition and concentration during the wet season and (2) the
444 influence of long-range transport from sources such as biomass burning during the dry season.
445 In terms of inter-annual variability, if we compare WS2015 and WS2016, values are slightly
446 higher in 2015 than in 2016 at the AT, CT and AWB sites. However, at the ADF site, EC
447 maximum values are observed in 2016, especially for UF particles. This is due to the source
448 which has more polluting combustion activities as previously explained. Indeed, in 2015, the
449 activities of fish and meat smoking were recent and not very well known by the population,
450 whereas they were expanded in 2016 with more workers, leading to more furnaces and
451 increased emissions.

452 EC concentrations are generally higher in DS2017 than in DS2016 for all the sites. This is not
453 due to the meteorology which is similar in both years. This is also not due to biomass burning
454 impacts. Indeed, when looking at MODIS burnt areas ([http://www.aeris-](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)
455 [data.fr/redirect/MODIS-MCD64A1](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)), burnt areas of west African savannas are higher in 2016
456 than in 2017. Therefore, EC concentrations should be higher in 2016. However, analysis of
457 back trajectories (Figure 4) reveals that biomass burning transport from northern areas are less
458 efficient in 2016 than in 2017, in both Abidjan and Cotonou. This leads to a counter effect
459 between biomass burning emission strength and air mass transport, indicating that biomass
460 burning impact could not explain the difference in EC between DS2016 and DS2017. Rather,
461 this is due to the variability of local sources. In DS2016 there was a general strike of civil
462 servants of the State with important consequences on urban activities: lower traffic and lower
463 fish smoking emissions were observed in DS2016 compared to DS2017, thus explaining the
464 lower EC concentrations at AT. Less activities were also noticed at CT.

465 OC size-speciated concentrations are presented in Figure 9 for each site and each campaign.
466 ADF OC values are always higher than at the other sites by a factor ranging from 6 to 30, for
467 all seasons and particle sizes, with highest values in DS2017. Minimum OC values are obtained
468 in DS2016. Explanations for OC variations are generally similar to the ones of EC. There are
469 less OC differences between WS2015 and WS2016 than for EC, even though WS2015 values
470 are also lower than those of WS2016, as for EC. In terms of size distribution, maximum OC
471 concentrations at the ADF site may be found in UF, then F, and finally C particles. The same
472 distribution is observed for the other sources in DS2016, however, for the other campaigns, OC
473 size distribution looks like the EC ones with higher concentrations in UF and C particles than
474 in F particles. Note that OC concentrations are higher in the CT site compared to AT for each
475 particulate size during DS, whereas during the WS, AT OC concentrations are slightly higher
476 than the CT values. This can be explained by the traffic source in each city. Indeed, the

477 consumption of petrol and diesel fuel by transport in Benin exceeds that of Côte d'Ivoire, which
478 could imply higher carbonaceous aerosol concentrations in Benin than in Abidjan in DS. In the
479 raining season, the lack of road infrastructure associated with poor road conditions prevents
480 motor vehicles from accessing certain districts in Cotonou. Traffic is thus assumed to be
481 reduced, implying lower OC concentrations in CT than in AT.

482 Table 3 compares our OC and EC values to those obtained by Djossou et al. (2018) and Xu et
483 al. (2019) for the same period and the same sites. More precisely, this comparison was done
484 between our data, Djossou's weekly data including our 3 days of measurements and Xu's daily
485 exposure data of population living closed to our sites. It is interesting to note that Djossou's
486 values are in general lower than ours. Indeed, for the wet and dry seasons, our OC
487 measurements are 4 and 1.4 times higher than Djossou's at the AT site, 2.1 and 5.7 times
488 higher at the CT site, and 2.5 and 2.5 times higher at the ADF site, respectively. As for PM_{2.5},
489 this can be explained by the different sampling times between our experiments which were
490 performed at the peak of urban activities, while Djossou's dataset represents weekly integrated
491 values. Indeed, Djossou includes diurnal measurements for the whole week including lower
492 traffic activities occurring during the nighttime and the week-end period. Differences at the
493 ADF site are largely explained by the temporal pattern of fish smoking activities which take
494 place every day, only in the morning, as such the associated pollution is not well represented in
495 the weekly sampling. Finally, there are less differences at the AWB site between both datasets
496 since waste burning emissions occur night and day throughout the week. Comparisons made
497 between our values and those of Xu's personal data show that both OC and EC are of the same
498 order at the ADF site, whereas Xu values are higher than ours at the CT and AWB sites. This
499 result is in agreement with what we found with PM_{2.5} concentrations as detailed above.

500 Finally, Table 4 presents OC and EC for the PM_{2.5} comparison between our values and other
501 recent studies dealing with traffic sites in other regions of the world and with similar operational
502 conditions. We find that our values are situated in the middle of the range observed in these
503 different studies.

504 3.2.1.2 OC to EC ratio

505 In our study, suitable linear correlations between EC and OC are obtained in the ultrafine
506 and fine modes in all campaigns, particularly during the last one ($r^2 = 0.8, 0.8, 0.9$ and 0.9) at
507 the ADF, AWB, CT and AT sites, respectively. This suggests that different studied sources can
508 be assessed as significant sources of both EC and OC. As shown in Figure 10, the highest
509 OC/EC values (e.g. 25 for F particles) are obtained for WS2016 at the ADF site, whereas the

510 lowest values are found in DS2017. This is the same at all traffic sites, with ratios lower than 2
511 for DS2017. For the other campaigns, OC/EC are never higher than 5, with AT ratios slightly
512 higher than CT ratios. OC/EC ratios are more variable at the AWB site with values in 1-10
513 range. Such variations can be explained by the type of the sources characterized by different
514 OC/EC ratios, as well as by secondary aerosol organic formation which can be detected for
515 OC/EC higher than 2 (Turpin et al. 1990; Hildermann et al. 1991; Chow et al. 1996). Such a
516 process is difficult to test in our study because the sites are situated very close to the source
517 level, with the exception of the AWB site (Renjian et al. 2012). However, we find comparable
518 results between our OC/EC ratios and the one measured at the source level by Keita et al.
519 (2018). Indeed, mean OC/EC ratio measured for wood burning source by these authors is
520 approximately 11.2, which is in agreement with our data at the ADF site. In addition, OC/EC
521 ratio for the waste burning source is about 7.6, whereas our values at the AWB site are in the
522 range 2 to 10.

523 There are no marked differences between OC/EC ratios when comparing values between the
524 CT and AT sites. OC/EC ratios are globally on the same order for WS2015, WS2016 and
525 DS2016, with values similar to that of gasoline emissions or old diesel vehicle. However, the
526 ratios are lower for DS2017, with values typical of those of diesel emission (Mmari et al., 2013,
527 Keita et al., 2018). The general strike occurring in DS2016 in Abidjan could explain such a
528 difference. Indeed, more EC emissions occurred in DS2017 than in DS2016 for constant OC
529 emissions. This can be the result of more diesel traffic.

530 Similar ratio values have also been previously reported for other megacities such as Agra, India
531 with 6.7 (Pachauri et al., 2013), Helsinki, Finland with 2.7 (Viidanoja, 2002), Cairo, Egypt with
532 2.9 (Favez, 2008), Paris, France with 3.5 (Favez, 2008), and Milan, Italy with 6.6 (Lonati et al.,
533 2007).

