

26 **Abstract**

27

28 The aerosol liquid water content (ALWC), an important component of atmospheric particles, has a  
29 significant effect on atmospheric optical properties, visibility and multiphase chemical reactions. In  
30 this study, ALWC is determined from aerosol hygroscopic growth factor and particle number size  
31 distribution (PNSD) measurements and also simulated by the ISORROPIA II thermodynamic model  
32 with measured aerosol chemical composition data at an urban site in Beijing from 8 November to 15  
33 December 2017. Rich measurements made during the experiment concerning virtually all aerosol  
34 properties allow us not only to derive the ALWC but also to study the contributions by various species  
35 for which little has been done in this region. The simulated ALWC including the contribution of  
36 organics and the calculated ALWC are highly correlated (coefficient of determination  $R^2 = 0.92$ ). The  
37 ALWC contributed by organics ( $ALWC_{Org}$ ) accounts for  $30 \% \pm 22 \%$  of the total ALWC during the  
38 sampling period. These results suggest a significant contribution of organics to ALWC, which is rather  
39 different from previous studies that showed negligible contributions by organics. Our results also show  
40 that ALWC correlates well with the mass concentrations of sulfate, nitrate, and secondary organic  
41 aerosols (SOA) ( $R^2 = 0.66, 0.56, \text{ and } 0.60$ , respectively). We further noted that accumulation mode  
42 particles play a key role in determining ALWC, dominating among all the aerosol modes. ALWC is an  
43 exponential function of ambient relative humidity (RH) whose strong diurnal variation influence the  
44 diurnal variation of ALWC. However, there is a three-hour lag between the extremes of ALWC and  
45 RH values, due to the diurnal variations in PNSD and aerosol chemical composition. Finally, a case  
46 study reveals that  $ALWC_{Org}$  plays an important role in the formation of secondary aerosols through  
47 multiphase reactions at the initial stage of a heavy haze episode.

48

49

50

## 51 1. Introduction

52 China has experienced rapid economic developments during the past few decades, resulting in  
53 frequent heavy haze events. Severe air pollution may harm human health and affect the regional  
54 climate through aerosol direct and indirect radiation effects (Li et al., 2016; G. X. Wu et al., 2016).  
55 However, air pollution formation mechanisms and aerosol climate effects remain highly uncertain due  
56 to the complex physical and chemical processes involved (Tao et al., 2012; Y. Wang et al., 2014).

57 Aerosol liquid water (ALW), a component of atmospheric particles in the atmosphere, exists  
58 universally and plays an important role in many atmospheric physical and chemical processes (Nguyen  
59 et al., 2016). For example, ALW can influence aerosol optical properties, resulting in increased  
60 extinction coefficients, lowered atmospheric visibilities, enhanced aerosol optical depths (AODs), and  
61 changes in the direct climatic effect of aerosols (Dougle et al., 1996; Adams et al., 2001; Liao et al.,  
62 2005; Seinfeld and Pandis, 2006). Secondary aerosols (SA) are considered to be the main source of  
63 particulate pollution during heavy haze events in China (Huang et al., 2014). Many studies now  
64 highlight the significance of aerosol liquid water content (ALWC) in the formation of SA through  
65 chemical reactions (e.g., Arellanes et al., 2006; G. Wang et al., 2016; Cheng et al., 2016). This is  
66 because ALW can dilute the absolute concentration of solutes, adjust aerosol acidity, and serve as a  
67 reactant, resulting in increases in trace gas (e.g.,  $\text{N}_2\text{O}_5$  and  $\text{HO}_2$ ) uptake coefficients (Wahner et al.,  
68 1998; Bertram et al., 2009; Abbatt et al., 2012). H. Wang et al. (2017) found that the uptake coefficient  
69 of  $\text{N}_2\text{O}_5$  can be high, which is related to high ALWC in Beijing, thereby increasing the formation of  
70 nitrates. ALW can also speed up the aqueous phase chemical reaction by serving as a reactor for the  
71 transformation of  $\text{SO}_2$  to sulfate (Zheng et al., 2015; G. Wang et al., 2016; Cheng et al., 2016). Some  
72 studies have found that ALWC can facilitate the formation of secondary organic aerosols (SOA)  
73 through aqueous-phase chemistry and photochemistry (Blando et al., 2001; Surratt et al., 2007;  
74 Hennigan et al., 2008; Song et al., 2019). Furthermore, observations in Beijing have shown that  
75 aqueous-phase processes play a dominant role in the additional formation of oxidized SOA (Xu et al.,

76 2017). Overall, investigating the formation of SA and haze in North China requires an examination of  
77 ALWC and its factors in this region.

