30 **Abstract**

31 Air pollution in West Africa has yet to be well characterized and was one of the principal
32 motivations of the “Air Pollution and Health” work package in the DACCIWA (Dynamics-
33 Aerosol-Chemistry-Cloud Interactions in West Africa) program. Intensive measurement
34 campaigns were performed in two West African capitals (Abidjan in Côte d’Ivoire and Cotonou
35 in Benin), in dry season (January 2016 and 2017) and wet season (July 2015 and 2016), in order
36 to examine the size distribution of particulate matter (PM) and their chemical composition
37 including elemental carbon (EC), organic carbon (OC), water-soluble organic carbon (WSOC),
38 water-soluble inorganic ions (WSI) and trace metals. In this study, we characterize PM from
39 different sites in Abidjan, which are representative of domestic fires (ADF), traffic (AT) and
40 waste burning (AWB) sources and from one traffic site in Cotonou (CT). All these sites,
41 impacted by large amount of pollution, are representative of the main  combustion sources in
42 South West Africa (SWA).

43 Results show very high PM concentrations at the SWA sites and a well-marked seasonality as
44 well as a strong spatial variation. The average PM_{2.5} mass concentrations during the wet season
45 are 517.3, 104.1, 90.3 and 69.1 $\mu\text{g}\cdot\text{m}^{-3}$ at the ADF, CT, AT and AWB sites, respectively. In the
46 dry season, PM_{2.5} concentrations decrease to 375.7 $\mu\text{g}\cdot\text{m}^{-3}$ at the ADF site, while they increase
47 to 269.7, 141.3 and 175.3 $\mu\text{g}\cdot\text{m}^{-3}$ at the CT, AT and AWB sites, respectively. The annual PM_{2.5}
48 levels at almost all sites are significantly higher than the WHO guideline level of 10 $\mu\text{g}\cdot\text{m}^{-3}$. As
49 for PM mass, carbonaceous aerosol concentrations are also maximum at ADF site, accounting
50 up to 69% of the total PM mass. The largest amount of these species on the ADF site in both
51 seasons are due to the intensive human activities such as domestic cooking using wood and
52 food smoking and roasting activities, known to be an important source of PM in SWA. Dust
53 contributions are dominant at CT (57-80%), AT (20-70%) and AWB (30-69%) sites and
54 specially in the coarse and fine particle modes at CT and in the coarse fraction at AT site, while
55 there is no clear distribution at AWB site. This result reflects the specificity of most of SWA
56 cities permanently impacted by dust emissions from the desert around and re-suspended
57 particles from the roads. The contributions of WSI to the total PM mass are highly variable but
58 remain less than 30%. Values are generally 1-3 times higher in the wet season than the dry
59 season. The total proportion of WSI is driven by the individual contribution of three species
60 such as chloride, nitrate and calcium, which may peak in the fine and/or large particles
61 according to the site. This means that different types of sources (anthropogenic emissions from
62 fuel combustion, nitrate formation by reaction processes and natural emissions) contribute to
63 WSI emissions in the studied sites. The concentrations of element traces well reflect the trends

64 of dust at the traffic and AWB sites, with a predominance of Al, Na, Ca, Fe and K, keys markers
65 of crustal dust.

66 Our study highlights the contribution of different traffic emissions in two major West African
67 cities to atmospheric aerosol composition. It also highlights the role of domestic fires and waste
68 combustion sources. It constitutes an original database that characterizes urban air pollution
69 from specific African combustion sources.

70

71 **Keywords:** atmospheric pollution, chemical composition, physicochemical characterization,
72 Particulate matter, traffic, waste burning, domestic, biomass burning.

73

74 **1. Introduction**

75 The impact of anthropogenic pollution on environment and health has been demonstrated by
76 numerous studies in Europe and North America, which have contributed to the implementation
77 of emission reduction policies. By contrast, air pollution in Africa is far from being well
78 characterized, although it is suspected to be responsible for negative health outcomes (*WHO*,
79 2014). This is a major problem since Africa is an intense emitter of pollution from
80 anthropogenic sources that includes domestic fires, vehicular traffic, waste burning as well as
81 growing oil and mining industries. It has also one of the fastest growing urban populations in
82 the world, especially in West and East Africa. As a consequence, it has been shown that massive
83 urbanization and rapid economic growth could be responsible for tripling anthropogenic
84 emissions in Africa between 2000 and 2030 (*Lioussé et al., 2014*). Moreover, it is important to
85 recall the impact of biomass burning and dust sources in the African atmospheric composition,
86 especially occurring during the dry season. All of this results in a major degradation of urban
87 air quality and an impact on the health of exposed populations. Only a few studies on this
88 subject have been conducted in West Africa (*Val et al., 2013; Dieme et al., 2012; Kouassi et*
89 *al., 2009*) despite the high atmospheric pollutant concentrations already measured to be of the
90 same order as in Asian megacities and well above WHO international standards (*WHO, 2014*).

91 West Africa is then an "unique laboratory" to study urban pollution. Previous studies conducted
92 under the framework of the AMMA (Analyses Multidisciplinaires de la Mousson Africaine)
93 and POLCA (POLlution des Capitales Africaines) programs, have revealed very high
94 particulate pollution concentration levels in Cotonou (Benin), Bamako (Mali), Dakar (Senegal)

95 and Yaoundé (Cameroun) during the dry season (*Doumbia et al., 2012; Val et al., 2013*),
96 suggesting that the population may be affected by negative health outcomes. For example, *Val*
97 *et al. (2013)* showed that the inflammatory impact of combustion aerosol depends on the type
98 of emission sources and determined the predominant role of particulate organic matter.
99 Moreover, fine and ultrafine aerosol fractions, as well as their content in trace metals and
100 organic compounds, have been shown to induce biological effects due to their ability to reach
101 the distal lung (*Cassee et al., 2013*). Such reasons highlight the need to better understand the
102 size-speciation of aerosol chemical composition for the main West African anthropogenic
103 sources during the different seasons. Within this context, the DACCIWA (Dynamics-Aerosol-
104 Chemistry-Cloud Interactions in West Africa) program, dedicated a specific work package to
105 “Air Pollution and Health” dealing with pollutant characterization related to health issues
106 through toxicological studies and epidemiological studies.

107 Intensive and extensive campaigns have been organized from December 2014 to March 2017
108 in Abidjan and Cotonou. The strategy was to measure aerosol chemical composition in different
109 sites, representative of the main prevailing urban sources in West Africa following *Liousse et*
110 *al. (2014)* and *Keita et al. (2018)*. Two typical traffic-sampling sites were chosen, one in
111 Abidjan (Côte d’Ivoire) and another one in Cotonou (Benin), to take into account differences
112 in terms of fleets, type of fuel used and quality of roads. Indeed, in Cotonou, the majority of
113 population uses two-wheel vehicles using gasoline fuel or gasoline and oil fuel, whereas in
114 Abidjan, the vehicle fleet is dominated by four-wheel engines using diesel fuel. Measurements
115 were also performed at domestic fire and waste burning sites, both located in Abidjan.

116 During the extensive campaign, PM_{2.5} mass and carbonaceous aerosol were weekly measured
117 and results are discussed in *Djossou et al. (2018)*. In this paper, we focus on the results from
118 the intensive campaigns. We present measurements obtained at each site during the wet and dry
119 seasons of the studied periods: (i) PM size distribution and mass concentrations and (ii) PM
120 chemical composition including carbonaceous aerosol, water-soluble organic carbon, water-
121 soluble inorganic ions, dust and trace elements in different size fractions. Experimental method
122 including description of sites, types of measurements and analyses, meteorological conditions,
123 will be presented in the section 2, whereas results and discussion are discussed in the sections
124 3 and 4 of the paper, respectively.

125

126 2. Experimental method

127 2.1. Description of sites

128 Measurement campaigns have been performed in wet season (July 20-26, 2015 and July
129 4-13, 2016) and dry seasons (January 7-15, 2016 and January 5-14, 2017) at three sites in
130 Abidjan (Côte d'Ivoire), representative of different sources, i.e. ADF for Abidjan Domestic
131 Fires, AWB for Abidjan Waste Burning and AT for Abidjan Traffic (Figure 1), as well as one
132 traffic site in Cotonou (Benin) (Figure 2).