534 3.2.1.3 Water-Soluble Organic Carbon

535 Concentrations of WSOC and WSOC/OC ratios are presented in Table 5 for each size
536 (UF, F, C and PM_{2.5}) and campaign. As seen, WSOC are always higher at the ADF site than
537 in other sites, at least by a factor of 12. Maximum values are obtained in WS2016 with an
538 average of 16.47, 17.08 and 79.68 $\mu\text{g}/\text{m}^3$ for coarse, fine and ultra-fine fractions, respectively,
539 followed by WS2015 and DS2017. WSOC concentrations are the lowest in DS2016, with an
540 average of 4.6 and 21.89 $\mu\text{g}/\text{m}^3$ for coarse, fine and ultrafine fractions, respectively.

541 The concentrations of WSOC at the Abidjan traffic site are higher than those recorded at the
542 Cotonou traffic site in the wet seasons of 2015 and 2016, but lower in dry periods. Finally, the

543 AWB site values are on the same order as at the AT and CT sites. In terms of seasonality, there
544 is not a clear trend in WSOC values at the AWB and AT sites, whereas at the CT and ADF
545 sites, we find WSOC values to be respectively higher and lower in dry seasons compared to
546 wet seasons.

547 It is also interesting to note that WSOC are maximum in UF sizes in the AT, ADF and AWB
548 sites. At the CT site, the highest values are found in the coarse particulate fractions, except
549 during DS2016. Several factors can explain such variabilities. Firstly, WSOC concentration
550 levels are linked to meteorological factors, such as high solar radiation, which can produce
551 intense photochemical reactions and secondary organic formation (Tang et al., 2016, Favez et
552 al., 2008). Also, more WSOC may be linked to high relative humidity, but lower than 80% as
553 mentioned by Liang et al. (2016). In our study, temperatures are roughly similar in both seasons,
554 with slightly higher values in DS than in WS. This could explain the higher WSOC values
555 obtained in DS than in WS at the CT site. However, this does not explain ADF WSOC
556 variations with higher values in WS than in DS, which could be due to RH variability, higher
557 in WS than in DS. This is in agreement with Favez et al. (2008) who shows that WSOC is not
558 an adequate SOA tracer in urban environments. Secondly, WSOC concentrations can be
559 dependent on the related sources. Values at the ADF site are much higher than at other sites.
560 This is expected since wood burning is an incomplete source which is well known to produce
561 more WSOC than traffic sources (Yu et al., 2018, Tang et al., 2016, Feng 2006, Saxena and
562 Hildemann, 1996). Third, the presence of dust can produce semi-volatile organic gas
563 scavenging, and therefore WSOC and OC enhancement. Such a phenomenon can also explain
564 the highest WSOC concentrations observed in DS at the CT site where dust concentrations are
565 highest (see below paragraphs). Moreover, this can also explain why WSOC concentrations are
566 maximum in coarse particles at CT, but in ultra-fine particles at the other sites.

567 As expected, WSOC is strongly correlated with OC ($r=0.7$ at ADF, 0.8 at AT, 0.4 at AWB and
568 0.7 at CT), whereas correlations with EC are weaker at the AWB and CT sites with values
569 ranging from 0.1 to 0.4 , respectively. The relationships between WSOC and OC and WSOC
570 and EC suggest similar primary sources and/or similar SOA formation processes. As previously
571 mentioned, source processes and characteristics explain ADF and AT values, underlining also
572 the impact of dust at the CT site. This is also confirmed by the correlation between WSOC and
573 K^+ at the ADF site. Finally, when looking at WSOC/OC ratios (Table 5), maximum values are
574 obtained at the ADF site with PM_{2.5} values as much as 43%, followed by the AT and AWB
575 sites with 32%. The lowest value (23%) is found at the CT site. The same reasons mentioned
576 earlier may explain differences in values between the ADF and other sites. However, the

577 difference between the AT and CT sites is difficult to explain since both the meteorological
578 factors and the traffic sources are similar. The only difference deals with the dust impact, higher
579 at CT than AT. It can be assumed that dust could limit WSOC formation, at high concentrations
580 or depending on sources (road dust, desert dust...). Also, Table 5 shows that there is no clear
581 seasonality in WSOC/OC values, excepted at ADF where maximum values occur during the
582 WS. Note as earlier, that ratios are maximum in ultra-fine and fine fractions for all sites except
583 at the CT site where the ratio for coarse fraction is highest.
584 Briefly, as presented in Table 6, it is interesting to compare our WSOC concentrations to
585 literature data for different traffic sites of the world. We note that our values are on the same
586 order as values found in Asia, and higher than those found in Europe.

587 3.2.2 Water-soluble ionic species

588 Figure 11 shows the relative contribution of the major ions to the total concentration of
589 water soluble inorganic species in the different particle modes (C, F and UF) collected at the
590 ADF, AWB, AT and CT sites for the different measurement campaigns. The concentrations of
591 different ions show significant variations from site to site. The dominant ionic species at the
592 ADF site is chloride (Cl^-), with concentrations in the range of 2.1-12.9 $\mu\text{g}\cdot\text{m}^{-3}$, accounting for
593 18-38% of the total ions, followed by soluble potassium (K^+), ranging from 0.9-6.6 $\mu\text{g}\cdot\text{m}^{-3}$ (8-
594 22%). The third most important element is ammonium (NH_4^+), with concentrations in the range
595 of 1.1-5.2 $\mu\text{g}\cdot\text{m}^{-3}$ (9-15%). The mass concentrations of soluble calcium (Ca^{2+}) (1.5-3.2 $\mu\text{g}\cdot\text{m}^{-3}$)
596 are on the same order of magnitude as the values for NO_3^- (0.9-3.9 $\mu\text{g}\cdot\text{m}^{-3}$), SO_4^{2-} (1.0-3.4 $\mu\text{g}\cdot\text{m}^{-3}$)
597 ³), and to a lesser extent, soluble sodium (Na^+) (0.5-2.2 $\mu\text{g}\cdot\text{m}^{-3}$). However, Ca^{2+} contributions,
598 ranging from 13 to 25% of total measured ions, are higher than those of NO_3^- (7-11%), SO_4^{2-} (9-
599 11%) and Na^+ (4-7%). The concentrations of magnesium (Mg^{2+}) are low, ranging from 0.5 to
600 1.1 $\mu\text{g}\cdot\text{m}^{-3}$ (3.6-3.8%), and are as high as the sum of the remaining species (oxalic, formic and
601 acetic), constituting 2.1-7.2% of the total ion mass at the ADF site. Chloride is most likely
602 associated with sea salt origin (55% of total composition of the sea water) or secondary aerosol
603 production (Li et al., 2016). Its highest concentration at the ADF site remains lower than the
604 typical concentration in sea water, suggesting a secondary production source. The size
605 distributions of Cl^- , K^+ , NH_4^+ and SO_4^{2-} (Figure 11a) support the conclusion that the
606 predominance of these elements in ultrafine particle mode at the ADF site could be associated
607 with anthropogenic emissions, particularly biomass combustion and domestic fires, or with
608 secondary inorganic aerosols origin. Contrarily, Ca^{2+} , NO_3^- contributions to the total ions at the
609 ADF site peak mainly in the large particle fraction and may be attributed to quasi natural origin,

610 primarily to dust emissions and nitrate formation by reaction processes, respectively. In
611 addition, Na^+ and Mg^{2+} display similar size distributions at the ADF site, with the major
612 contribution in the fine particle fraction, suggesting the common sea salt origin of these two
613 elements (Belis et al., 2013).

