21

22 **Abstract** As major chemical components of airborne fine particulate matter (PM_{2.5}), organic carbon
23 (OC) and elemental carbon (EC) have vital impacts on air quality, climate change, and human health.
24 Because OC and EC are closely associated with fuel combustion, it is helpful for the scientific
25 community and policymakers assessing the efficacy of air pollution control measures to study on
26 the impact of the control measures and regional transport on the OC and EC levels. In this study,
27 hourly mass concentrations of OC and EC associated with PM_{2.5} were semi-continuously measured
28 from March 2013 to February 2018. The results showed that annual mean OC and EC concentrations
29 declined from 14.0 to 7.7 µg/m³ and from 4.0 to 2.6 µg/m³, respectively, from March 2013 to
30 February 2018. In combination with the data of OC and EC in previous studies, an obvious
31 decreasing trend in OC and EC concentrations was found, which was caused by clean energy
32 policies and effective air pollution control measures. However, no obvious change in the ratios of
33 OC and EC to the PM_{2.5} mass (on average, 0.164 and 0.049, respectively) was recorded, suggesting
34 that inorganic ions still contributed a lot to PM_{2.5}. Based on the seasonal variations of OC and EC,
35 it appeared that higher OC and EC concentrations were still observed in the winter months, with the
36 exception of winter of 2017-2018. Traffic policies executed in Beijing resulted in nighttime peaks
37 of OC and EC, caused by heavy-duty vehicles and heavy-duty diesel vehicles being permitted to
38 operate from 0:00 to 6:00. In addition, the fact that there was no traffic restriction in weekends led
39 to higher concentrations in weekends compared to weekdays. Significant correlations between OC
40 and EC were observed throughout the study period, suggesting that OC and EC originated from
41 common emission sources, such as exhaust of vehicles and fuel combustion. OC and EC levels
42 increased with enhanced SO₂, CO and NO_x concentrations while the O₃ and OC levels enhanced
43 simultaneously when O₃ concentrations were higher than 50 µg/m³. Nonparametric wind regression
44 analysis was performed to examine the sources of OC and EC in the Beijing area. It was found that
45 there were distinct hot spots in the northeast wind sector at wind speeds of approximately 5 km/h,
46 as well as diffuse signals in the southwestern wind sectors. Source areas further away from Beijing
47 were assessed by potential source contribution function (PSCF) analysis. A high-potential source
48 area was precisely pinpointed, which was located in the northwestern and southern areas of Beijing
49 in 2017 instead of solely in the southern areas of Beijing in 2013. This work shows that improvement
50 of the air quality in Beijing benefits from strict control measures; however, joint prevention and

51 control of regional air pollution in the regions is needed for further improving the air quality. The
52 results provide a reference for controlling air pollution caused by rapid economic development in
53 developing countries.

56 Beijing

57

58 **1 Introduction**

59 Worldwide attention on atmospheric organic carbon (OC) and elemental carbon (EC) has been
60 paid by the public and the scientific community because OC and EC have vital effects on air quality,
61 atmospheric visibility, climate, and human health (Bond et al., 2013; Boucher et al., 2013; World
62 Health Organization (WHO), 2012). OC is composed of thousands of organic compounds and
63 occupies 10-50 % of the ambient PM_{2.5} mass (Seinfeld and Pandis, 1998) while EC, which is emitted
64 from fuel combustion, represents 1-13 % of the ambient PM_{2.5} mass (Shah et al., 1986; Tao et al.,
65 2017; Malm et al., 1994). Considering that OC and EC occupy high fractions of the PM_{2.5}, a decline
66 in OC and EC concentrations will improve air quality. Due to the light scattering potential of OC
67 and the light absorption ability of EC, high concentrations of OC and EC can impair the atmospheric
68 visibility. In addition, OC and EC can affect the atmospheric energy balance through scattering and
69 absorbing incoming and outgoing solar and terrestrial radiation (direct effect) and through
70 modifying the microphysical properties of clouds, like influencing cloud condensation nuclei and/or
71 ice nuclei (indirect effects). Direct and indirect effects of OC and EC remain one of the principal
72 uncertainties in estimates of anthropogenic radiative forcing (Boucher et al., 2013). In particular,
73 black carbon (BC also called EC) coated with secondary particles can enhance aerosol radiative
74 forcing (Wang et al., 2013; Zhang et al., 2008). BC is found to aggravate haze pollution in megacities
75 (Ding et al., 2016; Zhang et al., 2018). Most of all, OC and EC adversely affect human health. As
76 important constituents of OC, polycyclic aromatic hydrocarbons (PAHs) are well known as
77 carcinogens, mutagens, and teratogens and therefore pose a serious threat to the health and the well-
78 being of humans (Boström et al., 2002). Short-term epidemiological studies provide sufficient
79 evidence of all-cause and cardiovascular mortality and cardiopulmonary hospital admissions
80 associated with daily variations in BC concentrations; besides, cohort studies proved that all-cause
81 and cardiopulmonary mortality are linked with long-term average BC exposure (WHO, 2012). Thus,
82 long-term continuous observations of OC and EC are a prerequisite to further study air quality,
83 atmospheric visibility, climate effects, and human health. However, long-term continuous
84 observations of OC and EC in China are scarce.

85 In the world, China is considered as one of the regions of high emissions of OC and EC due to
86 high energy consumption and increasing vehicle population, accompanying rapid economic

87 development and urbanization for decades (<http://www.stats.gov.cn/tjsj/ndsj/2017/indexch.htm>). As
88 the capital of China, Beijing with a residential population of 21.7 million, domestic tourists of
89 2.9×10^2 million and foreign tourists of approximately 3.3 million in 2017
90 (<http://tjj.beijing.gov.cn/English/AD/>) faces severe air pollution problems, which have attracted
91 worldwide attention. A series of studies on OC and EC have already been performed in Beijing.
92 Lang et al. (2017) indicated that OC showed a downward trend and EC had almost no change before
93 2003, both increased from 2003 to 2007, but decreased after 2007. The decline in OC concentrations
94 was associated with coal combustion and motor vehicle emission control measures, while that in
95 EC was caused by the replacement of fossil fuel and control of biomass emissions. Tao et al. (2017)
96 stated that the nearly 30 % reduction in total carbon (TC) in recent years in Beijing can be taken as
97 a real trend. Lv et al. (2016) found that the concentrations of OC and EC remained unchanged from
98 2000 to 2010 in Beijing. Yang et al. (2011a) conducted a long-term study of carbonaceous aerosol
99 from 2005 to 2008 in urban Beijing and found a decline in the ratio of carbonaceous species to the
100 $PM_{2.5}$ mass in contrast to what was observed 10 years earlier, which indicated that the importance
101 of carbonaceous species in $PM_{2.5}$ had decreased. In addition, pronounced seasonal variations were
102 recorded with the highest concentrations occurring in winter and the lowest ones in summer. Overall,
103 these previous researches seem somewhat inconsistent with each other and they seldom focused on
104 studying the impact of air pollution control measures and regional transport on the carbonaceous
105 aerosol levels in detail.