133 As shown in Figure 3 which presents pictures of the different sampling sites, the ADF site (5°
134 19' 44" N, 4° 06' 21" W) is situated on a platform, 5 m above ground level, in Yopougon
135 Bracody district near a market (Figure 1). This geographical area is highly populated with
136 various small commercial activities such as a fish and meat-smoking by women. There are also
137 many formal and informal settlements, which mainly use wood and charcoal as a source of fuel
138 for private and professional combustion activities. Other sources of concern contributing to the
139 mix of pollutant emissions in the area include transportation-related emissions, biomass
140 burning, garbage bins or small landfills and various other fugitive sources. The AT site (5° 21'
141 14" N, 4° 01' 04" W) is located in Adjamé, on the roof of « 220 pharmacie logement building »,
142 about 7 m above ground level and roughly 10 m away from the main road. This site, close to
143 the Adjamé market and to a bus station, is highly affected by traffic (Gbaka, bus, taxi, woro-
144 woro, private cars...). The AWB site (5° 21' 12" N, 3° 56' 16" W) is located at Akouédo in the
145 district of Cocody, on the roof of « Talafigué », a building 15 m above ground level. This site
146 is close to the big waste  burning area of Abidjan established since 1965, which covers an area
147 of 153 ha. The Cotonou Traffic (CT) (6° 22' 19" N, 2° 26' 5" E) site is located in Cotonou, on
148 the «Sogema» building roof, about 7 m above ground level. This site is close to the Dantokpa
149 market and also to the biggest crossroad of Cotonou (intersection of 4 main roads). This site is
150 highly influenced by intense traffic activities. As previously mentioned, such a site is interesting
151 because the vehicle fleet and fuels are different in Cotonou compared to Abidjan: (1) there are
152 many two-wheel vehicles in Cotonou whereas a few only in Abidjan; (2) in Cotonou, gasoline
153 is of poor quality due to the illegal fuel transport from Nigeria and (3) the roads are in worse
154 conditions in Cotonou than in Abidjan.

155 2.2. Measurements

156 During each intensive campaign, two 3-hour samples collected with cascade impactors
157 operating in parallel are obtained for the consecutive days (i.e. six size-resolved samples per
158 site during each campaign), to allow size-speciated characterization of the aerosol chemical
159 composition. Note that the choice of the 3-hour periods is linked to the period of maximum
160 pollution for each site (e.g. morning at ADF site, afternoon at AT site, morning at CT site).
161 There is no specific period at AWB site since the activities are roughly the same during the day.
162 The first impactor with 4 stages ($PM_{>2.5}$; $PM_{2.5-1}$; $PM_{1-0.2}$; $PM_{<0.2}$) includes 4 quartz fiber filters
163 (QMA, Whatman) for mass and carbonaceous aerosol (EC, OC and WSOC analysis). The
164 second impactor with 3 stages ($PM_{>2.5}$; $PM_{2.5-1}$; $PM_{1-0.1}$) is equipped with three Teflon filters
165 (Zefluor, Pall Corporation®), dedicated for water-soluble ions species and trace elements. Due
166 to operational problems in July 2016, this second 3-stage cascade impactor is replaced by
167 another 3-stage cascade impactor with different size cuts ($PM_{>10}$, $PM_{10-2.5}$, $PM_{2.5-1}$). For
168 consistency, results will be presented as an ultrafine (UF), fine (F) and coarse (C) classification.
169 The two first stages ($PM_{>2.5}$ and $PM_{2.5-1}$) being considered as the coarse particulate fraction, the
170 $PM_{1-0.1}$ or $PM_{1-0.2}$ stage, the fine particulate fraction and the $PM_{<0.2}$ stage, the ultrafine fraction.
171 All the filters are prepared and analyzed at the Laboratoire d'Aerologie in Toulouse under
172 different protocols described in the following paragraphs. Note that the quartz filters are
173 pre-fired before sampling.

174 **2.3. Analyses**

175 **2.3.1. Gravimetric analyses**

176 Aerosol mass concentrations are obtained using a high-precision balance (SARTORIUS
177 MC21S), placed under a controlled temperature and humidity atmosphere (Person and Tymen,
178 2005). Before weighing, the filters are kept 24 hours in the weighing room at an ambient relative
179 humidity of $30 \pm 15\%$. The filters are weighed before and after sampling. Result of a gravimetric
180 measurement consists of the average of 2 to 4 weighing whose differences do not exceed $5 \mu\text{g}$.
181 The standard error on a gravimetric measurement is therefore less than $10 \mu\text{g}$, typically
182 representing less than 5% of the particles mass.

183 **2.3.2. Carbonaceous aerosols**

184 Carbonaceous aerosol is determined with thermal analysis with a two-step method
185 adapted from Cachier et al. (1989). Two aliquots of the same filter are separately analyzed.

186 One portion is directly analyzed for its total carbon content (TC). The other portion is
187 first submitted to a pre-combustion step (2 h at 340°C under pure oxygen) in order to eliminate
188 Organic Carbon (OC), and then analyzed for its Elemental Carbon (EC) content. Organic
189 carbon (OC) concentrations are calculated as the differences between TC and EC. Note that the
190 aerosol carbon content is quantified by a non-dispersive infrared (NDIR) detector with G4
191 ICARUS instrument with a detection limit of the order of 2 $\mu\text{gC}\cdot\text{cm}^{-2}$. Uncertainty is in the
192 order of 5% for TC, while being in the range of 5-20%, for EC and OC.

193 **2.3.3 Water Soluble Organic Carbon analysis**

194 WSOC measurements are performed using a total organic carbon analyzer (Sievers M9).
195 A detailed description of this technique is reported in Favez et al. (2008). Briefly, the full
196 oxidation of total organic carbon into CO_2 is obtained by coupling chemical oxidation (with
197 ammonium persulphate) and UV light. CO_2 is then quantified by conductivity. Analyses are
198 conducted on 20 ml of solution extracts. For UF samples, solutions to be analyzed are obtained
199 using a total filter surface of 3 cm^2 (6x0.5 cm^2 punches symmetrically taken out of each QMA
200 filter), whereas, for C and F sizes, due to the geometry of the spots at the surface of the filters,
201 samples are divided into equivalent parts (1/2 or 1/4 of 47 mm filters, rest of the filters being
202 used for carbonaceous analysis). The extraction protocol consists of 16h soaking under soft
203 shaking in an Erlen-Meyer containing 20mL of ultra-pure water. Prior to WSOC analysis, water
204 extracts are filtered through Teflon (PTFE) filters (0.2 μm pore size diameter) in order to remove
205 any suspended particle. Measurement uncertainty, given by the manufacturer, is of the order of
206 7%. The overall calculated blank value is of the order of $2.27 \pm 0.33 \mu\text{gC}\cdot\text{cm}^{-2}$, which represents
207 $16.4 \pm 8.5\%$ of the mean WSOC content. For each sample, duplicate analyses show a good
208 reproducibility.

209 **2.3.4. Water-soluble ionic species**

210 Water-soluble ionic species (Na^+ , NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , SO_4^{2-} , NO_3^- and Cl^-) are
211 analyzed using ion chromatograph (IC), following the analytical protocol described in Adon et
212 al. (2010). Briefly, the aerosol water-soluble fraction is first extracted from half-sampled Teflon
213 filter (the other part being used for trace element analysis), with a 10-min sonication in plastic
214 vials including 6 ml or 10 ml of purified water with a controlled resistivity of 18.2M Ω . Then
215 these vials are subjected to ionic chromatograph analysis or stored at +4°C if not analyzed
216 immediately. Cations are analyzed with Dionex DX-100 and anions with Dionex DX-500 with

217 a detection limit of 1 to 6 ppb depending on ionic species. Uncertainties in the range of 1-50%
218 is found depending on ionic species.

219 **2.3.5. Trace elements**

220 The protocol to measure trace element concentrations is developed and performed at the
221 Laboratory of Environmental Geosciences of Toulouse. Half-sampled Teflon filters (the other
222 part being used for water-soluble ionic species, see below) are mineralized by acid digestion
223 with a 10 ml concentrated HNO₃ and 0.5 ml HF solution (Lamaison, 2006) using a closed vessel
224 microwave accelerated reaction system (MARS 5, CEM Corporation) at high pressure (700 psi)
225 (Celo et al. 2010). The digestion is realized in 3 steps: a rise in temperature at 130°C in 3min
226 and holding for 1 min, then, a second rise at 160°C in 1 min and holding for 30 seconds and
227 finally a third rise to 180°C in 1 min and holding for 3min. After a 12 h cooling period, the
228 solutions are evaporated at 80°C, and concentrated in 7 ml of 2% concentrated HNO₃ solution,
229 before analysis by ICP-MS which are performed with a 7500 ce Agilent Technologies
230 instrument equipped with a collision cell, and using In and Re as internal standards. The
231 detection limit is less than 10 ppt. For all the samples, the final blank values and detection limit
232 on filters are taken into account for final concentrations calculations. 13 trace metals are
233 considered in this work: Al, Ti, Cr, Mn, Fe, Ni, Cu, Zn, Ba, La, Th, Pb and Cd.

234 **2.3.6. Dust calculation**

235 Many methods can be used to quantify dust concentrations. We have selected three
236 methods (Sciare et al. 2005, Guinot et al. 2007, Terzi et al. 2010) to underline the uncertainties
237 linked to dust estimates.

238 (1) Sciare et al. (2005) method consists of using soluble calcium data obtained with Ionic
239 Chromatography (IC), to estimate the dust concentrations following the relationship:
240 $\text{dust} = 10.96 * \text{nss-Ca}^{2+}$, where $\text{nss-Ca}^{2+} (=1.02 * \text{Ca}^{2+} - 0.038 * \text{Na}^+)$ refers to non-sea-salt
241 calcium concentration.