614 NO_3^- is the major ionic component at the AWB, AT and CT sites, representing 21-36% of the
615 total water soluble inorganic concentration (i.e. 1.8-6.4 $\mu\text{g}\cdot\text{m}^{-3}$), 12-33% (1.1-5.0 $\mu\text{g}\cdot\text{m}^{-3}$) and
616 12-32% (1.6-7.4 $\mu\text{g}\cdot\text{m}^{-3}$), respectively. The second major contributor is Cl^- , accounting for 12-
617 28% of the ion mass (1.1-2.9 $\mu\text{g}\cdot\text{m}^{-3}$) at AWB, 6-30% (0.6-2.8 $\mu\text{g}\cdot\text{m}^{-3}$) at AT and 7-27% (1.5-
618 4.6 $\mu\text{g}\cdot\text{m}^{-3}$) at CT, followed by SO_4^{2-} with percentages of 9-20% (1.0-3.5 $\mu\text{g}\cdot\text{m}^{-3}$) at AWB, 9-
619 15% (0.9-2.3 $\mu\text{g}\cdot\text{m}^{-3}$) at AT and 11-18% (1.5-4.1 $\mu\text{g}\cdot\text{m}^{-3}$) at CT. The proportion of Ca^{2+} is higher
620 at the CT site, representing 14-26% (2.4-6.0 $\mu\text{g}\cdot\text{m}^{-3}$) of the bulk ion mass compared to 5-21%
621 (0.5-2.3 $\mu\text{g}\cdot\text{m}^{-3}$) at AWB and 7-19% (1.1-1.9 $\mu\text{g}\cdot\text{m}^{-3}$) at AT, supporting the hypothesis of the
622 high influence of re-suspended road dust by wind and motor vehicles at the Cotonou site and/or
623 long range transport of dust. Na^+ concentrations measured at the AWB, AT and CT sites are
624 slightly lower than those of Ca^{2+} , with values from 0.4 to 3.1 $\mu\text{g}\cdot\text{m}^{-3}$ (5 to 18%), while Mg^{2+}
625 contribution remains lower than 2% of the total ions at all sites. Note that organic gases
626 contributions at AT, CT and AWB is slightly lower than at ADF with values lower than 4%.

627 In contrast to the ADF site, the proportion of Cl^- at the traffic sites (AT and CT) is most likely
628 dominated by coarse particles, while at the AWB site no clear trend is observed (Figures 11b-
629 d). These results suggest that Cl^- at AT and CT probably originated from sea salt emissions,
630 while at AWB it produced from a mix of sources, including fuel combustion and mineral salt
631 from sources around the measurement sites. SO_4^{2-} is mainly found in ultrafine mode at the AT,
632 AWB and CT sites, with maximum relative contributions ranging from 10 to 40% of the total
633 ions. Conversely, the maximum concentrations of NO_3^- are observed in the coarse or fine
634 particle modes, constituting a percentage of between 10 and 50% at all sites. The importance
635 of ultrafine sulphates at the three sites is in-line with pollution sources of human origin
636 (Seinfeld and Pandis, 1998), probably in the form of ammonium sulphate. The seasonal
637 variations of Cl^- , Na^+ and Mg^{2+} show that their individual contributions to total ions are
638 generally much higher in wet season than in the dry season for coarse and fine particles
639 combined ($>1\mu\text{m}$) (Figure 11). For example, the mean relative total percentages of Cl^- at the
640 CT site are 27 and 24% in the wet seasons of 2015 and 2016, respectively, while these
641 percentages decrease significantly to 9 and 7% in the dry seasons of 2016 and 2017,
642 respectively. The Cl^-/Na^+ ratios in these particle sizes are 1.4 in both seasons, except at the ADF

643 site where these ratios increase slightly to 1.6 and 1.5 in wet and dry season, respectively,
644 slightly higher than the typical sea water ratio (1-1.2) (Hara et al.,2004).
645 In addition, strong correlation coefficients (0.97-0.99) between Cl^- and Na^+ are obtained in
646 coarse particle sizes at all sites and in both seasons. Our analysis also shows that Cl^- in coarse
647 and fine fractions are highly correlated with Mg^{2+} (0.97 in wet season and 0.96 in dry season)
648 combining all sites, except at ADF for which these correlation coefficients decrease to 0.68 and
649 0.95 in the wet and dry season, respectively. As Cl^- , Na^+ and Mg^{2+} are associated with sea salt
650 origin or secondary aerosol production (Xiao et al., 2018), these results indicate that coarse Cl^-
651 , Na^+ and Mg^{2+} particles ($>1\mu\text{m}$) from this study have the same “sea salt” origin at AT, CT, and
652 C which is different at the ADF site. Their abundance in the wet season could be related to
653 the influence of the predominant wind direction mainly oriented towards the North-East (Figure
654 5) which transports marine aerosols to these sites. Contrarily, in the ultrafine particle mode,
655 these elements have higher percentages in the dry season than in the wet season, with correlation
656 coefficients between Cl^- and Na^+ (Cl^- and Mg^{2+}) from 0.44 (0.62) at the ADF site to 0.62 (0.70)
657 at the rest of the sites. This suggests secondary production of these very fine ions.
658 As shown in Figure 11, the relative percentage of SO_4^{2-} , NH_4^+ and NO_3^- in the different particle
659 modes is reduced in the wet season, except at the ADF site for which the proportions of
660 SO_4^{2-} and NH_4^+ tend to increase during that period, especially in the ultrafine particles. During
661 the wet season, the clean winds surrounding the ocean before reaching the measurement sites
662 (Figure 5, top) could contribute to lower the proportion of these species, in addition to the
663 scavenging processes during the rainy season. Unlike the wet season, a relatively good
664 correlation of 0.87 (SO_4^{2-} versus NH_4^+), 0.73 (NO_3^- versus NH_4^+) and 0.87 (SO_4^{2-} versus NO_3^-)
665 has been found in coarse particles ($>1\mu\text{m}$), indicating similar sources for these three species
666 during the dry season. In order to try to identify these sources, the ratio of $\text{SO}_4^{2-}/\text{Ca}^{2+}$ and
667 $\text{NO}_3^-/\text{Ca}^{2+}$ has been determined. The average $\text{SO}_4^{2-}/\text{Ca}^{2+}$ and $\text{NO}_3^-/\text{Ca}^{2+}$ ratios in combined
668 coarse and fine particles at all sites except ADF (1.07 and 2.58 during the wet season and 0.33
669 and 1.60 during the dry season) are higher than the corresponding ratios for soil (0.026 and
670 0.003, respectively). On the other hand, the $\text{SO}_4^{2-}/\text{Ca}^{2+}$ ratio increases in the ultrafine particles
671 (5.07 during the wet season and 2.53 during the dry season), while that of $\text{NO}_3^-/\text{Ca}^{2+}$ remains
672 almost constant (2.86 during the wet season and 1.65 during the dry season). This implies that
673 the atmosphere around the AWB, AT and CT sites is enriched by SO_4^{2-} -formed as
674 anthropogenic secondary particles, possibly from sulfur containing sources, particularly in
675 ultrafine particle mode, and by NO_3^- mostly coming from nitrogen containing sources in all