106 Notably, a series of the strictest measures on emission abatement and pollution control were
107 implemented in China from September 2013 (Jin et al., 2016). Substantial manpower and material
108 resources have been put into improving the air quality in the past five years and significant measures
109 are being taken for the atmospheric environment and ecosystem (Gao et al., 2017). To evaluate the
110 effectiveness of air pollution control measures, it is necessary to conduct a long-term continuous
111 observation of OC and EC and to study their long-term variation. Most of the previous studies
112 showed average information for certain periods based on filter sampling and laboratory analysis and
113 did not reflect the dynamic evolution processes of OC and EC with hourly resolution, which can
114 provide important and detailed information for the potential health risk in the area with frequent
115 occurrence of air pollution episodes. In addition, long-term measurements in urban areas of China

116 with high population density were scarce (Yang et al., 2005, 2011a; Zhang et al., 2011; Li et al.,
117 2015; Chang et al., 2017) and the knowledge on long-term continuous hourly observations is still
118 lacking, which is yet important for recognizing the influence of source emissions on air quality.

119 Based on the-above mentioned background, it is necessary to perform a long-term continuous
120 hourly observation to explore the characteristics of OC and EC, to examine the relationship between
121 OC and EC and with major air pollutants and their sources so as to better assess the influence of
122 emission control measures on the OC and EC levels. In this study, inter-annual, seasonal, weekly
123 and diurnal variation of OC and EC were investigated. The influence of local and regional
124 anthropogenic sources was evaluated using non-parametric wind regression (NWR) and potential
125 contribution source function (PSCF) methods. This study will be helpful for improving the
126 understanding of the variation and sources of OC and EC associated with PM_{2.5} and assessing the
127 effectiveness of local and national PM control measures and it provides a valuable dataset for
128 atmospheric modelling study and assessing the health risk. It also is the first time that a continuous
129 hourly measurement for a 5-year period based on the thermal-optical method is reported for urban
130 Beijing.

131 **2 Experimental**

132 **2.1 Description of the site**

133 The study site (39°58'28" N, 116°22'16" E, 44 m above ground) was set up in the second floor
134 in the campus of the State key laboratory of atmospheric boundary physics and atmospheric
135 chemistry of the Institute of atmospheric Physics, Chinese Academy of Science (Fig. 1). The site is
136 approximately 1 km south from the 3rd Ring Road (main road), 1.2 km north from the 4th Ring
137 Road (main road), 200 m west of the G6 Highway (which runs north-south) and 50 m south of the
138 Beitucheng West Road (which runs east-west), respectively. The annual average vehicular speeds in
139 the morning and evening traffic peaks were approximately 27.8 and 24.6 km/h, respectively, in the
140 past five years. During the whole study period the level of traffic congestion is mild based on the
141 traffic performance index published by the Beijing Traffic Management Bureau
142 (<http://www.bjtrc.org.cn/>), which indicated 1.5-1.8 times more time will be taken to publicly travel
143 during traffic peaks than during smooth traffic. The study site is surrounded by residential zones, a
144 street park and a building of ancient relics without industrial sources. The experimental campaign

145 was performed from March 1, 2013 to February 28, 2018. The periods of March 1, 2013 to February
146 28, 2014, March 1, 2014 to February 28, 2015, March 1, 2015 to February 28, 2016, March 1, 2016
147 to February 28, 2017 and March 1, 2017 to February 28, 2018 are, hereinafter, called for short 2013,
148 2014, 2015, 2016 and 2017, respectively.

149 **2.2 Instrumentation**

150 Concentrations of PM_{2.5}-associated OC and EC were hourly measured with semi-continuous
151 thermal-optical transmittance method OC/EC analyzers (Model 4, Sunset Laboratory Inc. Oregon,
152 United States of America (USA)). The operation and maintenance are strictly executed according to
153 standard operating procedures (SOP, <https://www3.epa.gov/ttnamti1/spesunset.html>). Volatile
154 organic gases are removed by an inline parallel carbon denuder installed upstream of the analyzer.
155 A round 16-mm quartz filter is used to collect PM_{2.5} with a sampling flow rate of 8 L/m. A modified
156 NIOSH thermal protocol (RT-Quartz) is used to measure OC and EC. The sampling period is 30
157 min and the analysis process lasts for 15 min. Calibration is performed according to the SOP. An
158 internal standard CH₄ mixture (5.0 %; ultra-high purity He) is automatically injected to calibrate the
159 analyzer at the end of every analysis. In addition, off-line calibration was conducted with an external
160 amount of sucrose standard (1.06 µg) every three months. The quartz fiber filters used for sample
161 collection were replaced by new ones before the laser correction factor dropped below 0.90. After
162 replacement, a blank measurement of the quartz fiber filters is carried out. The uncertainty of the
163 TC measurement has been estimated to be approximately ±20 % (Peltier et al., 2007). The
164 analyzers/monitors for O₃, CO, SO₂, NO_x and PM_{2.5}, and their precision, detection limits and
165 calibration methods have been described in detail elsewhere (Ji et al., 2014). Briefly, O₃ was
166 measured using an ultraviolet photometric analyzer (model 49i, Thermo Fisher Scientific (Thermo),
167 USA), CO with a gas filter correlation nondispersive infrared method analyzer (model 48i, Thermo,
168 USA), SO₂ using a pulsed-fluorescence analyzer (model 43i, Thermo, USA), NO-NO₂-NO_x with a
169 chemiluminescence analyzer (model 42, Thermo, USA) and PM_{2.5} using a US Environmental
170 Protection Agency Federal Equivalent Method analyzer of PM_{2.5} (SHARP 5030, Thermo, USA).
171 Meteorological data such as wind speed (WS), wind direction (WD), relative humidity (RH) and
172 atmospheric temperature (*T*) were recorded via an automatic meteorological station (Model
173 AWS310; Vaisala, Finland). The data were processed using an Igor-based software (Wu et al., 2018)

174 and the commercial software of Origin.

175 **2.3 NWR and PSCF methods**

176 **2.3.1 NWR method**

177 NWR is a source-to-receptor source identification model, which provides a meaningful
178 allocation of local sources (Henry et al., 2009; Petit et al., 2017). Wind analysis results using NWR
179 were obtained using a new Igor-based tool, named ZeFir, which can perform a comprehensive
180 investigation of the geographical origins of the air pollutants (Petit et al., 2017). The principle of
181 NWR is to smooth the data over a fine grid so that concentrations of air pollutants of interest can be
182 estimated by any couple of wind direction (θ) and wind speed (u). The smoothing is based on a
183 weighing average where the weighing coefficients are determined using a weighting function $K(\theta,$
184 $u, \sigma, h) = K_1(\theta, \sigma) \times K_2(u, h)$ (i.e., Kernel functions). The estimated value (E) given θ and u is
185 calculated by the following equations (1)-(3):

$$186 \quad E(\theta|u) = \frac{\sum_{i=1}^N K_1\left(\frac{\theta-W_i}{\sigma}\right) \times K_2\left(\frac{u-Y_i}{h}\right) \times C_i}{\sum_{i=1}^N K_1\left(\frac{\theta-W_i}{\sigma}\right) \times K_2\left(\frac{u-Y_i}{h}\right)} \quad (1)$$

$$187 \quad K_1(x) = \frac{1}{\sqrt{2\pi}} \times e^{-0.5x^2} \quad -\infty < x < \infty \quad (2)$$

$$188 \quad K_2(x) = 0.75 \times (1-x^2) \quad -1 < x < 1 \quad (3)$$

189 where σ and h were smoothing parameters, which can be suggested by clicking on the button of
190 suggest estimate in the software of Zefir; C_i , W_i , and Y_i are the observed concentration of a pollutant
191 of interest, resultant wind speed and direction, respectively, for the i th observation in a time period
192 starting at time t_i ; N is the total number of observations.