242 (2) Guinot et al. (2007) method is based on a chemical closure where fine and coarse
243 particle aerosols are separated in 4 components (EC, POM, WSI and dust). EC, WSI,
244 and total aerosol mass are directly experimentally determined (see below paragraphs).
245 POM concentrations are obtained from OC concentrations experimentally determined
246 and k, the OC/POM conversion factor. Dust concentrations are obtained from measured
247 Ca^{2+} concentrations and f, the abundance of calcium in dust. The k and f values are
248 obtained from a linear regression (L) between the reconstructed and the weighed aerosol

249 mass concentrations. Briefly, first step consists of focusing on the aerosol coarse
 250 fraction. k is fixed to 1.8 and as a result of (L) just mentioned, f is obtained to be in the
 251 range of 0.012 to 0.15 depending on our sites. Second step deals with the aerosol fine
 252 fraction. The f values just obtained for the aerosol coarse fraction are applied to the fine
 253 fraction and k ratios are estimated using (L) to be in the range of 1.2 to 2.1. Note that at
 254 all of our sites, the correlation between Ca^{2+} and the missing mass between the weighed
 255 and the reconstructed aerosol mass is sufficiently good ($r^2=0.9$) to support the
 256 consistency of this simple approach for the evaluation of dust. Also, f and k values are
 257 included in the range of values provided in the literature (He et al. 2001; Sun et al. 2004;
 258 Guinot et al. 2007). However, it is important to mention that the range of f and k
 259 coefficients are large which is due to the source mixing observed in this study.

260 (3) In Terzi et al. (2010) method, dust is obtained with the following relationship: dust =
 261 $1.89[\text{Al}] + 1.21[\text{K}] + 1.95[\text{Ca}] + 1.66[\text{Mg}] + 1.7 [\text{Ti}] + 2.14[\text{Si}] + 1.42[\text{Fe}]$. In our study,
 262 all these elements are determined except Silica (Si). Consequently, we used mean Si
 263 values obtained from different relationships available in the literature ($\text{SiO}_2 = 3*\text{Al}_2\text{O}_3$
 264 for Alastuey et al., 2005, $\text{Si} = 4.0*\text{Al}$ for Zhang et al., 2003 and $\text{Si} = 2.03*\text{Al}$ for
 265 Chiapello et al., 1997).

266 The results of dust concentrations estimated from the three methodologies above described are
 267 summarized in the Table 1 for wet season (WS) 2016 and dry season (DS) 2017. Indeed, Ca,
 268 Al, and Fe concentrations measured by ICP-MS are only available in WS2016 and DS2017 due
 269 to experimental problems, whereas Ca^{2+} concentrations measured by IC are available for all
 270 campaigns. As shown in table 1, the dust obtained from Ca^{2+} measured by IC (Sciare et al.,
 271 2005) and by the Guinot et al. (2007) method is lower than that obtained from trace elements
 272 (Terzi et al., 2010) for DS2017 whereas in the same order of magnitude in WS2016. Such
 273 results are in agreement with methodological aspects. Indeed, Al, Fe, Ca ... obtained by ICP-
 274 MS include both soluble and insoluble particles whereas Ca^{2+} measured by IC only include
 275 soluble particles. During the dry season, comparison of Ca measured by ICP-MS (not shown
 276 here) is higher than that of the IC, by a factor of 1.7, 1.8, 2.2 and 1.1, at the ADF, AWB, AT,
 277 and CT sites respectively. By contrast, this factor is low and constant (1.3) in the wet season
 278 for all the sites. In our study, due to the lack of trace element data for WS2015 and DS2016,
 279 dust estimations are performed from Guinot et al. (2007) method. This choice globally implies
 280 an underestimate of dust concentrations by a factor of 1.5 to  in DS2017.

281

282 **2.3.7. Aerosol chemical closure methodology**

283 As previously mentioned and detailed, aerosol chemical closure is performed following
284 the Guinot et al. (2007) methodology.

285

286 **2.4. Meteorological conditions**

287 In Figure 4, meteorological data (surface temperature, wind directions and speed) issued
288 from the NOAA Integrated Surface database (ISD; see [https:// www.ncdc.noaa.gov/isd](https://www.ncdc.noaa.gov/isd)) and the
289 ASECNA (Agence pour la Sécurité de la Navigation Aérienne en Afrique et à Madagascar) are
290 presented for the South-West Africa region including Abidjan and Cotonou. As expected, this
291 area is under the influence of the Convergence Zone of two air masses of a different nature, i.e.
292 Harmattan (hot and dry continental trade winds) from the north and Monsoon (humid maritime
293 trade winds) from the south (Figure 4). Ground contact between these two air masses constitutes
294 the intertropical front (ITF) of which the fluctuations during the year determine the seasons in
295 the Gulf of Guinea (Tapsoba, 1997). During the dry season (from November to March),
296 temperatures are relatively high with maximum around 30°C on the coast. The humidity is low,
297 since the prevailing Harmattan wind blows from the desert, usually bringing dust (Figure 4,
298 lower line). The period from June to September, especially in July is the wet season period
299 when daytime temperatures are slightly lower, with maximum around 26/28°C on the coast
300 (Figure 4, upper line). At this season, the humidity level is high across the region. On the coast,
301 rains may occur from March to November.

302 During our campaigns (not shown here), temperatures are roughly the same at Abidjan and
303 Cotonou, reaching 28°C and 26°C in the dry and wet seasons, respectively. Gentle to moderate
304 wind speeds are observed during the measurement campaigns at the two cities, with average
305 values of 15-20 and 15-22 km.h⁻¹ at Abidjan and Cotonou, respectively. There is no
306 precipitation at CT site during the studied periods. In Abidjan on the contrary, low rains occur
307 both in wet and dry periods with cumulative precipitation higher in DS2017 (7mm), than in
308 WS2016 (4.7mm) and WS2015 (2mm). There is no rain in DS2016 ([https://www.historique-
309 meteo.net/afrique/](https://www.historique-meteo.net/afrique/)).

310 **2.5. Backward trajectories**

311 The Hybrid Single-Particle Lagrangian Integrated Trajectory (HYSPLIT) modelling
312 system (Air resources laboratory, Draxler and Rolph, 2012) is used for the trajectory analysis.
313 HYSPLIT model is run to compute 120 h back trajectories ending at Abidjan and Cotonou at

314 50 m a.g.l. (Figure 5). Global Data Assimilation System reanalysis database is used as
 315 meteorological input, with a 0.25×0.25 degrees horizontal resolution. Results presented in
 316 Figure 5, confirm that air masses mainly come from the north with a few from the south-west
 317 in January, whereas from the south-west and the south in July. Therefore, in January, Abidjan
 318 and Cotonou are mainly impacted by polluted air masses from surrounding areas and northern
 319 countries with possible dust and west African biomass burning influences, whereas in July, the
 320 impact of oceanic sources and of long-range southern African biomass burning may be observed.

321

322 3. Results

323 3.1. Aerosol size distribution and mass concentration

324 In Figure 6, the relative mass distribution of PM for Coarse (C), Fine (F) and Ultra-Fine
 325 (UF) particle sizes in percentages are presented with bulk mass concentration averages
 326 indicated in the black boxes for each site and for each campaign. As it may be seen, bulk
 327 concentrations vary widely from site to site and from campaign to campaign. During the wet
 328 season, the average total concentrations range from 82 to 676 $\mu\text{g.m}^{-3}$ in 2015 and 56 to 358
 329 $\mu\text{g.m}^{-3}$ in 2016, with the maximum at the Abidjan Domestic Fire (ADF) site. While during the
 330 dry season, values range from 168 to 269 $\mu\text{g.m}^{-3}$ in 2016 and from 114 to 559 $\mu\text{g.m}^{-3}$ in 2017,
 331 with maximum concentration obtained at the Cotonou Traffic (CT) and ADF sites. In terms of
 332 size distribution, concentration peaks may be observed for all aerosol size-fractions which are
 333 found to exhibit different seasonal patterns. UF particles ($<0.2 \mu\text{m}$) represent the highest
 334 contributor to the bulk mass at the ADF site, by up to 60 % (335.3 $\mu\text{g.m}^{-3}$) in DS2017. F particles
 335 (1-0.2 μm) are the second most important contributor and both combined particle sizes account
 336 for more than 85 % of the total mass at the ADF site. In this site, ultra-fine and fine fractions
 337 are also found to be maximum during WS2015 and WS2016 by up to 90 and 83%, respectively.
 338 Let us note that C particle contribution in bulk is relatively higher in the traffic and waste
 339 burning sites than in ADF site (40%) whereas F and UF particle contributions are on the order
 340 of 60%.

341 In terms of $\text{PM}_{2.5}$, the results of this work are presented in Figure 7. The mass
 342 concentration of $\text{PM}_{2.5}$ averaged over DS2016 and DS2017 are $154 \pm 144 \pm 42$, 134 ± 7
 343 and $211 \pm 51 \mu\text{g.m}^{-3}$ at the ADF, AWB, AT and CT sites, respectively and 338 ± 24 , 45 ± 3 , 52
 344 ± 4 and $70 \pm 1 \mu\text{g.m}^{-3}$ over the wet seasons (2015-2016). The increase in $\text{PM}_{2.5}$ is of the order

345 of 54% at ADF from dry to wet season, whereas a sharp reduction (more than 60%) is obtained
346 at AWB, AT, and CT sites.