676 particle sizes. The higher contributions of these elements during the dry season could result
677 from a combination of several factors: 1) an atmosphere loaded with dust favoring
678 heterogeneous chemistry to obtain secondary aerosol and the rise of biomass burning emissions;
679 2) the increase of photochemical activity and higher concentrations of hydroxyl radicals in the
680 dry season, which can oxidize SO_2 from biomass combustion (Arndt et al., 1997) to SO_4^{2-} (Li
681 et al., 2014); and 3) the wind transport of anthropogenic secondary particles from the industrial
682 zone located upstream from our sites. As previously shown, maximum values of SO_4^{2-} , NH_4^+
683 and NO_3^- observed during the wet season the ADF site may be linked to anthropogenic
684 emissions, and more precisely smoking activities which pollute more in the wet than dry season.

685 3.2.3. Elemental concentrations

686 Table 7 shows the mean values of the major metallic elements of total particulate matter
687 at the different studied sites for the wet season 2016 and dry season 2017. Note that data of
688 elemental concentrations are not available for the wet season 2015 or dry season 2016. In
689 addition, only bulk metal concentrations and their corresponding relative abundances are
690 examined. As shown in Table 7, the concentrations of metal elements span a wide range, from
691 0.2 to 25.2 $\mu\text{g}\cdot\text{m}^{-3}$. Among the measured elements, Al, Na and Ca are the most abundant,
692 followed by Fe, K and Mg. The percentage of Al accounts for 13.7% of the total re-suspended
693 particles in the dry season 2017 (3.5% in the wet season 2016) at the AWB site, 12.3% (2.4%)
694 at the AT site, 1.8% (0.4%) at the ADF site and 5.7% (4.4%) at the CT site, while that of Na
695 represents 12.8% (6.6%) at the AWB site, 13.4 (3.1%) at the AT site, 1.2 (0.6%) at the ADF
696 site and 4.3 (5.8%) at the CT site. Ca contributes to 1.6% (0.8%) of the total PM mass at the
697 AWB site, 3.6% (0.4%) at the AT site, 0.8% (1.1%) at the ADF site and 2.3% (5.4%) at the CT
698 site. These major three elements (Al, Na and Ca) together have concentrations in the wet season
699 2016 (dry season 2017) of 6.2 (51.5) $\mu\text{g}\cdot\text{m}^{-3}$, 5.4 (33.5) $\mu\text{g}\cdot\text{m}^{-3}$, 14.3 (33.2) $\mu\text{g}\cdot\text{m}^{-3}$ and 7.6 (21.2)
700 $\mu\text{g}\cdot\text{m}^{-3}$, accounting for 11.0% (28.1), 5.9% (29.3), 15.5% (12.3) and 2.0% (3.8) of the total PM
701 mass at the AWB, AT, CT and ADF sites, respectively. The absolute (and relative) abundances
702 of Fe, K and Mg combined are 1.5 $\mu\text{g}\cdot\text{m}^{-3}$ (2.6%) in the wet season and 10.3 $\mu\text{g}\cdot\text{m}^{-3}$ (5.6%) in
703 the dry season at the AWB site. These values are 1.5 $\mu\text{g}\cdot\text{m}^{-3}$ (1.7%) and 5.7 $\mu\text{g}\cdot\text{m}^{-3}$ (5.0%) at
704 AT, 3.2 $\mu\text{g}\cdot\text{m}^{-3}$ (3.5%) and 9.3 $\mu\text{g}\cdot\text{m}^{-3}$ (3.4%) at CT and 3.9 $\mu\text{g}\cdot\text{m}^{-3}$ (1.1%) and 12.3 $\mu\text{g}\cdot\text{m}^{-3}$
705 (2.2%) at ADF. The highest metal concentrations are generally measured during the dry season
706 2017 at all sites, except at CT where relatively similar values are obtained for the two seasons.
707 The seasonal variability in all the mentioned traces elements may be attributed to drier
708 conditions during the dry season (Figure 4) in West Africa favoring dust particle re-suspensions.

709 In addition, the dry season in West Africa is marked by the Harmattan continental winds
710 bringing dust from the Saharan desert (Figure 5). Moreover, it is interesting to note that the lack
711 of seasonal variability at CT may be due to the much poorer road conditions found at Cotonou
712 compared to Abidjan.

713 Most all of these elements are generally considered to have natural origins such as the earth's
714 crustal dust and sea salt (Al-Momani, 2003). However, K can also be associated with biomass
715 burning (De Oliveira Alves et al., 2015). As previously mentioned, the seasonal cycle of Fe, K
716 and Mg together suggests contributions to the bulk mass which are about twice as high in the
717 dry season than in the wet season at all measurement sites. This trend is driven by the large
718 variability of the element K which shows percentages in the dry season 4 to 10 times higher
719 than those in the wet season, likely due to more biomass burning activity during the winter time.
720 The other metals (Ti, P, Zr, Zn, Cr, Mn, Pb and Ni) represent less than 0.5% and 2% in the wet
721 and dry seasons, respectively, at all sites, with Cr, Mn, Pb and Ni exhibiting less seasonal
722 variability compared to the rest of the metal elements. The low proportions of these non-crustal
723 elements in the studied sites suggest a small contribution of elements primarily emitted by
724 anthropogenic activities such as industrial processes (Viana et al., 2007; Viana et al., 2008;
725 Minguillón et al., 2014).

726 The highest contribution of metal elements is obtained at the AWB and AT sites, reaching 35.8
727 and 35.2% of the total PM mass in the dry season, respectively. These maximum percentages
728 are due to the large contribution of both Al and Na crustal elements which account for about
729 26%. The lower proportion of metal elements at the ADF site (6.5% of the bulk concentration)
730 can be explained by the less dominant influence of re-suspended dust particles compared to
731 domestic fire sources. At the CT site, all elemental concentrations contribute to 16.3 % of total
732 PM for the dry season. However, during the wet season, the highest metal contribution of 19.5%
733 is obtained at CT, followed by AWB (14%) and AT (8.2%). The value at ADF remains the
734 lowest (3.3%). Again, the maximum percentage at the CT site is a result of the fact that most
735 of the roads in Cotonou are unpaved, therefore particle resuspension occurs in all seasons.

736 To assess the relative contribution of crustal and non-crustal to elemental aerosol loadings,
737 source enrichment factor (EF), as well as elemental ratios, are often used as diagnostic tools
738 (Weckwerth, 2001; Voutsas et al., 2002). EF_{Al} calculated using both literature data of the
739 typical elemental composition of the upper continental crust (Mason and Moore, 1982; Taylor,
740 1964) and measured metal composition from this study. Using Al as a reference element, the
741 EF of an atmospheric element X is calculated using the following formula:

742

$$EF_x = \frac{\frac{[X]_{atm}}{[Al]_{atm}}}{\frac{[X]_{soil}}{[Al]_{soil}}}$$

743 Where $[X]_{atm}$ and $[Al]_{atm}$ are the concentrations of the chemical element X and Al in the
744 atmosphere, respectively, and $[X]_{soil}$ and $[Al]_{soil}$ are the typical concentrations of the element
745 X and Al in the earth's crust, respectively. Al is frequently used as a reference element assuming
746 that its anthropogenic sources in the atmosphere are negligible (Gao et al., 2002; Cao et al.,
747 2005; Xu et al., 2012). From the EF values, source contributions are estimated following the
748 method described by Arditoglou and Samara (2005). Note that these studies only refer to ratios
749 for a limited list of sources. Incomplete diagnostic may be expected due to the African source
750 specificities focused on here. Also, note that the literature data are sometimes different for the
751 same source.