193 After the calculation, graphs of the estimated concentration and the joint probability are
194 generated. The NWR graph of the air pollutant of interest, acquired directly via the NWR calculation,
195 represents an integrated picture of the relationship of estimated concentration of the specific
196 pollutant, wind direction and wind speed. The graph of the joint probability for the wind data,
197 equivalent to a wind rose, shows the occurrence probability distribution of the wind speed and wind
198 direction.

199 **2.3.2 PSCF method**

200 The PSCF method is based on the residence time probability analysis of air pollutants of
201 interest (Ashbaugh et al., 1985). Source locations and preferred transport pathways can be identified

202 (Poirot and Wishinski, 1986; Polissar et al., 2001; Lupu and Maenhaut, 2002). The potential
203 locations of the emission sources are determined using backward trajectories. A detailed description
204 can be found in Wang et al. (2009). In principle, the PSCF is expressed using equation (4):

$$205 \quad \text{PSCF}(i, j) = w_{ij} \times (m_{ij}/n_{ij}) \quad (4)$$

206 where w_{ij} is an empirical weight function proposed to reduce the uncertainty of n_{ij} during the study
207 period, m_{ij} is the total number of endpoints in (i, j) with concentration value at the receptor site
208 exceeding a specified threshold value (the 75th percentiles for OC and EC each year were used as
209 threshold values to calculate m_{ij}) and n_{ij} is the number of back-trajectory segment endpoints that fall
210 into the grid cell (i, j) over the period of study. The National Oceanic and Atmospheric
211 Administration Hybrid Single-Particle Lagrangian Integrated Trajectory model
212 (<https://ready.arl.noaa.gov/HYSPLIT.php>) was used for calculating the 48-h backward trajectories
213 terminating at the study site at a height of 100 m every 1 h from March 1 2013 to February 28 2018.
214 In this study, the domain for the PSCF was set in the range of (30-70 °N, 65-150 °E) with the grid
215 cell size of $0.25 \times 0.25^\circ$.

216 **3 Results and discussion**

217 **3.1 Levels of OC and EC**

218 Statistics for the OC and EC concentrations from March 1, 2013 to February 28, 2018 are
219 summarized in Table 1. Benefiting from the Air Pollution Prevention and Control Action Plan and
220 increasing atmospheric self-purification capacity (ASC, shown in Table S1), a decline in annual
221 average concentrations is on the whole recorded. In detail, the annual average concentrations of both
222 OC and EC peaked in 2014 and then started to decline gradually during the remainder of the study
223 period. Nonetheless, the annual average concentrations of $\text{PM}_{2.5}$ were generally decreasing from
224 2013 to 2017. To assess whether the decreases are statistically significant, 2-tailed paired t-tests
225 were applied for OC, EC and $\text{PM}_{2.5}$ using their monthly average concentrations in 2013 and 2016
226 as paired datasets. At a confidence level of 98%, from March to October, the paired data are
227 statistically different, indicating that the concentrations of OC, EC and $\text{PM}_{2.5}$ declined during the
228 above period from 2013 to 2016; however, the concentrations of OC, EC and $\text{PM}_{2.5}$ during
229 November and February from 2013 to 2016 are not statistically different. The decline in OC and EC
230 concentrations is closely associated with decreasing coal consumption, increasing usage of natural

231 gases and the implementation of a stricter vehicular emission standard and increasing atmospheric
232 self-purification capacity (Tables S1-S3). Knowledge of the relative contribution of OC and EC to
233 PM_{2.5} is important in formulating effective control measures for ambient PM (Wang et al., 2016a).
234 The ratios of OC and EC to PM_{2.5} varied little during the whole study period, suggesting that
235 vehicular emission might be an important contributor of OC and EC although several other pollution
236 sources also contributed to the OC and EC loadings. The ratios of OC to PM_{2.5} ranged from 15.5 to
237 17.8 % with the average of 16.4 %, while those of EC to PM_{2.5} ranged from 4.5 to 5.2 % with the
238 average of 4.9 %. OC accounted, on average, for 77.0 ± 9.3 % of the total carbon (TC, the sum of
239 OC and EC), while EC amounted for 23.0 ± 9.3 % of the TC. These results are consistent with those
240 in previous studies (Wang et al., 2016a; Tao et al., 2017, Lang et al., 2017). The contribution of TC
241 to PM_{2.5}, 21.3 ± 15.8 %, is also similar to those reported in previous studies, listed in Table S4, for
242 example, at urban sites of Hongkong, China (23.5-23.6 % in 2013), Hasselt (23 %) and Mechelen
243 (24 %) in northern Belgium, rural sites in Europe (19-20 %) and some sites in India (on average,
244 20 %, Bisht et al., 2015; Ram and Sarin, 2010; Ram and Sarin, 2012), but lower than those observed
245 historically at multiple sites in China (on average 27 %, Wang et al., 2016a), with Beijing (27.6 %,
246 from March 2005 to Feb 2006), Chongqing (28.3 %, from March 2005 to February 2006), Shanghai
247 (34.5 %, from March 1999 to May 2000) and Guangzhou (26.4 %, December 2008 to February
248 2009), in Budapest (40 %), Istanbul (30 %), and many sites in the USA, like Fresno (43.2 %), Los
249 Angeles (36.9 %) and Philadelphia (33.3 %) (Na et al., 2004). Compared to previous studies in
250 Beijing (Table S4), the TC to PM_{2.5} ratio became smaller in this study, indicating a relatively lower
251 contribution from carbonaceous aerosols to PM_{2.5} in this study. The difference in the TC/PM_{2.5} ratio
252 could be ascribed to two factors. One factor is the difference in characteristics of sampling locations
253 between that in our study and those in the earlier studies. However, our site and those in the previous
254 studies used for comparison are all located in urban areas of Beijing (Chaoyang and Haidian district,
255 respectively). It is reasonable to assume that they are affected by common sources since the
256 surrounding environments exhibit similar features. Besides, the annual average PM_{2.5}
257 concentrations in both districts published by the Ministry of Environmental Protection, China
258 (<http://106.37.208.233:20035/>) were quite comparable to each other from 2013 to 2017 ($y=0.99x$,
259 $r^2=0.92$), indicating that both areas had particle pollution of a similar degree. The other factor is that

260 the contribution from secondary inorganic ions to the PM_{2.5} became more important because of a
261 stronger atmospheric oxidation capacity (the annual average O₃ concentrations were 102, 109, 116,
262 119, and 136 µg/m³, respectively, from 2013 to 2017 in the Beijing-Tianjin-Hebei region; published
263 by <http://106.37.208.233:20035/>), which could give rise to a lower TC to PM_{2.5} ratio. A higher TC
264 to PM_{2.5} ratio suggests that there is a lower contribution from secondary inorganic ions to PM_{2.5},
265 while a lower ratio may indicate a larger contribution from secondary inorganic ions to PM_{2.5}. The
266 carbonaceous aerosol (the sum of multiplying the measured OC by a factor of 1.4 and EC)
267 represented on average, 27.7 ± 16.7 % of the observed PM_{2.5} concentration, making it a dominant
268 contributor to PM_{2.5}.