347 **3.2. Carbonaceous aerosol**

348 **3.2.1. EC and OC concentrations**

349 In Figure 8, EC relative mass contributions are presented for each size, site and
350 campaign: wet season 2015 (WS2015), wet season 2016 (WS2016), dry season 2016 (DS2016)
351 and dry season 2017 (DS2017). Mean EC bulk mass concentrations are added in the black boxes
352 for each size and for each campaign. The most striking feature is that the ADF site
353 concentrations are higher than at the other sites in WS2016 and in DS2017, whereas of the same
354 order of CT site concentrations in the other seasons. Mean concentration at the CT site ($16\mu\text{g}\cdot\text{m}^{-3}$)
355 is slightly higher than at the AT site ($10\mu\text{g}\cdot\text{m}^{-3}$), whereas the lowest concentrations are found
356 at the AWB site. Results of the EC size distribution are very consistent among the different
357 sites (Figure 8). Whatever the site and the season, higher EC concentrations are found in C
358 (42%) and UF (43%) particles compared to F particles.

359 Same data are presented for OC concentrations in Figure 9. It may be underlined that
360 ADF OC values are always higher than in the other sites by a factor ranging from 6 to 30, for
361 all seasons and particle sizes, with highest and lowest values respectively in DS2017 and DS
362 2016. In terms of size distribution, maximum OC concentrations at the ADF site may be found
363 in UF (53%), then F (29%) and finally C (18%) particles. The same distribution is observed for
364 the traffic sites in DS2016, however, for the other campaigns, OC size distribution looks like
365 the EC ones with higher concentrations in UF and C particles than in F particles.

366 As shown in Figure 10, the highest OC/EC ratios are always obtained at the ADF site
367 with a value as high as 25 for F particles in WS2016 whereas the lowest values are found in
368 DS2017. This is the same feature for the other sites with ratios lower than 2 in DS2017. OC/EC
369 ratios in AWB site are higher than in the traffic sites. Note that values at AT site are higher than
370 CT values in the wet season whereas lower in the dry season. Finally, it is interesting to
371 underline that linear correlations between EC and OC are obtained in the ultrafine and fine
372 modes in all campaigns, particularly in DS2017 ($r^2 = 0.8, 0.8, 0.9$ and 0.9) at the ADF, AWB,
373 AT and CT sites, respectively. This suggests that different studied sources can be assessed as
374 significant sources of both EC and OC.

375

376 **3.2.2. Water-Soluble Organic Carbon**

377 Concentrations of WSOC and WSOC/OC ratios are presented in Table 2 for each size
378 (UF, F, C and PM_{2.5}) and campaign. As seen, WSOC are always higher at the ADF site than in
379 other sites, at least by a factor of 12. Maximum values are obtained in WS2016 with an average
380 of 16.47, 17.08 and 79.68 $\mu\text{gC}\cdot\text{m}^{-3}$ for coarse, fine and ultra-fine fractions, respectively,
381 followed by WS2015 and DS2017. WSOC concentrations are the lowest in DS2016, with an
382 average of 4.14, 6.95 and 21.89 $\mu\text{g}\cdot\text{m}^{-3}$ for coarse, fine and ultrafine fractions, respectively. In
383 terms of seasonality, there is not a clear trend in WSOC values at the AWB and AT sites,
384 whereas at the CT and ADF sites, WSOC values are found to be respectively higher and lower
385 in dry seasons compared to wet seasons. It is also interesting to note that WSOC are maximum
386 in UF sizes in the AT, ADF and AWB sites. At the CT site, the highest values are found in the
387 coarse particulate fractions, except in DS2016.

388 As expected, WSOC is strongly correlated with OC ($r=0.7$ at ADF, 0.8 at AT, 0.5 at
389 AWB and 0.7 at CT), whereas correlations with EC are weaker, especially at the AWB and CT
390 sites with values ranging from 0.1 to 0.4 , respectively. Finally, when looking at WSOC/OC
391 ratios (Table 2), maximum values are obtained at the ADF site with PM_{2.5} ratios as high as
392 43%, followed by the AT and AWB sites with 32%. The lowest value (23%) is found at the CT
393 site. Also, Table 2 shows that there is no clear seasonality in WSOC/OC values, excepted at
394 ADF where maximum values occur during the wet season. Note as for WSOC, that ratios are
395 maximum in UF and F fractions for all sites except at the CT site where the ratio for coarse
396 fraction is the highest.

397 **3.3. Water-soluble ionic species**

398 Figure 11 shows the relative contribution of the major ions to the total concentration
399 (also given) of the ions in the different particle modes (C and F) at the ADF, AWB, AT and CT
400 sites for the different measurement campaigns. Let us recall here that only C and F fractions
401 may be documented due to the our experimental protocol. Total concentrations present
402 maximum values in ADF and CT sites. Values in AWB and AT sites are of the same order of
403 magnitude and lower by a factor of 2 than in ADF and CT sites. The contribution of different
404 ions show significant variations from site to site. The dominant ionic species at the ADF site
405 over all campaigns is chloride (Cl^-), with a 26% contribution, followed by nitrate (NO_3^-) (16%),
406 calcium (Ca^{2+}) (13%) and potassium (K^{2+}) (12%). Sulfate (SO_4^{2-}), ammonium (NH_4^+), sodium

407 (Na⁺) and to a lesser extent magnesium (Mg²⁺) contributions are lower, ranging from 4 to 7%
 408 of the total ion species. The lowest contribution is for organic acids with their total value lower
 409 than 5%. NO₃⁻ is the major ionic component at the AWB and AT sites, representing 24% and
 410 29% of the total water soluble inorganic concentration, respectively. The second major
 411 contributor in AWB and AT is SO₄²⁻, accounting for 21% and 17% of the ion mass, respectively
 412 followed by Ca²⁺ (12% and 15%) and Cl⁻ (15% and 13%). In CT, Ca²⁺ is predominant with a
 413 relative abundance of 24%, followed by NO₃⁻ (23%), SO₄²⁻ (19%) and Cl⁻ (13%). Na⁺, NH₄⁺
 414 and K⁺ contributions are lower and in the same order of magnitude in AT, AWB and CT sites,
 415 ranging from 4 to 9% of the total ion species. Note that organic gases contributions at AT, CT
 416 and AWB is of the same order than in ADF, with lower values at CT. It is interesting to
 417 underline in the Figure 11, that NO₃⁻ contribution is always higher in the coarse than in the fine
 418 size. Conversely, K⁺ is always higher in the fine than in the coarse size. In CT, Ca²⁺ in the fine
 419 fraction is as high as in the coarse fraction whereas in AT, AWB and ADF, Ca²⁺ coarse fraction
 420 is predominant. Fine particle contribution may be noticed for Cl⁻ in ADF whereas in the other
 421 sites, Cl⁻ is most likely dominated by coarse particles. Finally, SO₄²⁻ is mainly found in the fine
 422 mode at the AT, AWB and CT sites, but in the coarse mode in ADF site.

423 In terms of seasonal variations, it may be shown in Figure 11 that higher Cl⁻ values are found
 424 in wet seasons than in the dry seasons everywhere, except in ADF site where there is no marked
 425 difference between seasons. For example, the mean relative total percentages of Cl⁻ at the CT
 426 site are 38 and 24% in the WS2015 and WS2016, respectively, while these percentages decrease
 427 significantly to 18 and 13% in the DS2016 and DS2017, respectively. The Cl⁻/Na⁺ ratios are
 428 about 1.5 everywhere in both seasons, in agreement with the typical sea water ratio (1-1.2)
 429 (Hara et al.,2004), except at the ADF site where these ratios increase to 4 and 5 in wet and dry
 430 season, respectively and at the AWB site in the dry season (2). K⁺ and Ca²⁺ are always higher
 431 in dry season than in wet season except for Ca²⁺ in ADF where values are of the same order.
 432 Finally, the same trend is observed for NO₃⁻ and SO₄²⁻ with higher values in dry than in wet
 433 seasons at AWB and CT sites whereas values at ADF and AT sites are of the same order of
 434 magnitude for the two seasons.

435 3.4. Trace element concentrations

436 Table 3 shows the mean values of the major trace elements in bulk aerosol at the
 437 different studied sites in WS2016 and DS2017, with their corresponding relative abundances in
 438 the total aerosol mass into brackets. Let us recall that data are not available in WS2015 and
 439 DS2016. The concentrations of trace elements span a wide range, from 0.2 to 25.2 µg.m⁻³.

440 Among the measured elements, Al, K, Na and Ca are the most abundant, followed by Fe and
 441 Mg. In DS2017, Al and Na concentrations are higher in AWB than in the other sites. The
 442 minimum value for these species is found in ADF site. Values in traffic sites are of the same
 443 order of magnitude and higher than in ADF site. Maximum of Ca and K values may be found
 444 in CT and ADF site respectively. It is interesting to note that Al, K, Na concentrations are higher
 445 in the dry season than in the wet season. Such feature is less clear for Ca, whose seasonal
 446 variability is less marked except in AWB and AT sites. In terms of Mg, maximum values are
 447 observed in ADF site and of the same order of magnitude whatever the season. Fe abundance
 448 is higher in AWB and CT sites than in ADF and AT sites and higher in DS2017 than in WS2016
 449 everywhere. The other metals (Ti, P, Zr, Zn, Cr, Mn, Pb and Ni) represent less than 0.5% and
 450 2% of the total mass in WS2016 and DS2017, respectively, at all sites, with Cr, Mn, Pb and Ni
 451 exhibiting less seasonal variability compared to the rest of the metal elements.