752 In all sampling sites, EF values typically lower than 5 are obtained for several trace elements
753 (Be, Sc, Ti, V, Fe, Ga, Sr, Nb, Rh, Ba, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb,
754 Lu, Ta, Th, U). This suggests natural origin of these species and therefore a negligible
755 contribution of anthropogenic emissions (Freitas et al., 2007; Gao et al., 2002). The most
756 enriched elements ($EF > 100$) are Sb, Sn, Zn, Se, Te, Cd, Pb, Bi and Mo at nearly all of the sites,
757 indicating significant anthropogenic origin (Wang et al., 2006). These elements are mainly
758 emitted into the atmosphere through fossil fuel combustion, traffic emission, wear of brake
759 lining materials and industrial processes (Watson and Chow, 2001; Samara and al., 2003).

760 Different elemental ratios have been used as diagnostic tools to identify sources of atmospheric
761 particles, including Cu/Sb, As/V, V/Ni, Zn/Pb and Zn/Cd (Weckwerth, 2001; Samara et al.,
762 2003; Herut et al., 2001; Foltescu et al., 1996; Arditoglou and Samara, 2005). As mentioned,
763 incomplete diagnostic is expected and the literature values can be different for the same source.

764 The mean values of selected elemental ratios in TSP from the Abidjan (ADF, AWB and AT)
765 and Cotonou (CT) sites are presented in Table 8. The Cu/Sb ratio is proposed as a good indicator
766 for brake lining wear (Weckwerth, 2001; Sternbeck et al., 2002) and, consequently, as a tracer
767 for traffic sources. Weckwerth (2001) and Sternbeck et al. (2002) reported a Cu/Sb ratio close
768 to 5 as a diagnostic criteria for brake wear particles in the ambient air. In this study, very low
769 ratios of 0.28 ± 0.21 in the wet season 2016 and 0.56 ± 0.21 in the dry season 2017 are found at
770 the ADF site. Relatively similar values are obtained at the CT site (0.57 in the wet season and
771 0.19 ± 0.16 in the dry season). These ratios are on the same order of magnitude as those typical
772 for soil (0.3) (Watson et al. 2001). At both the AWB and AT sites, Cu/Sb ratios ranging between
773 0.01 and 0.16 are obtained in the dry season 2017, which seems to also indicate an influence of

774 re-suspended particles at these two sites during that period. In the other three sites (ADF, AT
775 and CT), however highly influenced by traffic, our Cu/Sb ratios do not compare with brake
776 lining wear ratios, but rather with soil ratios only. In contrast, very high and large ranges of
777 ratios varying from 238.7 to 3725.9 are calculated at the AWB site during the wet season 2016.
778 Arditsoglou and Samara (2005) proposed a Cu/Sb ratio of 700 as a tracer of diesel vehicle
779 emissions. Here high values could be also be explained by waste burning materials, values
780 which are not known in literature to our knowledge 
781 Typically, an As/V ratio of 0.02 indicates that the emissions are from burning oil, 0.03 for
782 cement plant, 0.1 for soil or agricultural soil, 0.3 for metal scrap incineration source and 2.3 for
783 petrol and diesel origin (Lee et al., 2000; Watson and Chow, 2001; Samara et al., 2003). The
784 aerosols in Abidjan have an As/V ratio ranging from 0.28 to 0.95 during the dry season 2017,
785 implying an anthropogenic origin for As, including petrol and diesel vehicles. Only one value
786 of 0.07, four times lower than the lower limit of the As/V ratio found in the dry season, is
787 present in Abidjan during the wet season. This is not enough to determine a possible seasonal
788 variation of the ratio As/V in Abidjan. However, in Cotonou, similar As/V ratios (0.15 ± 0.19 in
789 the wet season and 0.15 ± 0.06 in the dry season) are observed for both seasons, and these values
790 remain lower than those from Abidjan. This result suggests more dust origin for As in Cotonou.
791 This is in-line with values reported in the literature: Watson et al. (2001) and Lee et al. (2000)
792 reported a ratio of 0.1 as tracer of soil or agricultural soil.

793 The V and Ni trace elements are frequently used as fingerprint makers for petroleum derived
794 hydrocarbons (Laden et al., 2000). The V/Ni ratio for oil combustion has been reported to range
795 from 2 to 5 (Foner and Ganor, 1992; Almeida et al., 2005; Arditsoglou and Samara, 2005),
796 while that of vehicle emissions are generally lower than 2 (0.15 for diesel, 0.4 for a mixture
797 gasoline and diesel, 0.02 for gasoline, Samara et al., 2005; Watson and Chow, 2001). In
798 Abidjan, the average ratio of V/Ni is 0.17 ± 0.11 at ADF, 0.20 ± 0.20 at AWB and 0.22 ± 0.11 at
799 AT with ratios in the dry season higher than those in the wet season, except at the AT site for
800 which the ratio is slightly larger during the wet period (Table 4). In Cotonou, the V/Ni ratio is
801 relatively higher than in Abidjan, varying from 0.13 to 0.66, with values in the wet period 1.4
802 times larger than during the dry season (Table 8). These results suggest that oil combustion is
803 a minor source of Ni and V in both Abidjan and Cotonou, which is due to the absence of
804 industrial pollution from the combustion of heavy-fuel oil. On another hand, these low Ni/V
805 ratios seem to support the assumption of the strong influence of vehicle emission sources on all
806 studied sites.

807 The ratio of Zn/Pb has been used to distinguish between transported and local aerosols. From
808 this study, ranges of the Zn/Pb ratio (1.8-8.2 at ADF, 3.6-17.4 at AWB, 8.3-25.5 at AT and 3.5-
809 22.5 at CT site) are representative of the ratios found for gasoline and diesel vehicles (1.7-2.4,
810 Qin et al., 1997 ; Sakata et al., 2000 ; Watson et al., 2001 ; Chiang et al., 2012), for roadside
811 (4.2-4.4, Zhang et al., 2018), for soil and agricultural soil (3.1-4.0, Watson et al., 2001 ; Lee et
812 al., 2000), for earth's crust and road dust (5.4-5.5, Mason and Moore, 1982 ; Shen et al., 2016),
813 for biomass burning and metal scrap incineration (7.2-8.4, Lee et al., 2000 ; Samara et al., 2003)
814 and combustion of petrol oil from road transport (10.6-24.4, Pulles et al., 2012). Zn/Pb ratios
815 calculated at both the ADF and AT sites during the dry season (2.8 ± 1.3 and 14.8 ± 3.8 ,
816 respectively) are lower than those observed during the wet season (7.1 ± 3.4 and 19.9 ± 14.7 ,
817 respectively), while at Cotonou a lower Zn/Pb ratio is found during the wet period (3.3 ± 2.3)
818 compared to the dry period (18.5 ± 8.5). This seasonal variation of the ratio Zn/Pb suggests that
819 TSP in Abidjan is more affected by local emissions during dry season, while aerosols in
820 Cotonou are more influenced by transported and re-suspended dust, which is in agreement with
821 our previous conclusions. Also it is important to note that the mean values found at AT and CT
822 (on the order of 18) are indicative of combustion of petrol from road transport origin (Pulles et
823 al., 2012), whereas that of the ADF site (7.1) could suggest possible links to biomass burning
824 (Samara et al., 2003).