269 Table 3 lists recently published results for OC and EC mass concentrations in major megacities.
270 Although the observation periods were not same, a comparative analysis of OC and EC
271 concentrations between different megacities could show the status of energy consumption for
272 policymakers, drawing lessons and experience from other countries. It is obvious that the PM_{2.5}-
273 associated OC and EC levels in the megacities in the developing countries were far higher than
274 those in the developed countries. The PM_{2.5}-associated OC and EC concentrations in Beijing were
275 higher than those in Athens, Greece (2.1 and 0.54 µg/m³), Los Angeles (2.88 and 0.56 µg/m³) and
276 New York (2.88 and 0.63 µg/m³), USA, Paris, France (3.0 and 1.4 µg/m³), Seoul, South Korea (4.1
277 and 1.6 µg/m³), Tokyo, Japan (2.2 and 0.6 µg/m³) and Toronto, Canada (3.39 and 0.5 µg/m³). That
278 is because clean energy has widely been used and strict control measures are taken to improve the
279 air quality step by step in the developed countries. Of the megacities in the developing countries,
280 OC and EC concentrations in Beijing were lower than those in most other megacities, like Mumbai
281 and New Delhi, India, and Xi'an and Tianjin, China, but close to those in Shanghai and Hongkong,
282 China, and higher than those in Lhasa, China. These differences/similarities indicate that OC and
283 EC gradually declined in Beijing and that a series of measures had progressive effects. However, to
284 further improve the air quality, more synergetic air pollution abatement measures of carbonaceous
285 aerosols and volatile organic compounds (VOCs) emissions need to be performed.

286 Fig. 2 shows the mass fractions of carbonaceous aerosols in different PM_{2.5} levels classified
287 according to PM_{2.5} concentrations during the whole study period. There were 571, 561, 310, 169,
288 142 and 74 days for excellent, good, slightly polluted, moderately polluted, heavily polluted and

289 severely polluted air quality levels during the whole period. It was obvious that OC and EC
290 concentrations increased with the degradation of air quality. OC and EC concentrations were 6.3
291 and 1.7, 10.2 and 2.9, 13.7 and 4.1, 17.3 and 5.3, 24.6 and 7.9 and 35.5 and 11.3 $\mu\text{g}/\text{m}^3$ for excellent,
292 good, slightly polluted (LP), moderately polluted (MP), heavily polluted (HP) and severely polluted
293 (SP) air quality days, respectively. However, the percentages of OC and EC accounting to $\text{PM}_{2.5}$
294 decreased with the deterioration of air quality. OC and EC made up for 31.5 % and 8.3 %, 18.9 %
295 and 5.4 %, 14.7 % and 4.4 %, 13.4 % and 4.1 %, 12.9 % and 4.2 % and 11.4 % and 3.6 % during
296 excellent, good, slightly polluted, moderately polluted, heavily polluted and severely polluted air
297 quality days, respectively. The percentage for OC decrease from 31.4 to 11.4 % while that for EC
298 decreased from 8.3 to 3.6 % with the deterioration of air quality, indicating that other $\text{PM}_{2.5}$
299 constituents than OC and EC contributed more to the increased $\text{PM}_{2.5}$ levels. This is consistent with
300 previous studies showing that secondary inorganic ions play a more important role in the increase
301 in $\text{PM}_{2.5}$ concentrations (Ji et al., 2014, 2018).

302 **3.2 Inter-annual variation of OC and EC**

303 To evaluate the effect of the clean air act over a prolonged period, our OC and EC data were
304 combined with the data of previous studies for Beijing (He et al., 2011; Zhao et al., 2013; Ji et al.,
305 2016; Tao et al., 2017; Lang et al., 2017). As shown in Fig. 3, a decreasing trend in OC and EC
306 concentrations is on the whole observed. Table S2 summarizes a variety of policies and actions to
307 reduce pollutant emissions in power plants, coal-fired boilers, residential heating and traffic areas
308 in Beijing since 2002. Although the gross domestic product, population, energy consumption and
309 vehicular population rapidly increased (Table S3), the general decreasing trends in OC and EC
310 concentrations could be attributed to the combined effect of the more stringent traffic emission
311 standards and traffic restriction, the energy structure evolving from intensive coal and diesel
312 consumption to replacement with natural gas and electricity, and retrofitting with SO_2 and NO_2
313 removal facilities to meet the new emission standards applicable to different coal-fired facilities, etc.
314 In particular, there is an obvious dividing line of OC and EC concentrations in 2010. After 2010, the
315 OC and EC concentrations became substantially lower than those observed previously. In addition
316 to the measures mentioned in Table S2, the relocation of Shougang Corporation, which is one of the
317 China's largest steel companies, and other highly polluting factories out of Beijing might have

318 helped to some extent; all the small coal mines in Beijing were shut down and plenty of yellow label
319 (heavy-polluting) vehicles were forced off road. Note that the OC and EC levels in 2008 and 2009
320 were also somewhat lower, which was caused by a series of radical measures to improve the air
321 quality for the Olympic Games in 2008 and a decline in industrial production because of China's
322 exports crash in 2009, respectively. It suggests that a stringent clean air act and rectifying industry
323 played important roles in the air quality improvement.

324 In this study, the fire spots were counted in the domain of (30-70° N, 65-150° E) using the
325 MODIS Fire Information for Resource Management System (Giglio, 2013). Note also that the
326 effective control of biomass burning might contribute to the decrease in OC and EC concentrations.
327 In Fig. 3, it can be seen that the annual average EC concentration and fire spot counts exhibit a
328 rather similar variation from 2004 to 2017, except in the year 2012, which suggests that the EC
329 levels are somewhat correlated with the biomass burning; this might indicate that biomass burning
330 contributed somewhat to the EC levels. The reduction in fire spot counts from 2014 to 2017, which
331 resulted from efforts to control the agricultural field residue burning since 2013, helped to reduce
332 the EC concentrations to some extent, but the low EC levels during 2014-2017 are likely mostly due
333 to the implementation of the clean air act. With regard to the anomaly in the year 2012, based on
334 the MODIS data for this year, a very non-uniform distribution of fire spots in the BTH region was
335 observed, with a distinct decrease of fire spot counts in Beijing, but higher fire spot counts in the
336 southern Hebei Province; this may be ascribed to the fact that the policy of Banning Straw Burning
337 in Summer and Autumn was executed to different degrees in the whole region, with better
338 implementation in Beijing area and worse action in the other parts.
339 (http://www.beijing.gov.cn/zfxxgk/110029/qtwj22/2012-12/11/content_357114.shtml). In addition,
340 for the years from 2002 to 2017, the highest precipitation volume in Beijing was recorded in 2012,
341 i.e., 733.2 mm, and the rainy days mainly occurred in the intensive straw burning periods,
342 accounting for 76.4% of all rainy days in 2012. The frequent wet scavenging might have suppressed
343 the EC concentrations during the intensive straw burning periods, so that the annual EC level for
344 2012 was comparable to those recorded from 2011 onward.

345 Similar to OC and EC, the annual mean SO₂ and NO₂ concentrations also showed a decreasing
346 trend. As well-known, SO₂ originates from coal combustion and sulfur-containing oil (Seinfeld and

347 Pandis, 1998). With the replacement of coal for industrial facilities, residential heating and cooking
348 by clean energy (e.g., natural gases, electricity and lower sulfur content in oil), a clear decline in
349 annual SO₂ concentrations was observed in the Beijing area starting from 2002. As compared to
350 SO₂, the annual decreasing rate of NO₂ was relatively lower. Besides the power plants and other
351 boilers, traffic emissions are another major source of NO₂. The rapid increase of vehicle population
352 may partly offset the great effort in reducing coal consumption to lower the NO₂ level despite the
353 transition to more stringent traffic emission standards.