452 To assess the relative contribution of crustal and non-crustal origin of elemental aerosol
 453 loadings, source enrichment factor (EF) of a trace element X have been first calculated with the
 454 following formula using both literature data of the typical elemental composition of the upper
 455 continental crust (Mason and Moore, 1982; Taylor, 1964), measured elemental composition
 456 from this study and Al as a reference element :

$$457 \quad EF_X = \frac{\frac{[X]_{atm}}{[Al]_{atm}}}{\frac{[X]_{soil}}{[Al]_{soil}}}$$

458 Where $[X]_{atm}$ and $[Al]_{atm}$ are the concentrations of the chemical element X and Al in the
 459 atmosphere, respectively, and $[X]_{soil}$ and $[Al]_{soil}$ are the typical concentrations of the element
 460 X and Al in the earth's crust, respectively. Al is frequently used as a reference element assuming
 461 that its anthropogenic sources in the atmosphere are negligible (Gao et al., 2002; Cao et al.,
 462 2005; Xu et al., 2012). In all sampling sites, EF values typically lower than 5 are obtained for
 463 several trace elements (Be, Sc, Ti, V, Fe, Ga, Sr, Nb, Rh, Ba, La, Ce, Pr, Nd, Sm, Eu, Gd, Tb,
 464 Dy, Ho, Er, Tm, Yb, Lu, Ta, Th and U). This suggests a natural origin of these species (Freitas
 465 et al., 2007; Gao et al., 2002). The most enriched elements ($EF > 100$) are Sb, Sn, Zn, Se, Te,
 466 Cd, Pb, Bi and Mo at nearly all of the sites, indicating significant anthropogenic origin (Wang
 467 et al., 2006). These elements are mainly emitted into the atmosphere through fossil fuel
 468 combustion, traffic emission, wear of brake lining materials and industrial processes (Watson
 469 and Chow, 2001; Samara and al., 2003). Secondly, source contributions have been estimated
 470 from these EF values following the method described by Arditsoglou and Samara (2005). Note
 471 that this study refers to ratios for a limited list of sources, perhaps not including the African

472 source specificities. As a result, it may be seen that 30% of trace element concentrations is of
473 anthropogenic origin at ADF site whereas about 17 % at the others sites.

474 3.5. Dust

475 Figure 12 shows dust concentrations calculated from Guinot et al. (2007) methodology
476 (see paragraph 2.3.6) for C and F particle sizes at the different sites for each season. Note that
477 as for WSI and trace element and due to our sampling procedure, there are values for fine and
478 coarse particles for all seasons excepted for WS2016 with values for coarse particles only.

479 During the wet season, coarse dust concentrations range from 5 to 25 $\mu\text{g.m}^{-3}$ in 2015 and 9 to
480 37 $\mu\text{g.m}^{-3}$ in 2016, with higher values at the CT and ADF sites in 2015 and at AT, CT and ADF
481 in 2016. In WS2015, fine dust concentrations range from 12 to 49 with maximum values at
482 ADF and CT sites also. During the dry season, values range from 38 to 156 $\mu\text{g.m}^{-3}$ in 2016 and
483 from 41 to 116 $\mu\text{g.m}^{-3}$ in 2017, with maximum concentrations obtained at the CT site, followed
484 by AWB site. When considering mean values of the dry seasons, total dust at Cotonou traffic
485 (CT) is 2.4 times the values found at AT, 1.6 times at AWB and 3.4 times at ADF. Seasonal
486 comparison shows that total dust concentration is higher in the dry seasons than in WS2015 by
487 a factor of 3 in AT, 2.6 in CT and 4 in AWB, but of the same order of magnitude in ADF site.

488 3.6. Aerosol chemical closure

489 The aerosol chemical closure obtained using the Guinot et al. (2007) method (see below)
490 at the different sites for each season is presented in Figure 13. Results show clear intra- and
491 inter-annual variations at all of the sites, as well as significant differences among the sites. In
492 total, dust accounts for 39 to 75% of the bulk PM mass at both traffic sites, with no clear
493 seasonal cycle and higher contributions in Cotonou (Figures 13c and 13d). These percentages
494 vary from 32 to 64% at the AWB site, and from 18 to 35% at the ADF site, with percentages
495 1.8 times higher in the dry season than in the wet season in AWB and no clear seasonal
496 difference in ADF (Figures 13a and 13b). Carbonaceous aerosol, the sum of EC and POM,
497 show large contributions at the ADF site (from 49 to 69% of the total PM mass), with relatively
498 similar proportions in each season (Figure 13a). The absence of a clear seasonal pattern is also
499 observed in CT whereas carbonaceous aerosol is slightly higher in WS than in DS in AWB (23
500 and 16% respectively) and AT (37 and 21% respectively) (Figures 13b-d). Carbonaceous
501 aerosol contribution accounts for about 11- 49% of the total mass at both traffic sites with higher
502 values in AT (mean of 30%) than in CT (13%). The ion percentages in PM fractions present
503 the same pattern at AT, CT and AWB sites with higher values in wet than in dry seasons. In

504 these sites, we may notice that coarse particles are larger in the wet season whereas of the same
505 order of magnitude than fine particles in the dry seasons. In ADF, no marked difference may
506 be found between the seasons and the sizes (Figure 13).

507

508 **4. Discussion**

509 A discussion of the results site by site (Abidjan domestic fire site, traffic sites both together and
510 waste burning site) will be first proposed. We will scrutinize (1) the proximity between the sites
511 and the sources; (2) the source specificity with more or less incomplete combustion (e.g. wood
512 combustion and two-wheel vehicle emission factors are higher than gasoline emission factors
513 (Keita et al., 2018); (3) the relative influence of other local sources or transported sources to
514 the studied sites such as dust and biomass burning; (4) the occurrence of continental air masses;
515 (5) the variation of the boundary layer height (as reported by Colette et al., 2007); and (6) the
516 meteorological parameters (e.g. temperature, relative humidity and wet deposition) to explain
517 the differences of pollutant concentrations and their seasonal and inter-annual variabilities.

518 In a second part, we will present comparison of our values with other DACCIWA values and
519 also with literature values for other intensive campaigns in Africa.

520

521 **4.1. Abidjan Domestic Fires (ADF)**

522 As shown in the above paragraphs, maximum values are obtained at the ADF site, for aerosol
523 mass, EC, OC, WSOC, water-soluble ionic species (e.g. Cl^- , NO_3^- , Ca^{2+} and K^+) and some trace
524 elements such as Mg and K (whereas Al, Na and Fe are lower than in the other sites). Also,
525 aerosol $\text{PM}_{2.5}$ values are well above the annual and daily WHO guidelines of 25 and 10 $\mu\text{g}\cdot\text{m}^{-3}$
526 respectively, whatever the season.

527 Such pattern is due to the proximity of the ADF site to the studied combustion source: in that
528 area, the use of wood combustion is very active due to commercial activities of women drying
529 fish and meat and domestic cooking. This is also confirmed by the high relative importance of
530 total carbon in aerosol mass whatever the size (49 to 69%) and by values of source enrichment
531 factor. Indeed, at least 30% of trace element concentrations are of anthropogenic origin at ADF
532 site. In addition, wood combustion is well known to be highly pollutant due to incomplete
533 combustion: this is shown here by the measurements of very high OC/EC ratios at ADF, on the
534 order of the one measured at the source level by Keita et al. (2018). This is also shown by
535 WSOC relative importance which is expected for wood burning following Yu et al. (2018),

536 Tang et al. (2016), Feng (2006) and Saxena and Hildemann (1996) and by the strong correlation
537 of WSOC with biomass burning K^+ tracer.

538 Chloride is most likely associated with sea salt origin (55% of total composition of the sea
539 water) or secondary aerosol production (Li et al., 2016). Its high concentration at the ADF site
540 remains lower than the typical concentration in sea-water suggesting a secondary production
541 source. The size distributions of Cl^- , K^+ , NH_4^+ and SO_4^{2-} support the conclusion that the
542 predominance of these elements in fine particle mode at the ADF site could be associated with
543 anthropogenic emissions, particularly biomass combustion and domestic fires, or with
544 secondary inorganic aerosols origin. This is confirmed by Cl^-/Na^+ ratio values as shown earlier.
545 Contrarily, Ca^{2+} and NO_3^- contributions to the total ions at the ADF site peak mainly in the large
546 particle fraction and may be attributed to quasi natural origin, primarily to dust emissions and
547 nitrate formation by reaction processes, respectively. In addition, Na^+ and Mg^{2+} display similar
548 size distributions at the ADF site, with the major contribution in the coarse particle fraction,
549 suggesting the common sea salt origin of these two elements (Belis et al., 2013).