825 Finally, the Zn/Cd ratio has been also examined. A value of 29 close to ratio reported for
826 gasoline vehicle (27, Qin et al., 1997) is obtained for the ADF site, indicating that this site is
827 also impacted by traffic sources. A values of 56 is obtained for the AWB site which is in close
828 agreement with values reported for oil burning (Watson et al., 2001, Samara et al., 2003). That
829 could indicate that oil might be one of the waste burning materials.

830 **3.2.4 Dust**

831 As shown in the methodology part and in the previous paragraph, we can see that desert
832 dust and parent soils are mainly composed of clays, feldspar, and quartz, therefore contain high
833 contents of silicon, aluminium, calcium and iron (Schütz and Rahn 1982; Laurent, 2005), the
834 main elements from which dust concentrations are obtained. Figure 12 shows dust
835 concentrations calculated from Ca^{++} values following the Sciare et al. (2005) relationship (see
836 paragraph 2.3.6) for Coarse (C), Fine (F) and UltraFine (UF) particle sizes at the different sites
837 for each season. Note that no UF value exists for the wet season 2016 due to our sampling
838 procedure at this time.

839 During the wet season, the average total concentrations range from 5.2 to 25.2 $\mu\text{g}\cdot\text{m}^{-3}$ in 2015
840 and 13.5 to 43.0 $\mu\text{g}\cdot\text{m}^{-3}$ in 2016, with slightly higher values at the CT and ADF sites, whereas
841 during the dry season, values range from 16.8 to 66.2 $\mu\text{g}\cdot\text{m}^{-3}$ in 2016 and from 17.6 to 61.3
842 $\mu\text{g}\cdot\text{m}^{-3}$ in 2017, with maximum concentrations obtained at the CT site. When considering mean
843 values of the wet and dry seasons respectively, total dust at Cotonou traffic (CT) are 2.2 and
844 3.1 times the values found at AT, 4.4 and 2.9 times at AWB and 1.2 and 3.1 times at ADF.
845 Seasonal comparison shows that mean dust concentration are higher in the dry seasons than in
846 WS 2015 by a factor of 1.1 for ADF, 1.8 for AT, 2.5 for CT and 4.1 for AWB. A striking feature
847 is that wet season 2016 presents higher values by a factor of 1.6 to 2.6 than wet season 2015.
848 Also, it is interesting to note that the dust content in coarse particles is higher in DS2017 than
849 in DS2016. Moreover, dust is maximum for coarse particles during the wet season 2016,
850 whereas for fine and ultrafine particles during the dry seasons and the wet season 2015. Such
851 variations may be explained by different factors: road dust resuspension processes, long range
852 transport of desert dust from Bodélé depression in Tchad (Prospero et al., 2002; Washington et
853 al., 2003; Knippertz et al., 2011) and/or from northern dusty countries (Mali, Niger) (Ozer,
854 2005) by northerly winds in dry season (Balarabe et al., 2016), and meteorological factors such
855 as wind intensity and direction, and precipitation. It is important to note that the latter factor
856 does not explain any trends since precipitation and wind are similar between the two wet
857 seasons. We recall that the long-range transport of dust occurs at low elevations during the dry
858 season, and often at higher altitudes during the rest of the year following the northward
859 movement of the intertropical front (Afeti and Resch, 2000; Middleton et al., 2001). To go
860 further in our analysis, AOD at 550nm from MODIS satellite images ([http://www.aeris-](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)
861 [data.fr/redirect/MODIS-MCD64A1](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)) associated with back trajectories (Figure 4) were
862 examined for each date of our intensive campaigns in Abidjan and Cotonou. No clear
863 indication were found since images do not cover our area for all periods. The interesting pattern
864 shown in Figure 13 is the AOD difference between Cotonou and Abidjan for DS2017, with
865 higher values at Cotonou than in Abidjan for the campaign period, likely because dust events
866 have a larger impact in Benin than Côte d'Ivoire. This is confirmed by the DACCWA
867 sunphotometer AOD and Angström coefficient (AE) measurements at Abidjan and Cotonou
868 (Léon et al., 2019; Djossou et al., 2018). Indeed, in DS2017, during our period of
869 measurements, mean AOD in Cotonou is of the order of 1.3 versus 0.9 in Abidjan for an AE of
870 0.6 for both sites, which clearly indicates the presence of coarse dust particles. Also, when
871 comparing DS2016 and DS2017 at Cotonou, we can see that lower AOD values (mean: 0.99)
872 with higher AE values (mean: 1.1) are observed. This is in agreement with the increase of dust

873 concentrations in the coarse fraction observed between 2016 and 2017 shown in Figure 12. If
874 we focus now on the two wet seasons, as mentioned earlier, dust concentrations are much higher
875 in 2016 than in 2015 at the CT and ADF sites. It is consistent with observed AOD values at CT
876 which increased by a factor of 2 between 2015 and 2016. No AOD value is given by Léon et
877 al. (2019) at Abidjan in WS2015 to allow such comparison in Abidjan. Moreover, during the
878 WS, an AE on the order of 1 may be found at CT, indicating smaller particles which could be
879 due to road resuspension. It is interesting to note that during WS 2016, AOD and AE are
880 respectively higher and lower at Abidjan than at Cotonou. Again, this is consistent with our
881 dust concentrations at CT. In Abidjan, we could assume that another source of Ca^{++} , which is
882 not taken into account in our dust calculations, may explain our dust concentration data. That
883 may be the result of anthropogenic Ca^{++} emissions from residential combustion, more important
884 in 2016 than in 2015 as shown earlier
885 (http://naei.beis.gov.uk/overview/pollutants?pollutant_id=84).

886 3.3 Aerosol chemical closure

887 The aerosol chemical closure obtained using the Guinot et al. (2007) method (see below)
888 at the different sites for each season is presented in Figure 14. Results show clear intra- and
889 inter-annual variations at all of the sites, as well as significant differences among the sites. In
890 total, dust accounts for 25 to 60% of the bulk PM mass (depending on the measurement
891 campaign) at both traffic sites, with no clear seasonal cycle for the year 2016, and higher
892 contributions in Cotonou (Figures 14c and 14d). These percentages vary from 30 to 65% at the
893 AWB site, and from 10 to 30% at the ADF site, with percentages 1.5 and 2 times higher in the
894 dry season than in the wet season for the year 2016 (Figures 14a and 14b). This high
895 contribution is related to the Saharan dust transport occurring during the dry season as
896 demonstrated earlier. The largest percentage observed in Cotonou can be explained by the
897 influence of local dust, mainly from unpaved roads (only 8% of roads are paved compared to
898 59.4% in Abidjan (UVICOCI, 2018)). The relative contribution of dust generally peaks in the
899 coarse mode and, to a lesser extent, in the fine mode, at all sites considered, reflecting their
900 natural origin. However, the dust contribution in the ultrafine mode remains important. It is
901 interesting to note that the dust contribution observed in this study for the year 2016 at the
902 Abidjan sites is in agreement with the results of Xu et al. (2019) which show a $\text{PM}_{2.5}$ dust
903 contribution of 35-50% compared to our values of 18-52%.