78 However, directly measuring real-time ALWC is difficult because of technical limitations,  
79 especially under high RH conditions (Kuang et al., 2018). Four indirect methods have been proposed  
80 to calculate real-time ALWC: (1) the aerosol particle number size distribution (PNSD) under dry  
81 conditions and ambient relative humidity (RH) conditions are first measured, then ALWC is calculated  
82 as the difference between dry and ambient aerosol volumes (Stanier et al., 2004); (2) the increased  
83 aerosol volume due to water uptake (i.e., ALWC) is calculated according to the measured dry PNSD,  
84 size-dependent aerosol hygroscopicity, and ambient RH (Kitamori et al., 2009; Bian et al., 2014; Tan  
85 et al., 2017); (3) the dry and ambient aerosol volumes are first estimated using the measured aerosol  
86 optical enhancement and Ångström exponent, then ALWC is calculated as the difference between dry  
87 and ambient aerosol volumes (Kuang et al., 2018); and (4) ALWC is simulated using thermal  
88 equilibrium models such as the ISORROPIA thermodynamic model (Nenes et al., 1998), Aerosol  
89 Inorganics Model models (Wexler and Clegg, 2002), the Simulating Composition of Atmospheric  
90 Particles in Equilibrium model (Kim et al., 1993), and the Gibb's Free Energy Minimization model  
91 (Ansari et al., 1999) with aerosol chemical composition information as input.

92 ALWC mostly depends on aerosol PNSD, chemical composition, and ambient RH. Hodas et al.  
93 (2014) reported that ALWC in the Po Valley in Italy is driven by locally formed anthropogenic nitrates.  
94 The implications for the lifetimes of water-soluble organic compounds and its potential influence on  
95 SOA formation were also discussed. Another study also revealed that ALWC in Beijing was driven by  
96 secondary inorganic aerosols (SIA; Z. Wu et al., 2018). Most previous studies have focused on the  
97 interaction between inorganic salts and ALWC, but the impact of organic species on ALWC been  
98 ignored to our knowledge (Blando et al., 2001; Surratt et al., 2007; Hennigan et al., 2008; Carlton et  
99 al., 2014). A thorough understanding of the association of ALWC with organic aerosols in the  
100 atmosphere is lacking.

101 In this study, ALWC is calculated using the indirect method (2) and simulated using the  
102 ISORROPIA II model, i.e., indirect method (4), discussed previously. The effects of inorganic aerosols,  
103 organic aerosols, PNSD, and ambient RH on ALWC are then investigated separately. We demonstrate  
104 the significant contribution of organics to ALWC in Beijing and provide evidence that the ALW  
105 contributed by organics serves as a reactor for sulfate and SOA formation.

## 106 2. Data and measurements

### 107 2.1. Sampling site

108 The Air Pollution and Human Health (APHH) winter field campaign took place from 8 November  
109 to 15 December 2016 at the Chinese Academy of Sciences' Institute of Atmospheric Physics Tower  
110 Branch in Beijing. Beijing is located in the northwest part of the North China Plain, which has  
111 experienced rapid economic developments during the last few decades. A large amount of gaseous  
112 precursors and other air pollutants are emitted in this region every year, causing serious air pollution  
113 problems. The sampling site is located in the northwestern urban area of Beijing (39.97°N, 116.37°E),  
114 between the north third and fourth ring roads and surrounded by restaurants. Traffic and cooking  
115 emissions are thus the main pollutants at the site. Aerosols at this site can, therefore, well represent  
116 anthropogenic aerosols in highly polluted areas. Sun et al. (2013) and Y. Wang et al. (2017) provide  
117 more detailed descriptions of the sampling site.