550 As we have shown above, the lower proportion of metal elements at the ADF site (6.5% of the
551 bulk concentration) can be explained by the less dominant influence of re-suspended dust
552 particles compared to traffic sources. Elements such as Cr, Mn, Pb and Ni have less seasonal
553 variability than other metallic elements. These small proportions of these non-crust elements
554 suggest a low contribution of elements emitted mainly by anthropogenic activities such as
555 industrial processes (Viana et al., 2007 and 2008; Minguillón et al., 2014). Finally, the Zn/Cd
556 ratio has been also examined. A value of 29 close to ratio reported for gasoline vehicle (27, Qin
557 et al., 1997) is obtained for the ADF site, indicating that this site is also impacted by traffic
558 sources.

559 High values of WSOC/OC ratios are expected to be harmful to health (Ramgolam et al., 2009,
560 Val et al., 2013). This effect is being enhanced by the particulate size measured at this site (Kim
561 et al., 2003; Wilson et al., 2002). Indeed, the relative mass distribution of PM and OC particle
562 sizes shows a major contribution of particles less than $1 \mu m$ (as high as 85% for PM). This
563 could be due to the fact that carbonaceous aerosols are formed near emission sources and are
564 mainly of submicron size (Boucher, 2012). Note that EC also presents large coarse particle
565 contribution.

566 In terms of seasonality, higher concentrations of aerosol mass, OC, WSOC, EC and total water
567 soluble ionic species (SO_4^{2-} , NH_4^+ and NO_3^-) are observed in WS2015 and WS2016 than in
568 DS2016. This may be explained by a more incomplete combustion in the wet seasons than in
569 DS2016 due to the use of moist wood for cooking and smoking fish, which leads to large

570 amount of smoke and higher particulate emission factor values. Note that DS2017 values are
571 as important as the ones of wet seasons, which will be explained later in the text. With regard
572 to WSOC, their variabilities may be also linked to meteorological factors, such as solar radiation
573 (Tang et al., 2016; Favez et al., 2008) and relative humidity (Liang et al., 2016). At ADF site,
574 temperatures are roughly similar in both seasons. However, RH variability may play a role since
575 it is higher in wet season than in dry season. Finally, our results indicate no clear seasonal cycle
576 for Cl^- , which confirms its anthropogenic origin, as previously shown.

577

578 **4.2. Traffic sites (Abidjan traffic and Cotonou Traffic sites)**

579 Let us recall first that the two traffic sites have been chosen since they are representative of the
580 traffic diversity in West Africa. At CT site, both personal cars, taxis and an important two-
581 wheel fleet may be found whereas at AT site, there are buses, taxis and personal cars. Also, the
582 distance between the site and the traffic sources is the same for the two traffic sites, slightly
583 larger than the distance between the site and the wood burning sources at ADF site.

584 In these two sites, concentrations are high with $\text{PM}_{2.5}$ values well above the WHO guidelines.
585 Average aerosol mass, EC, OC, dust and water soluble ionic concentrations (with NO_3^- and
586 Ca^{2+} maximum at AT and CT sites respectively) are higher at CT than at AT site by a factor of
587 1.5 to 2. Note that this poor air quality found in Cotonou has been reported by Cachon et al.
588 (2014). The higher values found in Cotonou could be due to more intense traffic in Cotonou
589 than in Abidjan. Also in Cotonou, this traffic is associated with the lack of public transportation
590 and the use of highly polluted mopeds (aged over 15 years) (Gounougbe, 1999; Avogbe et al.,
591 2011), despite the effort in the last 10 years to restrict their use. Several studies such as MMEH
592 (2002) have shown that more than 94,000 mopeds and 350,000 second-hand vehicles are in
593 circulation in Cotonou. Other factors contributing to the local pollution include outdoor
594 restaurants using charcoal and motorcycle garages, which are more present around the Cotonou
595 traffic site compared to Abidjan site. It also includes anthropogenic dust. Indeed, at Cotonou,
596 the lack of road infrastructure favours the resuspension of dust particles. Finally, other sources
597 may potentially influence aerosol seasonal composition in these two sites, including marine
598 aerosols, transported dust and biomass burning particles as well as anthropogenic aerosols from
599 the surrounding countries (Figure 5). Note also that source enrichment factor values show that
600 about 17% of trace element concentrations are of anthropogenic origin at both traffic sites and
601 that the relative importance of total carbon in mass is higher at AT than at CT sites. As a
602 consequence, aerosol mass, composition and size depend on the season and the two traffic sites
603 are differently affected.

604 The EC and OC concentrations measured in both traffic sites, are higher in dry than in wet
605 season. Such variations may be explained by several factors: particulate wet deposition
606 occurring during the wet season, reduction of traffic flow due to school vacations and
607 meteorological influence. Higher EC concentrations are obtained at CT than at AT sites at both
608 seasons. Similar pattern is observed for OC in dry season. In contrast, lower values are obtained
609 at CT than at AT sites in wet season. Differences between OC values in wet season between
610 the two sites can be due to the influence of long-range transport of biomass burning aerosols
611 coming from Southern Africa, which could be more important in Abidjan than in Cotonou, as
612 shown by the backtrajectory patterns given in Figure 5. On the contrary, in the dry season,
613 higher OC values at Cotonou may be explained by local sources as already detailed, but also
614 by surrounding sources such as Niamey in anthropogenic and biomass burning sources (Figure
615 5).

616 In terms of WSOC concentrations, concentrations at the AT site are on average higher than
617 those recorded at the CT site in the wet season, but lower in dry season. The presence of dust
618 can produce semi-volatile organic gas scavenging and therefore WSOC and OC enhancement.
619 Such a phenomenon can explain the highest WSOC concentrations observed in dry season at
620 the CT site where dust concentrations are highest (see dust paragraph). Moreover, this can also
621 explain why the maximum WSOC are in coarse particles at CT, while at AT maximum values
622 are in ultra-fine particles.

623 Total WSI concentrations are larger at AT site in the wet than in the dry season with higher
624 values in coarse particles. At CT site, total WSI concentrations in fine particles are higher in
625 the dry than in the wet season whereas same values are obtained in coarse particles for both
626 seasons. Note that CT values are generally higher than AT values with a more important
627 contribution of fine particles in the dry season. These WSI variations can be explained by the
628 relative importance of Ca^{2+} , SO_4^{2-} and NO_3^- in both sites.

629 First, Ca^{2+} contribution to total WSI is higher in CT site than in AT site with no clear seasonal
630 variation at CT site and higher values in dry season than in wet season at AT site. Also at CT,
631 fine and coarse Ca^{2+} particles are in the same range, whereas coarse Ca^{2+} particles are
632 predominant at AT site. Such feature may be explained by the impact of dust sources including
633 long-range dust transport at Abidjan and a combination of long-range dust transport and road
634 resuspension at Cotonou.

635 Second, the relative contribution of SO_4^{2-} , NH_4^+ and NO_3^- as a percentage of total WSI in the
636 different particle modes is reduced in the wet season. During the wet season, the clean winds
637 surrounding the ocean before reaching the measurement sites could contribute to lower the

638 proportion of these species, in addition to the scavenging processes during the rainy days.
639 Unlike the wet season, a relatively good correlation of 0.87 (SO_4^{2-} versus NH_4^+), 0.73 (NO_3^-
640 versus NH_4^+) and 0.87 (SO_4^{2-} versus NO_3^-) has been found in coarse particles, indicating similar
641 sources for these three species during the dry season. In order to try to identify these sources,
642 the ratio of $\text{SO}_4^{2-}/\text{Ca}^{2+}$ and $\text{NO}_3^-/\text{Ca}^{2+}$ has been determined. The average $\text{SO}_4^{2-}/\text{Ca}^{2+}$ and
643 $\text{NO}_3^-/\text{Ca}^{2+}$ ratios in combined coarse particles (1.07 and 2.58 during the wet season and 0.33 and
644 1.60 during the dry season) are higher than the corresponding ratios for typical soil (0.026 and
645 0.003, respectively). On the other hand, the $\text{SO}_4^{2-}/\text{Ca}^{2+}$ ratio increases in the fine particles (5.07
646 during the wet season and 2.53 during the dry season), while that of $\text{NO}_3^-/\text{Ca}^{2+}$ remains almost
647 constant (2.86 during the wet season and 1.65 during the dry season). This implies that the
648 atmosphere at AT and CT sites is enriched by SO_4^{2-} formed as anthropogenic secondary
649 particles, possibly from sulfur containing pollution sources (Seinfeld and Pandis, 1998),
650 particularly in fine particle mode, and by NO_3^- mostly coming from nitrogen containing sources
651 in all particle sizes. The higher contributions of these elements during the dry season could
652 result from a combination of several factors: 1) an atmosphere loaded with dust favoring
653 heterogeneous chemistry to obtain secondary aerosol and the rise of biomass burning emissions;
654 2) the increase of photochemical activity and higher concentrations of hydroxyl radicals in the
655 dry season, which can oxidize SO_2 from combustion (Arndt et al., 1997) to SO_4^{2-} (Li et al.,
656 2014) ; and 3) the wind transport of anthropogenic secondary particles from the industrial zone
657 located upstream from our sites. Finally, the proportion of Cl^- relative to the total mass of ions
658 is highest for coarse particles at both traffic sites especially during the wet season, suggesting
659 that Cl^- at AT and CT sites is from natural origin and probably from sea salt emissions.