904 Carbonaceous aerosol, the sum of EC and POM, show large contributions at the ADF site (up
905 to 75% of the total PM mass), with relatively similar proportions in each season (Figure 14a).

906 The absence of a clear seasonal pattern is also observed at the other sites, except at AWB where
907 carbonaceous aerosol contributes to 35% of the bulk PM mass in the wet season, and 15% in
908 the dry season of 2016 (Figures 14b-d). However, carbonaceous aerosol contribution accounts
909 for about 18-25% of the total mass at both traffic sites. As seen in Figure 14, in most of the
910 cases, carbonaceous aerosol contribution sharply increases from the coarse to ultrafine mode in
911 all sites during both seasons, with the exception of the ADF site during the wet season 2015.
912 As shown previously, the importance of carbonaceous aerosol at the ADF site reveals, on one
913 hand, the proximity between active sources such as domestic fires and the sampling site, and
914 on the other hand, the specificity of the site characterized by lots of wood burning activities.
915 These activities are responsible of high incomplete combustions with high emission factor
916 values (Keita et al., 2018). In addition, as an indicator of incomplete source, the EC-to-POM
917 ratio obtained for the ADF site is 3 to 4 times lower than the values calculated for the other sites
918 (Figure 14).

919 The average total concentrations of ionic species are $27.4 \mu\text{g}\cdot\text{m}^{-3}$ in the wet season ($19.0 \mu\text{g}\cdot\text{m}^{-3}$
920 3 in the dry season), 12.5 ($11.3 \mu\text{g}\cdot\text{m}^{-3}$), 13.2 ($7.8 \mu\text{g}\cdot\text{m}^{-3}$) and 14.8 ($17.3 \mu\text{g}\cdot\text{m}^{-3}$) at the ADF,
921 AWB, AT and CT sites, accounting for 5.7 (5.4%), 19.2 (6.5%), 14.7 (5.7%) and 14.4 (6.4%)
922 of bulk PM, respectively. The percentages of the total WSI to PM mass (15-20%) at the three
923 Abidjan sites (ADF, AWB and AT) are on the same order of magnitude than the data from
924 PM_{2.5} personal exposure samples collected at the same locations in 2016 by Xu et al. (2019).
925 Our results also are very close to the ionic contribution of 9% of the PM₁₀ mass found at the
926 urban curbside site in Dar es Salaam in Tanzania during the wet season 2005 by Mkoma (2008).
927 Our results indicate no clear seasonal cycle. The highest WSI concentration during the wet
928 season at both sites can be explained by the impact of marine aerosols during this season. In
929 addition, at the ADF site, the large use of moist wood for cooking can play a role. At the CT
930 site, and to a lesser extent at AWB site, WSI concentrations are almost constant in the two
931 seasons, indicating that WSI originates more from anthropogenic than natural sources.

932 The ion percentages of C, F and UF PM fractions are 4.8, 6.1 and 10.4% for ADF, 13.7, 24.9
933 and 22.8% for AWB, 11.5, 24.7 and 12.4% for AT and 12.4, 26.3, 13.0% for CT, respectively,
934 indicating higher values in fine mode except at ADF where the contribution is largest for the
935 UF mode (Figure 14). These results suggest that WSI at the ADF site are from direct
936 anthropogenic emissions, while at the rest of the sites they originate from fresh marine aerosols.

937

938 **4- Conclusions**

939 This paper presents the mass and the size-specified chemical composition of particulate matter
940 (PM) during the dry and wet seasons in Abidjan and Cotonou. Measurements were performed
941 at three sites in Abidjan, representative of domestic fire (ADF), waste burning (AWB) and
942 traffic (AT) sources, and at one traffic site in Cotonou (CT). The total PM mass concentrations
943 show large variabilities ($56\text{--}676\ \mu\text{g}\cdot\text{m}^{-3}$) and a clear seasonality with concentrations in the dry
944 season 1.5 to 3 times higher than those in the wet season, except at the ADF site where values
945 in the wet period are larger. The ADF site is the most polluted site and a significant fraction of
946 the aerosol mass is in ultrafine (UF) and fine (F) particle modes, which can have the largest
947 impact on the respiratory tract. It is interesting to note that all these values are well above the
948 WHO guideline of $25\ \mu\text{g}/\text{m}^3$, irrespective of season and size. This is a warning signal for
949 pollution levels in African capitals if nothing is done to reduce emissions in the future. The
950 analysis of chemical species indicates a predominance of particulate organic matter (POM) at
951 the ADF site, especially in the UF and C fractions, while at CT, dust particles are the major
952 constituent. The specificity of the ADF site is likely related to the presence of burning activities
953 where women dry fish and meat using wood before selling them. In the wet season, the wood
954 is moist and combustion is highly incomplete, producing a lot of smoke and much higher
955 aerosol concentrations than in the dry season. The large contribution of dust to the African
956 aerosols results from road dust resuspension processes, and the long-range transport of desert
957 dust associated with the Bodélé depression. The largest percentage observed at Cotonou may
958 be explained by the more predominant influence of local dust, mainly from unpaved roads (only
959 8% of roads are paved, compared to 59.4% in Abidjan). The comparison of traffic sites reveals
960 that concentrations at the CT site are higher than those at AT. This can be explained not only
961 by the strong influence of dust in Cotonou, but also by the consumption of petrol and diesel
962 fuel by transport which exceeds the one of Abidjan. The carbonaceous aerosols generally peak
963 in the UF and F particle modes. This is likely associated with anthropogenic emissions,
964 particularly biomass and waste combustion, domestic fires and traffic.

965 Results from the chemical closure indicate clear seasonal and inter-annual variability within the
966 same site, as well as significant differences between the sites. In total, dust accounts for 25 to
967 60% of the bulk PM mass at both traffic sites, with no clear seasonal cycle for the year 2016,
968 and higher contribution at Cotonou. These percentages vary from 30 to 65% at the AWB site
969 and from 10 to 30% at the ADF site. The relative contribution of dust generally peaks in the

970 coarse mode, and to a lesser extent, in the fine mode for all sites, reflecting their natural origin.
971 Nevertheless, the dust contribution in the ultrafine mode remains important.
972 Carbonaceous aerosol, the sum of EC and POM, shows large contributions at the ADF site (up
973 to 75% of the total PM mass), with relatively similar proportions in each season. The absence
974 of seasonality is also observed at the other sites, except at AWB where carbonaceous aerosol
975 contributes to about 35% of the bulk PM mass in the wet season and 15% in the dry season of
976 2016. However, based on 2016, carbonaceous aerosol accounts for about 18-25% of the total
977 mass at both traffic sites. In most cases, the carbonaceous aerosol contribution sharply increases
978 from coarse to ultrafine mode for all sites and seasons, except at the ADF site during the wet
979 season 2015. This result is consistent with previous studies showing that carbonaceous aerosol
980 generally peaks in the fine mode due to their anthropogenic origin. The importance of
981 carbonaceous aerosol at the ADF site reveals both the proximity between the active sources
982 such as domestic fires to the sampling site, as well as the specificity of the site characterized by
983 intense wood burning activities, which lead to high incomplete combustions. In addition, as an
984 indicator of incomplete source, the EC-to-POM ratio obtained at the ADF site is 3 to 4 times
985 lower than the values calculated at the other sites.