354 **3.3 Monthly and seasonal variations**

355 Fig. S1 shows the monthly mean OC and EC concentrations at our study site for the whole 5-
356 year period. Similar variations are observed with generally higher mean OC and EC levels in the
357 cold season (from November to March next year when the centralized urban residential heating is
358 provided) and lower ones in the warm season (from April to October). The highest average OC and
359 EC concentrations were $24.1 \pm 18.7 \mu\text{g}/\text{m}^3$ in December 2016 and $9.3 \pm 8.5 \mu\text{g}/\text{m}^3$ in December
360 2015, respectively. However, the lowest OC and EC levels were not observed in the warm months;
361 they were $5.0 \pm 4.6 \mu\text{g}/\text{m}^3$ in January, 2018 and $1.5 \pm 1.7 \mu\text{g}/\text{m}^3$ in December, 2017, respectively;
362 this was associated with both frequent occurrence of cold air mass and the implementation of a
363 winter radical pollution control action plan (Chen and Chen, 2019) in Beijing from November, 2017.
364 Overall, the increased fuel consumption for domestic heating in addition to unfavorable
365 meteorological conditions (lower mixing layer height, temperature inversion and calm wind) in the
366 colder months is considered to lead to higher OC and EC levels (Ji et al., 2014). In addition, the
367 lower air temperature in the cold months led to shifting the gas-particle equilibrium of semi-volatile
368 organic compounds (SVOCs) into the particle phase, leading to the higher OC levels. In the cold
369 months, the cold start of vehicles (5.64 million vehicles in Beijing at the end of 2017) also increased
370 the emission of OC. In the warm season, lower OC and EC levels were observed, which could be
371 attributed to the following factors: no extra energy consumed for domestic heating, strong wet
372 scavenging by frequent precipitation occurring in these months, and more unstable atmospheric
373 conditions favorable for pollutant dispersion; in addition, during this period, the monthly mean OC
374 and EC concentrations generally decreased from year to year. In contrast, for the cold season, the
375 monthly mean OC and EC concentrations did not show a clear decreasing trend from year to year

376 except for October. In addition to the more intensive energy consumption in the cold season, the EC
377 and OC levels could also be enhanced strongly by regional transport and stagnant meteorology
378 leading to ground surface accumulation in the autumn and winter (Wang et al., 2019; Yi et al., 2019);
379 this would have counteracted the efficacy of the energy structure change in the Beijing-Tianjin-
380 Hebei region in the past few years. It is worth pointing out that, on a year to year basis, the monthly
381 average OC and EC concentrations in the cold seasons of 2017 and 2018 were generally lower than
382 those in 2016, demonstrating to some extent the effectiveness of the execution of the radical
383 pollution control measures for cities on the air pollution in the Beijing-Tianjin-Hebei region. The
384 interquartile ranges of OC and EC in the warm months were narrower than in the cold months,
385 indicating that there was more substantial variation in concentration in the latter months. The larger
386 variation in the colder months could be caused by the cyclic accumulation and scavenging processes.
387 In this region, due to these processes, the concentration of particulate matter increases rapidly when
388 the air mass back trajectories change from the northwest and north to the southwest and south over
389 successive days in Beijing; in contrast, the concentration of particulate matter declines sharply when
390 a cold front causes a shift of back trajectories from the southwest and south to the north and
391 northwest (Ji et al., 2012). The accumulation processes are closely associated with unfavorable
392 meteorological conditions, which give rise to higher OC and EC concentrations, while more
393 scavenging of aerosols by cold fronts leads to lower levels.

394 As to the seasonality in OC and EC, similar seasonal variations are observed in the various
395 years with generally higher mean concentrations in autumn and winter and lower levels in spring
396 and summer (Fig. 4). Remarkably, the OC and EC concentrations in the autumn and winter of 2017
397 were lower than those in the previous years. This was due to the combined effect of controlling
398 anthropogenic emissions strictly and favorable meteorological conditions. Since September 2017, a
399 series of the most stringent measures within the Action Plan on Prevention and Control of Air
400 Pollution was implemented to improve the air quality; these measures included restricting industrial
401 production by shutting down thousands of polluting plants, suspending the work of iron and steel
402 plants in 28 major cities and limiting the use of vehicles and reducing coal consumption as a heating
403 source in northern China. In addition, the air quality improvement in the autumn and winter of 2017
404 was closely tied to frequent cold fronts accompanied by strong winds, which was favorable for

405 dispersing the pollutants. The average OC and EC concentrations in the winter were 1.69 and 1.14,
406 2.17 and 1.93, 1.49 and 2.14, 2.41 and 2.29 and 0.80 and 0.88 times higher than those in the summer
407 for 2013, 2014, 2015, 2016 and 2017, respectively. The difference in the ratios for 2017 was due to
408 the series of the most stringent measures taking effect and favorable meteorology. The Beijing
409 municipal government in particular has made great efforts to replace coal by natural gases and
410 electricity-powered facilities. Besides, new energy vehicles are increasingly used to replace the
411 gasoline vehicles.

412 **3.4 Diurnal variation and weekly pattern for OC and EC**

413 As can be seen in Figs. S2 and S3, a clear diurnal variation is observed for both OC and EC in
414 each year. This variation is closely tied to the combined effect of diurnal variation in emission
415 strength and evolution of the PBL. The pattern for EC with higher concentrations in the nighttime
416 (from 20:00 to 4:00) and lower levels in the daytime (from 9:00 to 16:00) is largely linked to the
417 vehicular emissions. The EC concentrations increased starting from 17:00, corresponding with the
418 evening rush hours, emission from nighttime heavy-duty diesel trucks (HDDT) and heavy-duty
419 vehicles (HDV) and the formation of a nocturnal stable PBL. As regulated by the Beijing Traffic
420 management Bureau (<http://www.bjjtgl.gov.cn/zhuanti/10weihao/>), HDV and HDDT are allowed to
421 enter the urban area inside the 5th Ring Road from 0:00 to 06:00 (local Time). At other times, both
422 the higher PBL height and lower traffic intensity resulted in lower EC concentrations. The amplitude
423 of the diurnal variation in the EC concentrations was smaller in the last three years. The maximum
424 peak concentration (22:00-7:00) was 1.68, 1.62, 1.43, 1.40 and 1.40 times higher than that observed
425 in the valley period (13:00-15:00) for 2013, 2014, 2015, 2016 and 2017, respectively. Similar to EC,
426 the diurnal pattern for OC was also characterized by higher concentrations in the nighttime (from
427 20:00 to 4:00) and lower levels in the daytime (from 14:00 to 16:00). However, the formation of
428 secondary organic carbon from gas-phase oxidation of VOCs with increased solar radiation during
429 midday gave rise to a small additional peak of OC. Like for EC, the amplitude of the diurnal
430 variation in the OC concentrations was smaller in the last three years. The maximum peak
431 concentration (19:00-3:00) was 1.47, 1.47, 1.30, 1.34 and 1.26 times higher than that observed in
432 the valley period (14:00-16:00) for 2013, 2014, 2015, 2016 and 2017, respectively. It was pity that
433 no diurnal variation in traffic counts can be available but the hourly average traffic counts in 2015,

434 2016 and 2017 could be found in (Beijing Transportation Annual Report,
435 <http://www.bjtrc.org.cn/JGJS.aspx?id=5.2&Menu=GZCG>). Considering that the hourly average
436 traffic counts varied little in urban Beijing and they were 5969/hr, 5934/hr and 6049/hr in 2015,
437 2016 and 2017, respectively, the small amplitude of the diurnal variation in the last three years might
438 be related to local emission intensities; these might have been significantly affected by the
439 enforcement of a series of traffic emission control measures since 2015, including more strict
440 restriction of emission from heavy-duty diesel vehicle public buses, wider usage of electric public
441 buses, and scrappage of all the high-emitting (yellow-labelled) vehicles, etc. (Tab. S2). All these
442 actions led to a decline in emissions of OC and EC and narrowed the amplitude of the diurnal
443 variation in the EC concentration.