660 If we focus now on dust during the two wet seasons, concentrations are higher in 2016 than in
661 2015 at CT and AT sites for coarse particles (no data of fine particles are available in WS2016).
662 This is consistent with observed aerosol optical depth (AOD) values at CT, which increased by
663 a factor of 2 between 2015 and 2016. No AOD value is given by Léon et al. (2019) at Abidjan
664 in WS2015 to allow such comparison in Abidjan. Moreover, during the wet season, an
665 Angström coefficient (AE) on the order of 1 has been found at CT site, indicating smaller
666 particles that could be due to road resuspension. It is interesting to note that during WS2016,
667 AOD and AE are respectively higher and lower at Abidjan than at Cotonou. Again, this is
668 consistent with our dust concentrations at CT site. In Abidjan, we could assume that another
669 source of Ca^{2+} , which is not taken into account in our dust calculations, may explain our dust
670 concentration data. That may be the result of anthropogenic Ca^{2+} emissions from residential

671 combustion, more important in 2016 than in 2015 as shown earlier
672 (http://naei.beis.gov.uk/overview/pollutants?pollutant_id=84).

673 The relative contribution of dust generally peaks in the coarse mode and, to a lesser extent, in
674 the fine mode, reflecting their natural origin. It is interesting to note that the dust contribution
675 observed in this study for the year 2016 at the Abidjan site is in agreement with the results of
676 Xu et al. (2019) which show a PM_{2.5} dust contribution of 35-50% compared to our values of
677 18-52%.

678

679 **4.3. Abidjan Waste Burning site**

680 Concentrations measured at AWB site are slightly lower than values found in the other sites.
681 This could be explained by the distance of the site to the studied source (here waste burning
682 source) which is more important than in the other sites. However, PM_{2.5} values are also higher
683 than WHO guidelines.

684 Aerosol mass, EC and OC concentrations are higher in dry than in wet season, which suggests
685 less waste burning activities during the wet season or impacts of other local anthropogenic
686 sources or long-range biomass burning sources. Highest values are found in DS2017 with the
687 lowest OC/EC ratio, as at AT site. OC/EC ratio is highly variable at AWB (1-10) which
688 confirms that AWB site may be impacted by different types of sources as well as by secondary
689 aerosol organic formation which can be detected for OC/EC higher than 2 (Turpin et al. 1990;
690 Hildermann et al. 1991; Chow et al. 1996). Note that OC/EC typical for waste burning source
691 is of the order of 8 (Keita et al., 2018).

692 It is also observed that at the AWB site, PM mass concentrations are mainly distributed in C
693 mode (30-44%) over the entire period of study, excepted during the WS2015, and to a lesser
694 extend in F mode (21-44%). EC and OC being mainly distributed in C and UF modes. Water-
695 soluble fraction of organic carbon is important (32%) and on the order of the one found at AT
696 site. Same for WSI concentrations and WSI composition. At AWB, WSI values are globally
697 slightly higher in wet than in dry season. However, it is interesting to underline that Ca²⁺ is
698 much higher in dry season than in wet season, especially in DS2017. This is in agreement with
699 dust concentrations and trace element concentrations, which have been found to be maximum
700 at AWB, reaching 35.8% of the total PM mass in the dry season. These maximum percentages
701 are due to the large contribution of both Al and Na crustal elements which account for about
702 26%. Also note that Cu/Sb of 0.08 in DS2017, which indicate an influence of re-suspended
703 particles. A Zn/Cd value of 56 is obtained for the AWB site which is in close agreement with

704 values reported for oil burning (Watson et al., 2001, Samara et al., 2003). That could indicate
705 that oil might be one of the waste burning materials.

706 Our result suggests that AWB aerosol mass is influenced by a mix of sources, including fuel
707 combustion and mineral salt from sources around the measurement site, associated to long-
708 range source impact of dust and biomass burning which will be further discussed in the next
709 paragraph.

710

711 **4.4. Interannual variability of aerosols in Abidjan and Cotonou**

712 EC and OC concentrations are generally higher in DS2017 than in DS2016 for all the sites. This
713 is not due to the meteorological condition, which is similar in both years. This is also not due
714 to biomass burning impacts. Indeed, when looking at MODIS burnt areas for our period of study
715 (<http://www.aeris-data.fr/redirect/MODIS-MCD64A1>), burnt areas of west African savannas
716 are higher in 2016 than in 2017. Therefore, carbonaceous aerosol concentrations should be
717 higher in 2016. Then, this could be due to a counter effect between biomass burning emission
718 strength and air mass transport efficiency. As a result, biomass burning impact could not explain
719 the difference in EC and OC during the dry season between 2016 and 2017. Rather, this is due
720 to the variability of local sources. In DS2016 in Abidjan, there was a general strike of civil
721 servants of the State with important consequences on urban activities. Lower activities were
722 observed (lower fish smoking emissions, lower traffic ..) in DS2016 compared to DS2017, thus
723 explaining the lower EC and OC concentrations at Abidjan sites. In Cotonou, highest
724 carbonaceous aerosol values in DS2017 may be explained by backtrajectory patterns: Cotonou
725 would be impacted by air masses coming from the high polluted Lagos (Nigeria) area in that
726 period whereas from less polluted northern areas in DS2016. Such an assumption is validated
727 by the AOD values at 550nm from MODIS satellite images ([http://www.aeris-](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)
728 [data.fr/redirect/MODIS-MCD64A1](http://www.aeris-data.fr/redirect/MODIS-MCD64A1)), which show very high particulate concentrations in the
729 Guinean Golf (Figure 14).

730 This figure also shows the AOD difference between Cotonou and Abidjan for DS2017, with
731 higher values at Cotonou than in Abidjan for the campaign period, in agreement with our
732 measurements of aerosol mass, EC, OC and dust. This is confirmed by the DACCIWA
733 sunphotometer AOD and Angström coefficient (AE) measurements at Abidjan and Cotonou
734 (Léon et al., 2019; Djossou et al., 2018). Indeed, in DS2017, during our period of
735 measurements, mean AOD in Cotonou is of the order of 1.3 versus 0.9 in Abidjan for an AE of
736 0.6 for both sites, which clearly indicates the presence of coarse dust particles.

737 Finally, aerosol mass and dust concentrations have been seen to be higher in DS2016 than in
738 DS2017 in Abidjan whereas values are on the same order of magnitude at Cotonou. Such high
739 values at Abidjan in DS2016 can be explained by the back-trajectory pattern with air-masses
740 all coming from northern dusty areas in DS2016 (Bodélé depression in Tchad, Prospero et al.
741 (2002), Washington et al., (2003), Knippertz et al. (2011), Balarabe et al., (2016)) and/or from
742 northern dusty countries (Mali, Niger) (Ozer, 2005), whereas in DS2017, contribution of
743 southern marine clean air-masses may also be noted.

744 In the wet season, aerosol mass, EC and OC are higher in WS2015 than in WS2016. This may
745 be due to particulate wet deposition, more efficient in WS2016 which have been seen earlier to
746 be more rainy (4.7mm) than in WS2015 (2mm). Moreover, at AT site, dust concentrations are
747 higher for coarse particles in WS2016 than in WS2015. Such variations may be explained by
748 long-range dust sources and/or road dust resuspension processes. As no dust event has been
749 noticed, local source explanation seems to be more evident.

750 Finally, in AT, CT and AWB, OC/EC ratios are globally on the same order for WS2015,
751 WS2016 and DS2016, with values similar to that of gasoline emissions or old diesel vehicles.
752 However, the ratios are lower for DS2017, with values typical of those of diesel emission
753 (Mmari et al., 2013; Keita et al., 2018). The general strike occurring in DS2016 in Abidjan
754 could explain such a difference. Indeed, more EC emissions occurred in DS2017 than in
755 DS2016 for constant OC emissions. This can be the result of more diesel traffic. Similar ratio
756 values have also been previously reported for other megacities such as Agra in India with 6.7
757 (Pachauri et al., 2013), Helsinki in Finland with 2.7 (Viidanoja, 2002), Cairo in Egypt with 2.9
758 (Favez, 2008), Paris in France with 3.5 (Favez, 2008), and Milan in Italy with 6.6 (Lonati et al.,
759 2007).