986 The average total concentrations of ionic species are $27.4 \mu\text{g}\cdot\text{m}^{-3}$ in the wet season
987 ($19.0 \mu\text{g}\cdot\text{m}^{-3}$ in the dry season), 12.5 ($11.3 \mu\text{g}\cdot\text{m}^{-3}$), 13.2 ($7.8 \mu\text{g}\cdot\text{m}^{-3}$) and 14.8 ($17.3 \mu\text{g}\cdot\text{m}^{-3}$) at
988 the ADF, AWB, AT and CT sites, accounting for 5.7 (5.4%), 19.2 (6.5%), 14.7 (5.7%) and 14.4
989 (6.4%) of the bulk PM, respectively. At the ADF site, maximum values of SO_4^{2-} , NH_4^+ and
990 NO_3^- observed during the wet season may be linked to the impact of anthropogenic emissions
991 and, more precisely, to smoking activities which pollute more in the wet than in the dry season.
992 However, our results indicate no clear seasonal cycle for WSI. The higher WSI concentration
993 during the wet season at the other sites can be explained by the impact of marine aerosols during
994 this season.

995 The WSI percentages in C, F and UF PM fractions for the ADF, AWB, AT and CT sites,
996 respectively, indicate a peak in the fine mode except at ADF where the contribution is largest
997 in the UF mode. These results confirm that WSI at ADF is due to anthropogenic emissions. In
998 terms of trace elements, they present a well-marked seasonal evolution. The highest
999 concentrations registered during the dry season are for the Al specie, followed by Fe. The mean
1000 values of selected trace element ratios in TSP for the Abidjan (ADF, AWB and AT) and
1001 Cotonou (CT) sites indicate the influence of dust particles at these sites during that period. At
1002 the ADF, AT and CT sites, As/V ratios from 0.28 to 0.95 in DS2017, indicate the anthropogenic
1003 origin of As, especially from petrol and diesel vehicles. The seasonal variation of the Zn/Pb

1004 ratio suggests that TSP in Abidjan is more affected by local emissions during the dry season,
1005 while Cotonou aerosols are more influenced by transported and re-suspended dust, which is in
1006 agreement with our previous conclusions. Finally, the Zn/Cd ratio has been also examined, with
1007 a value of 29 at the ADF site. This indicates that the ADF site is also impacted by traffic sources.
1008 Finally, WSOC concentrations for each site, size and season have also been evaluated. It is
1009 interesting to note that such values are maximum at the ADF site for the wet season. At this
1010 site, the WSOC/OC and WSOC/K ratios highlight the primary origin of WSOC due domestic
1011 fire emissions. We also note the high concentrations of WSOC at CT in the dry season which
1012 is related to large dust concentrations and heterogeneous chemistry.

1013 Our study constitutes an original database to characterize urban air pollution from
1014 specific African combustion sources. The next step will be to cross such an exhaustive aerosol
1015 chemical characterization to biological data in order to evaluate the impact of aerosol size and
1016 chemical composition on aerosol inflammatory properties.

1017

1018 **Acknowledgements.** The research leading to these results has received funding from the
1019 European Union 7th Framework Programme (FP7/2007-2013) under Grant Agreement no.
1020 603502 (EU project DACCIWA: Dynamics-aerosol-chemistry-cloud interactions in West
1021 Africa). The authors greatly thank all the colleagues and operators who contribute to sampling
1022 during the different campaigns.

1023

1024 **Author Contributions**

1025 J.A. and C.L. conceived and designed the study. J.A., C.L. and T.D. contributed to the
1026 literature search, data analysis/interpretation and manuscript writing. J.A., C.L., A.B., TD. and
1027 contributed to manuscript revision. J.A., C.L., J.F.L, H.C, V.Y., A.A, C.G, C.Z, E.C and S.K.
1028 carried out the particulate samples collection and chemical experiments, analyzed the
1029 experimental data.

1030 **Additional Information**

1031 Fig. S1 and Appendix A-D accompany this manuscript can be found in Supplementary
1032 Information.

1496 Figure 1: Map of the city of Abidjan reporting the geographical location of DACCIWA urban
1497 sampling sites.

1498 Figure 2: Map of the city of Cotonou reporting the geographical location of DACCIWA urban
1499 sampling site.

1500 Figure 3: Pictures of the different sampling sites : (a) Traffic in Cotonou (Benin, CT station),
1501 (b) Waste burning in Abidjan (Côte d'Ivoire, AWB station), (c), Domestic fire, showing
1502 smoking activity in Yopougon, Abidjan (Côte d'Ivoire, ADF station), (d) " woro-woro
1503 and Gbaka " traffic in Abidjan (Côte d'Ivoire, AT station).

1504 Figure 4: Wind, pressure and temperature diagram at Abidjan and Cotonou during the different
1505 campaigns.

1506 Figure 5: Back trajectories arriving at Abidjan (a) and Cotonou (b) for each season (WS2015,
1507 WS2016, DS2016 and DS2017).

1508 Figure 6: Aerosol Mass concentrations at the different study sites for each campaign and for the
1509 different sizes (C in black, Fine in light Grey, Ultra-fine in grey).  aerosol mass is
1510 indicated in boxes.

1511 Figure 7: Comparison of PM 2.5 mass concentrations in $\mu\text{g}/\text{m}^3$ at the four sites with those
1512 obtained by Djossou et al. (2018) and Xu et al. (2019) for the same site and period.

1513 Figure 8: EC relative concentrations in each size classes (C in black, Fine in light grey, Ultra-
1514 fine in grey) at the different study sites for each campaign. Bulk EC concentration for
1515 each site is indicated in boxes.

1516 Figure 9: OC relative concentrations in each size classes (C in black, Fine in light grey, Ultra-
1517 fine in grey) at the different study sites for each campaign. Bulk OC concentration for
1518 each site is indicated in boxes.

1519 Figure 10: OC/ EC ratio for the different campaigns and sites for each aerosol size (C in black,
1520 Fine in light grey, Ultra-fine in grey). Each box shows the median and the first and the
1521 third quartiles.

1522 Figure 11: Water-soluble ionic species speciation for each site, each campaign and each aerosol
1523 size.

1524 Figure 12: Dust concentrations at the different study sites for each campaign and for the
1525 different sizes (C in black, Fine in light grey, Ultra-fine in grey).

1526 Figure 13: MODIS Aerosol optical depth regional distribution over West Africa. Data are for
1527 2017, focusing on our campaign date at Abidjan (a-c 01/11-12-left part) and Cotonou
1528 (b-d 01/6-7, right part).

1529 Figure 14: Size-specified aerosol chemical composition for each site, for each campaign and
1530 each aerosol size.