444 Separate diurnal variations of OC and EC for each season in each year are shown in Figs S4
445 and S5. Similar patterns are observed in in the four seasons but the difference between peak and
446 valley levels is larger in the winter than in the other three seasons. The larger variation in the winter
447 is due to the additional emission from residential heating and more unfavorable meteorological
448 conditions (Ji et al., 2016).

449 The difference in diurnal pattern between weekdays and weekends was also examined, see Figs.
450 S6 and S7. Similar diurnal variations are found on weekdays and weekend days. The maximum
451 peak concentration for EC (22:00-7:00) was 1.55, 1.43, 1.55, 1.51, 1.51, 1.46 and 1.59 times higher
452 than the valley concentration (13:00-15:00) for Monday, Tuesday, Wednesday, Thursday, Friday,
453 Saturday and Sunday, respectively, while the maximum peak concentration for OC (19:00-3:00)
454 was 1.41, 1.32, 1.38, 1.43, 1.37, 1.31 and 1.43 times higher than the valley concentration (14:00-
455 16:00) for Monday, Tuesday, Wednesday, Thursday, Friday, Saturday and Sunday, respectively. In
456 contrast to previous studies (Grivas et al., 2012; Jeong et al., 2017; Chang et al., 2017), OC and EC
457 exhibited statistically significant higher concentrations on weekends than on weekdays in this study
458 (statistically significant based on the analysis of the weekly data using *t*-test statistics, $p < 0.05$). The
459 average OC and EC concentrations on Saturday and Sunday were $13.2 \pm 11.8 \mu\text{g}/\text{m}^3$ and 3.9 ± 2.7
460 $\mu\text{g}/\text{m}^3$ and $12.0 \pm 10.4 \mu\text{g}/\text{m}^3$ and $3.7 \pm 3.6 \mu\text{g}/\text{m}^3$, respectively, whereas the average OC and EC
461 levels during the weekdays were $11.8 \pm 10.8 \mu\text{g}/\text{m}^3$ and $3.6 \pm 3.5 \mu\text{g}/\text{m}^3$, respectively. This indicates
462 that there is no significant decline in anthropogenic activity in the weekends compared to weekdays.

463 In fact, enhanced anthropogenic emissions could be caused by no limit on driving vehicles based
464 on license plate on weekends. The larger OC and EC concentrations in the weekend are thus mainly
465 attributed to enhanced traffic emissions, which is consistent with higher NO₂ and CO concentrations
466 in the weekend (on average $56.6 \pm 35.9 \mu\text{g}/\text{m}^3$ for NO₂ and $1.16 \pm 1.18 \text{ mg}/\text{m}^3$ for CO on weekdays
467 (number of samples = 29492); $57.8 \pm 37.0 \mu\text{g}/\text{m}^3$ for NO₂ and $1.25 \pm 1.18 \text{ mg}/\text{m}^3$ for CO on
468 weekends (number of samples = 11881)).

469 **3.5 Relationship between OC and EC and with gaseous pollutants**

470 The relationship between particulate OC and EC is an important indicator that can give
471 information on the origin and chemical transformation of carbonaceous aerosols (Chow et al., 1996).
472 Primary OC and EC are mainly derived from vehicular emissions, coal combustion, biomass
473 burning, etc. in urban areas (Bond, et al., 2013). Primary OC and EC could correlate well with each
474 other under the same meteorology. However, the correlation would become gradually less
475 significant with the enhancement of secondary OC formation via complex chemical conversion of
476 VOCs (gas-to-particle or heterogeneous conversion). In addition, it should be noted that EC is more
477 stable than OC (Bond, et al., 2013). Hence, the relationship between OC and EC can to some extent
478 be used as a parameter reflecting the source types and contributions (Blando and Turpin, 2000). Fig.
479 5 presents the regression between the OC and EC concentrations for the PM_{2.5} samples of the
480 separate years 2013 to 2017. Significant correlations (R^2 ranging from 0.87 to 0.66) were observed
481 with the slopes declining from 3.6 to 2.9 throughout the study period. The significant correlations
482 suggest that in most cases OC and EC originated from similar primary sources. The slopes are
483 consistent with the OC/EC ratios ranging from 2.0 to 4.0 for urban Beijing in previous studies (He
484 et al., 2001; Dan et al., 2004; Zhao et al., 2013; Ji et al., 2016). In addition, the average OC/EC
485 ratios observed in this study are comparable to those observed at other urban sites with vehicular
486 emission as a dominant source in China and foreign countries, but lower than those in cities where
487 coal is an important source of the energy needed (Table 3). The decline in the OC/EC ratio may be
488 caused by decline in coal consumption and restriction in biomass burning. Coal combustion,
489 biomass burning and secondary formation give rise to higher OC/EC ratios while vehicular emission
490 result in lower ones (Cao et al., 2005).

491 EC and part of the OC originate from primary anthropogenic emissions, including fossil fuel
492 combustion and biomass burning (Bond et al., 2013), and secondary OC is formed along with ozone
493 formation. Hence, long-term and concurrent measurement of OC, EC, SO₂, NO_x, CO and O₃ is
494 helpful for understanding the emission features or formation processes and for providing tests to
495 current emission inventories. The variation in the OC and EC as a function of the SO₂, NO_x, CO
496 and O₃ concentration is shown in Fig. 6. There is a clear increase in OC and EC with increasing
497 SO₂, NO_x and CO, suggesting that the latter played a role in the enhancement of the former and that
498 these various species shared common sources although they have a different lifetime. OC and EC
499 increased, on average, by approximately 8.9 µg/m³ and 5.7 µg/m³, respectively, with an increase of
500 2 mg/m³ in CO. Considering that CO has a long lifetime (Liang et al., 2004) and that its increase
501 depends on source strength and meteorology, high CO concentrations usually occur in the heating
502 season when unfavorable meteorological conditions prevail. At very high CO concentrations, the
503 increase in OC becomes slower than that in EC. This can be explained by that local emissions
504 became dominant because the unfavorable meteorological conditions corresponding with the high
505 CO concentrations resulted in a weak exchange of air on the regional scale. The OC/EC ratio
506 declined at very high CO concentrations. This could be because vehicular emissions played an
507 important role in the OC and EC loadings (Ji et al., 2019). As documented by previous studies
508 (Schauer et al., 2002, Na et al., 2004), emission of gasoline vehicles results in an OC/EC ratio
509 varying from 3 to 5 while that of diesel vehicles is below 1. The above results are consistent with
510 previous studies which showed that gasoline and diesel vehicles give rise to higher CO emissions
511 (Wu et al., 2016).