760 761 **4.5. Comparison with DACCIWA and literature measurements**

762 Firstly, the comparison between our data and other DACCIWA results including other time
763 sampling focuses on PM_{2.5} levels, since these particle sizes are relevant for health impact studies
764 (Xing et al., 2016). In addition to our values, Figure 7 presents data from Xu et al. (2019) using
765 personal samplers collected in the same area and at the same dates in 2016 during 12h on women
766 at the ADF site, students at the AWB site and drivers at the CT site, and from Djossou et al.
767 (2018) study based on weekly measurements collected at the same areas and for the same
768 periods as this study. We note that PM_{2.5} directly measured on women are 2.3 and 0.9 times our
769 values obtained at the ADF site in dry and wet seasons, respectively, and 3.4 and 4.9 times
770 higher on students than at the AWB site, and 1.6 and 2.1 times higher on drivers than at the CT

771 site. Also, our values are on average 1.6, 3, 5 and 8 times higher than weekly values of Djossou
772 et al. (2018) including our 3 days of measurements at the AWB, ADF, AT and CT sites
773 respectively. As it may be seen, the lowest concentrations are observed in Djossou et al. (2018),
774 whereas the highest concentrations are recorded in Xu. et al. (2019). This is valid for all sites,
775 seasons and campaigns. Differences between our values and Djossou values may be explained
776 by the sampling times of the two studies. Indeed, Djossou measurements are weekly, taking
777 into account diurnal activities during all the week, including week-end and nights which have
778 expected lower PM_{2.5} concentrations. Our study includes only maximum pollution conditions
779 for each site. The highest differences occur for the traffic sites. This may be clearly understood
780 since diurnal and weekly variations of traffic sources are the most variable. Comparison
781 between our values and Xu et al. (2019) values is also interesting. Indeed, it is at the ADF site
782 that on-site and women PM_{2.5} concentrations are the closest, which shows that this site is the
783 most representative of the pollution exposure to women. The biggest differences are found at
784 the AWB site. As already mentioned, distance from the site to the waste burning source is more
785 important than for other sites, which explains why street concentrations are much higher than
786 on-site concentrations. At the Cotonou traffic site, measurements taken from people are also
787 higher than on site measurements. Such differences can be explained by additional pollution
788 exposure as people move around. Note that the sampling technique may also play a role in such
789 a comparison. In terms of seasonal variation, our results are in agreement with long-term EC
790 measurements conducted by Djossou et al. (2018) for the same sites and period. Finally, Table
791 4 compares our PM_{2.5} results to literature data for different traffic sites in the world including
792 the same daily sampling time. It is interesting to note that our values are situated at the higher
793 end of the range of PM_{2.5} data observed from the other sites.

794 Secondly, Table 5 compares our OC and EC values to those obtained by Djossou et al. (2018)
795 and Xu et al. (2019) as previously described for the same period and the same sites. It is
796 interesting to note that Djossou's values are in general lower than ours. Indeed, for the wet and
797 dry seasons, our OC measurements are 4 and 1.4 times higher than Djossou's at the AT site,
798 2.1 and 5.7 times higher at the CT site, and 2.5 and 2.5 times higher at the ADF site,
799 respectively. As for PM_{2.5}, this can be explained by the different sampling times between our
800 experiments that were performed at the peak of urban activities, while Djossou's dataset
801 represents weekly integrated values. Differences at the ADF site are largely explained by the
802 temporal pattern of fish smoking activities which take place every day, only in the morning, as
803 such the associated pollution is not well represented in the weekly sampling. Finally, there are
804 less differences at the AWB site between both datasets since waste burning emissions occur

805 night and day throughout the week. Comparisons made between our values and those of Xu's
806 personal data show that both OC and EC are of the same order at the ADF site, whereas Xu
807 values are higher than ours at the CT and AWB sites. This result is in agreement with what we
808 found with PM_{2.5} concentrations as detailed above. Finally, Table 6 presents OC and EC for the
809 PM_{2.5} comparison between our values and other recent studies dealing with traffic sites in other
810 regions of the world and with similar operational conditions. We find that our values are situated
811 in the middle of the range observed in these different studies. Briefly, as presented in Table 7,
812 it is interesting to compare our WSOC concentrations to literature data for different traffic sites
813 of the world. We note that our values are on the same order as values found in Asia and higher
814 than those found in Europe.

815 Thirdly, the percentages of the total WSI to PM mass (15-20%) at the three Abidjan sites (ADF,
816 AWB and AT) are in the same order of magnitude than the data from PM_{2.5} personal exposure
817 samples collected at the same locations in 2016 by Xu et al. (2019). Our results also are very
818 close to the ionic contribution of 9% of the PM₁₀ mass found at the urban curbside site in Dar
819 es Salaam in Tanzania during the wet season 2005 by Mkoma (2008).

820

821 5. Conclusion

822 This paper presents the mass and the size-speciated chemical composition of particulate matter
823 (PM) during the dry and wet seasons in 2015, 2016 and 2017. Measurements were performed
824 at three sites in Abidjan, representative of domestic fire (ADF), waste burning (AWB) and
825 traffic (AT) sources, and at one traffic site in Cotonou (CT).

826 It is important to underline that our results and their temporal variations are very sensitive to
827 (1) the source activities whose pollution levels are highly linked to socio-economic status of
828 each city; (2) the impact of imported pollution (sea-salt, biomass burning, dust, anthropogenic
829 emissions from neighboring countries), according to air mass origins; and (3) the particle wet
830 deposition.

831 The comparison between our results and literature data underlines the importance of the
832 distance of the chosen site to the sources. At the source level (such as ADF), pollution results
833 at the site are in agreement with exposure of people living at this site. However, at the other
834 sites, comparison is more difficult since the sites are under the influence of a mix of transported
835 sources. That shows the key importance of exposure studies to estimate air quality and health
836 impacts.

837 The main striking feature is that PM_{2.5} values are well above the annual and daily WHO
838 guidelines of 25 and 10 µg.m⁻³, respectively, whatever the site and the season. Also, measured

839 concentrations from this study are situated in the middle to the high part of the range of
840 worldwide urban aerosol concentrations. In addition, we have stressed the importance of ultra-
841 fine and fine particles in the studied aerosol and of species such as particulate organic matter
842 and water soluble organic carbon, which are well known to be particularly harmful. This is
843 again a warning signal for pollution levels in African capitals if nothing is done to reduce
844 emissions in the future.

845 Our study constitutes an original database to characterize urban air pollution from
846 specific African combustion sources. The next step will be to cross such an exhaustive aerosol
847 chemical characterization to biological data in order to evaluate the impact of aerosol size and
848 chemical composition on aerosol inflammatory properties.

849

850 **Acknowledgements.** The research leading to these results has received funding from the
851 European Union 7th Framework Programme (FP7/2007-2013) under Grant Agreement no.
852 603502 (EU project DACCIWA: Dynamics-aerosol-chemistry-cloud interactions in West
853 Africa). The authors greatly thank all the colleagues and operators who contribute to sampling
854 during the different campaigns.

855

856 **Author Contributions**

857 J.A. and C.L. conceived and designed the study. J.A., C.L. and E.T.D. contributed to the
858 literature search, data analysis/interpretation and manuscript writing. J.A., C.L., A.B. and
859 E.T.D. contributed to manuscript revision. J.A., C.L., J.F.L, H.C, V.Y., A.A, C.G, C.Z, E.C and
860 S.K. carried out the particulate samples collection and chemical experiments, analyzed the
861 experimental data.

862

1249 Figure 1: Map of the city of Abidjan reporting the geographical location of DACCIWA urban
1250 sampling sites.

1251 Figure 2: Map of the city of Cotonou reporting the geographical location of DACCIWA urban
1252 sampling site.

1253 Figure 3: Pictures of the different sampling sites : (a) Traffic in Cotonou (Benin, CT station),
1254 (b) Waste burning in Abidjan (Côte d'Ivoire, AWB station), (c), Domestic fire, showing
1255 smoking activity in Yopougon, Abidjan (Côte d'Ivoire, ADF station), (d) " woro-woro
1256 and Gbaka " traffic in Abidjan (Côte d'Ivoire, AT station).

1257 Figure 4: Wind, pressure and temperature diagram at Abidjan and Cotonou during the different
1258 campaigns.

1259 Figure 5: Back trajectories arriving at Abidjan (a) and Cotonou (b) for each season (WS2015,
1260 WS2016, DS2016 and DS2017).

1261 Figure 6: Aerosol Mass concentrations at the different study sites for each campaign and for the
1262 different sizes (C in black, Fine in light Grey, Ultra-fine in grey). Bulk aerosol mass is
1263 indicated in boxes.

1264 Figure 7: Comparison of PM 2.5 mass concentrations in $\mu\text{g}\cdot\text{m}^{-3}$ at the four sites with those
1265 obtained by Djossou et al. (2018) and Xu et al. (2019) for the same site and period.

1266 Figure 8: EC relative concentrations in each size classes (C in black, Fine in light grey, Ultra-
1267 fine in grey) at the different study sites for each campaign. Bulk EC concentration for
1268 each site is indicated in boxes.

1269 Figure 9: OC relative concentrations in each size classes (C in black, Fine in light grey, Ultra-
1270 fine in grey) at the different study sites for each campaign. Bulk OC concentration for
1271 each site is indicated in boxes.

1272 Figure 10: OC/ EC ratio for the different campaigns and sites for each aerosol size (C in black,
1273 Fine in light grey, Ultra-fine in grey). Each box shows the median and the first and the
1274 third quartiles.

1275 Figure 11: Water-soluble ionic species speciation for each site, each campaign and each aerosol
1276 size.

1277 Figure 12: Dust concentrations at the different study sites for each campaign and for the
1278 different sizes (C in black, Fine in light grey, Ultra-fine in grey).

1279 Figure 13: Size-speciated aerosol chemical composition for each site, for each campaign and
1280 each aerosol size.

1281 Figure 14: MODIS Aerosol optical depth regional distribution over West Africa. Data are for
1282 2017, focusing on our campaign date at Abidjan (a-c 01/11-12-left part) and Cotonou
1283 (b-d 01/6-7, right part).