512 Given that NO_x and CO have some common emission sources (Hassler et al., 2016), the OC
513 and EC levels were also analyzed in different intervals of NO_x concentrations. Both OC and EC are
514 enhanced with increasing NO_x concentrations. Their enhancements were 5.0 µg/m³ and 2.1 µg/m³,
515 respectively, for an increase in NO_x concentration of 40 µg/m³. Although NO_x are highly reactive
516 and have a short lifetime (Seinfeld and Pandis, 1998) in contrast to CO, the OC/EC ratio also
517 declined at very high NO_x concentrations, be it to a lesser extent than was the case at very high CO
518 concentrations. As was the case for high CO concentrations, more stable meteorological conditions
519 and local emissions became prevailed when higher concentrations of NO_x were observed. In fact,

520 63.5 % of all NO_x emissions come from vehicular emissions based on the statistical data of air
521 pollutant emissions in Beijing
522 (<http://www.bjepb.gov.cn/bjhrb/xxgk/ywdt/zlkz/hjtj37/827051/index.html>).

523 Examining the variation of OC and EC for different intervals of SO₂ concentrations allows us
524 to further study the impacts of industrial production or coal combustion on the OC and EC levels.
525 Similar to the relationship between CO and the carbonaceous species, the OC and EC concentrations
526 enhanced with increasing SO₂ concentrations. Their enhancements were 2.8 µg/m³ and 0.7 µg/m³,
527 respectively, for an increase in SO₂ concentration of 10 µg/m³. An increase in the OC/EC ratio
528 occurred at large SO₂ concentrations, suggesting that coal consumption provided a substantial
529 contribution to the OC and EC levels in Beijing. Because oil with a low sulfur content has been
530 widely used in Beijing since 2008 and little coal was used in the urban areas of Beijing, the SO₂
531 mostly originated from industrial production in the surrounding areas of Beijing and from coal
532 combustion for residential heating in the suburban and rural areas of Beijing. Previous studies also
533 showed that a higher OC/EC ratio is due to coal consumption and not from vehicular emissions
534 (Cao et al., 2005). Hence, coal combustion (for industrial production) on the regional scale led to
535 the enhancement of both the OC/EC ratio and SO₂ concentrations in Beijing via long-range transport.

536 Emissions of primary air pollutants lead through multiple pathways to the formation of ozone
537 and secondary organic carbon (SOC) (Seinfeld and Pandis, 1998), both of which are the principal
538 components of photochemical smog. The relationship between OC and O₃ is of use for
539 understanding their variation and formation. The OC concentrations were highest for an O₃
540 concentration of 50 µg/m³, which is approximately the average O₃ concentration in Beijing in winter
541 (Cheng et al., 2018). During the period of an O₃ concentration of 50 µg/m³, low atmospheric
542 temperature (9.4±9.9 °C), relatively high RH (59.2±23.7 %), lower WS (1.1±0.8 m/s) and higher
543 NO_x concentrations (72.7±57.5 ppb) were observed and a lower mixed layer height was recorded in
544 winter (Tang et al., 2016), which were favorable for accumulation and formation of OC. A relatively
545 lower temperature is beneficial for condensation/absorption of SVOCs into existing particles (Ji et
546 al., 2019), which would then experience further chemical reactions to generate secondary organic
547 aerosol (SOA). Note that a low temperature does not significantly reduce SOA formation rates
548 (Huang et al., 2014) in the winter. In addition, processes including aqueous-phase oxidation and

549 NO₃-radical-initiated nocturnal chemistry may contribute to or even dominate SOA formation
550 during winter (Hallquist et al., 2009; Rollins et al., 2012; Huang et al., 2014). Hence, the above
551 factors gave rise to the higher OC concentration at an O₃ concentration of 50 µg/m³ particularly in
552 winter. In addition, scattering and absorbing effects of aerosols that were trapped in the lower mixed
553 layer height led to less solar radiation reaching the ground and further restrained the O₃ formation
554 in the cold season (Xing et al., 2017; Wang et al., 2016b). OC declined when O₃ concentrations
555 increased from 50 to 100 µg/m³. Usually moderate O₃ concentrations accompanying lower OC
556 concentrations are caused by increasing *T* (19.5±8.3 °C), increasing WS (2.0±1.3 m/s) and less
557 titration of relatively lower observed NO concentrations (6.4±14.6 ppb). It can also be seen that
558 there was a concurrent increasing trend of OC and ozone when the O₃ concentration was above 100
559 µg/m³, which generally occurred in the warmer season. Besides the impact of meteorological
560 conditions, such a trend might not be dominated by gas-to-particle partitioning of low-volatility
561 organic compounds but by the oxidation of VOCs driven by hydroxyl radicals to generate both SOC
562 and O₃ with relatively long lifetimes (>12 h; Wood et al., 2010).

563 **3.6 Impact of atmospheric transport on the OC and EC concentrations**

564 Figs. 7 and 8 show the results of the NWR analysis applied to 1-h PM_{2.5}-associated OC and
565 EC concentrations measured from 2013 and 2017 in Beijing. Fig. S8 presents the gridded emissions
566 of OC and BC for the Beijing-Tianjin-Hebei (BTH) region and China, based on emission inventory
567 (Zheng et al., 2018). The NWR results exhibit distinct hot spots (higher concentrations) in the
568 northeast wind sector at wind speeds of approximately 0-6 km/h, which were closely associated
569 with local emissions under stagnant meteorological conditions (low wind speed), as well as diffuse
570 signals in the southwestern wind sector. The joint probability data in Figs. 7 and 8 show prevailing
571 winds were from N to E and from S to W with wind speeds of approximately 1-6 km/h and of
572 approximately 4-9 km/h, respectively. Note further that the hot spots of OC are broader than those
573 of EC in the graphs of estimated concentrations; this might be due to the fact that the VOCs (the
574 precursors of SOC) emitted from upwind areas at the relatively higher WS in contrast to EC,
575 including the SW wind sector, led to an increase in OC concentrations at the receptor site while the
576 EC concentrations slowly declined due to dilution and deposition.

577 Considering that the NWR analysis can only provide an allocation of local sources, the PSCF

578 analysis is a helpful complement to investigate potential advection of pollution over larger
579 geographical scales (Petit et al., 2017). Fig. 9 presents the PSCF results for OC and EC for the years
580 2013 to 2017. Similar to the NWR analysis, the PSCF results indicated that local emissions and
581 regional transport from southerly areas were important contributors to the OC and EC loadings
582 during the whole study period. Only slight differences in the potential source regions are observed
583 between the different years. In 2013, a clear high potential source area was recorded for both OC
584 and EC; it was located in the southern plain areas of Beijing, particularly in the adjacent areas of
585 the Hebei, Henan, Shandong, Anhui and Jiangsu provinces. This was because there were intensified
586 anthropogenic emissions from those in 2013. The high pollutant emissions were caused by rapid
587 economic growth, urbanization and increase in vehicle population, energy consumption and
588 industrial activity in the southern plain areas of Beijing (Zhu et al., 2018), which resulted in a high
589 aerosol loading in the downwind areas. This result is consistent with previous studies (Ren et al.,
590 2004; Wu et al., 2014; Ji et al., 2018). In contrast to 2013, in the years 2014 to 2017 the high potential
591 source regions for OC and EC stretched to the juncture of Inner Mongolia and the Shaanxi and
592 Shanxi provinces, and even to the juncture of Inner Mongolia and the Ningxia Hui Autonomous
593 Region and of Inner Mongolia and the Gansu province. This is consistent with coal power plants
594 being abundant in the above areas (Liu F. et al., 2015). As well known, coal power plants are also
595 important emitters of SO₂, and those emissions were seen in satellite images (Li et al., 2017; Zhang
596 et al., 2017), thus proving evidence for those sources. The potential source areas for OC and EC
597 were similar in 2013 and 2014. Overall, the potential source areas were more intense for OC than
598 for EC. The emission of OC precursors (i.e., volatile organic compounds) from the Hebei, Henan,
599 Shandong, Anhui, Jiangsu, Shanxi and Shaanxi provinces led to OC concentrations downwind via
600 chemical conversion during the atmospheric transport. The widest potential source areas for OC and
601 EC were recorded in 2016 and they expanded into the eastern areas of Xinjiang Uyghur Autonomous
602 Region. They are probably associated with the economic boom in the western areas of China. In
603 2015, the potential source areas were like in 2013 and 2014 also more intense for OC than for EC.
604 Although the winter action plan was enforced in Beijing, Tianjin and 26 surrounding cities (the so-
605 called “2+26 cities”), whereby the industrial output was curtailed, inspections of polluting factories
606 were ramped up and small-scale coal burning was banned at the end of 2017, there was still a clear

607 spatial difference in emission of air pollutants, with relatively higher PM_{2.5} concentrations in the
608 southern areas of Beijing. Hence, these areas still contributed substantially to OC and EC loading
609 in Beijing.

610 As found in earlier studies (Ji et al., 2018; Zhu et al., 2018), the southern areas of Beijing were
611 main source areas. Despite the ever-stringent air pollution control measures, which are enforced in
612 key areas of China, the economic booming in the western areas of China gave rise to substantial air
613 pollution in the adjacent areas of several provinces and the northwestern areas of China. To further
614 improve the air quality in Beijing, strict emission restrictions should be launched in the above areas
615 and joint control and prevention of air pollution should be enforced on the regional scale. It should
616 be avoided that polluted enterprises, which are closed in key regions, are moved to the western areas
617 of China or to areas where there is no supervision and control of the emission of air pollutants.

618 **4 Conclusions**

619 In this study, hourly mass concentrations of OC and EC in PM_{2.5} were semi-continuously
620 measured from March 1, 2013 to February 28, 2018 at a study site in Beijing. The inter-annual,
621 monthly, seasonal and diurnal variations in OC and EC are presented, the relationship between the
622 carbonaceous species and other pollutants was examined and the source regions were assessed using
623 both NWR and PSCF analysis. The impact of the air pollution control measures and of the regional
624 transport on carbonaceous species in the fine particulate matter was investigated. The following
625 main conclusions can be drawn:

626 (1) OC and EC occupied a high fraction of the observed PM_{2.5} concentrations, making it a dominant
627 contributor of PM_{2.5}. Their concentrations increased with the degrading air quality whereas their
628 percentage in PM_{2.5} declined, which was consistent with previous studies showing that secondary
629 inorganic ions played a relatively more important role in increasing PM_{2.5} concentrations.

630 (2) A clear decline in OC and EC levels was observed after a series of energy policies for air
631 pollution abatement and control had been implemented. To further improve air quality, more
632 synergistic air pollution abatement measures of carbonaceous aerosols and VOCs emissions are
633 needed.

634 (3) OC and EC showed marked seasonal, monthly, weekly and diurnal variations. The seasonal
635 patterns were characterized by higher concentrations in the colder months (from November to

636 February) and lower ones in the warm months (from May to October) of the various years. Because
637 of stringent measures for air pollution abatement, the difference between the winter and summer
638 levels decreased. The EC diurnal pattern was characterized by higher concentrations in the nighttime
639 (from 20:00 to 4:00) and lower ones in the daytime (from 9:00 to 16:00). The higher OC and EC
640 levels during the weekend can be attributed to the traffic regulation in Beijing. The diurnal
641 fluctuation in OC and EC was closely tied to a combined effect of change in emission sources and
642 evolution of the PBL.

643 (4) Significant correlations between OC and EC were observed throughout the study period,
644 suggesting that OC and EC originated from common sources, such as vehicle exhaust, coal
645 combustion, etc. The contribution of coal combustion and biomass burning decreased and this
646 resulted in lower OC/EC ratios. The OC and EC concentrations increased with higher SO₂, CO and
647 NO_x levels, while the O₃ and OC concentrations increased simultaneously for O₃ levels above 50
648 µg/m³.

649 (5) Local emissions and regional transport played an important role in the OC and EC concentrations.
650 Higher concentrations were observed for winds from the northeast sector at wind speeds of
651 approximately 5 km/h, but there were also diffuse signals in the southwestern wind sectors. The
652 potential source regions of OC and EC stretched to the broader areas in northwestern and western
653 regions where coal and coal power plants are abundant. Some slight differences in the potential
654 source regions were observed from 2013 to 2017, which was closely associated with the economic
655 boom in the western areas of China. In addition, the southern areas of Beijing still contributed a lot
656 to OC and EC loading in Beijing.

657 In summary, this study will be helpful for improving the understanding the sources of OC and
658 EC associated with PM_{2.5} and for assessing the effectiveness of local and national PM control
659 measures. In addition, it provides valuable datasets for modelling studies and for assessing the health
660 risk.

1049

1050 Table 2. Mean or median OC and EC mass concentrations (in $\mu\text{g}/\text{m}^3$) observed in major megacities of the world published in the literature and obtained in this study.

1051

1052

Megacities	Method	Period	Number or frequency of sampling	OC	EC	Literature
Athens	TOT	May 2008 to April 2013	Once everyday	2.1	0.54	Paraskevopoulou et al., 2014
Beijing	TOT	March 2017-February 2018	Hourly	7.7	2.6	This study
Hongkong	TOR	from July to October 2014 and December 2014 to March 2015	N=161	7.8	2.2	Chen et al., 2018
Lhasa	TOR	May 2013 to March 2014	once each week	3.27	2.24	Li et al., 2016
Los Angeles	TOT	March 2017-February 2018	once every 3 days	2.88	0.56	US EPA*
Mexico	TOT	March 2006	Hourly	5.4-6.4	0.6-2.1	Yu et al., 2009
Mumbai	TOT	March-May 2007, October-November 2007 and December-January 2007-2008	15 days in a season	20.4-31.3	5.0-9.2	Villalobos et al., 2015
New Delhi	TOR	January 2013 -May 2014	N=95	17.7	10.3	Sharma and Mandal, 2017
New York	TOT	March 2017-February 2018	Once every 3 days	2.88	0.63	US EPA*
Paris	TOT	from 11 September 2009 to 10 September 2010	Once everyday	3.0	1.4	Bressi et al., 2013
São Paulo	TOT	2014	Once each Tuesday	10.2	7	Pereira et al., 2017
Shanghai	TOT	from July 2013 to June 2014	Hourly	8.4	3.1	Xu et al., 2018
Soul	TOT	from January 2014 to December 2014	Hourly	4.1	1.6	Park et al., 2015
Tianjin	TOR	from Dec 23, 2013, to Jan 16, 2014	N=25	30.53	8.21	Wu et al., 2015
Tokyo	TOT	from July 27 to August 15, 2014	Once everyday	2.2	0.6	Miyakawa et al., 2016
Toronto	TOT	December 1, 2010-November 30, 2011	Hourly	3.39	0.5	Sofowote et al., 2014
Wuhan	TOT	From August 2012 to July 2013	Once every six days	16.9	2.0	Zhang et al., 2015
Xi'an	TOR	Four months of 2010	N=56	18.6	6.7	Wang et al., 2015