### 118 2.2. Instrumentation

119 Sampling instruments used during the field campaign included a scanning mobility particle sizer  
120 (SMPS) equipped with a long differential mobility analyzer (DMA; model 3081A, TSI) and a  
121 condensation particle counter (CPC; model 3772, TSI). A custom-built hygroscopicity tandem  
122 differential mobility analyzer (H-TDMA) was installed in an air-conditioned mobile container at  
123 ground level. The temperature inside the container was maintained at 20–25°C. A high-resolution

124 aerosol mass spectrometer (HR-AMS) was set up in a sampling room located on a two-story roof,  
125 about 25 m north from the container. Sampled air went through a PM<sub>2.5</sub> cyclone inlet fixed on the top  
126 of the container before entering the instruments. The RH of the sampled air was dried to below 20 %  
127 by a dryer system consisting of a tube filled with silica gel and a Nafion dryer (model PD-70T-24ss,  
128 Perma Pure Inc., USA). Various meteorological parameters, including wind speed (WS), wind  
129 direction (WD), temperature (*T*), and RH, were measured from a 325-m meteorological tower located  
130 ~20 m west of the container. In this study, all times are reported in Beijing local time (UTC+8 h).

131 PNSDs with electrical-mobility diameters ranging from 10 to 600 nm were measured by a  
132 scanning mobility particle sizer (SMPS) at a 5-min time resolution. PNSDs were extended to diameters  
133 ranging from 0.6 to 1 μm by fitting the measured PNSDs with functions consisting of three-mode log-  
134 normal distributions (Hussein et al., 2005). Thus generated are PNSDs with a diameter range of 10 nm  
135 to 1 μm.

136 The H-TDMA system developed by the Guangzhou Institute of Tropical and Marine Meteorology  
137 measured the size-dependent aerosol hygroscopic growth factor (GF). The H-TDMA system mainly  
138 consists of four parts. The first part is a Nafion dryer to keep the RH of sampled air below 20 % and a  
139 bipolar neutralizer (soft X-ray, model 3088, TSI Inc.) to equilibrate the particle charge (Wiedensohler  
140 et al., 1988). Next, the sampled air passes through the first differential mobility analyzer (DMA1;  
141 model 3081L, TSI Inc.) to produce mono-dispersed particles. In this study, the diameters were set to  
142 40, 80, 110, 150, and 200 nm. The sampled air then went through a Nafion humidifier (model PD-70T-  
143 24ss, Perma Pure Inc., USA) used to humidify the RH of sampled air to 90 %. The last part of the H-  
144 TDMA is the second DMA (same model as the DMA1) and a water-based condensation particle  
145 counter (model 3787, TSI Inc.), used to measure the number size distribution of humidified particles  
146 in the five selected diameters. Y. Wang et al. (2017) provide a detailed introduction to the H-TDMA  
147 system.

148 Size-resolved non-refractory sub-micron aerosol chemical species, including organics (Org),

149 sulfate ( $\text{SO}_4^{2-}$ ), nitrate ( $\text{NO}_3^-$ ), ammonium ( $\text{NH}_4^+$ ), and chloride ( $\text{Cl}^-$ ), were measured by the HR-AMS.  
150 The sampled air dried by diffusion silica gel dryers was drawn into the HR-AMS through a  $\text{PM}_{2.5}$   
151 cyclone inlet to remove coarse particles larger than  $2.5 \mu\text{m}$ . The HR-AMS was calibrated with pure  
152 ammonium nitrate following the procedures detailed in Jimenez et al. (2003). Sun et al. (2016b)  
153 provide operational details about the HR-AMS.

### 154 3. Method

#### 155 3.1. ALWC calculation based on H-TDMA measurements

156 The ALWC is calculated based on measurements of the aerosol GF and particle number size  
157 distribution. Briefly, H-TDMA data are first used to derive the size-resolved particle GFs at various  
158 RHs. Then ALWC is calculated as the increased aerosol volume due to hygroscopic growth attributed  
159 to water uptake.

160 Chen et al. (2012) show how to calculate size-resolved particle GFs at different RHs. First, a three-  
161 mode log-normal distribution is applied to fit the measured PNSD to produce fitting parameters for  
162 each mode. The hygroscopicity parameter ( $\kappa$ ) in any mode is assumed to be constant. The H-TDMA-  
163 derived size-dependent  $\kappa$  can then be used to deduce the corresponding  $\kappa$  for the nucleation mode, the  
164 Aitken mode, and the accumulation mode of PNSDs according to the following equation:

$$165 \quad \kappa(D_p) = \frac{\sum_{i=1}^3 \kappa_i N_i(D_p)}{\sum_{i=1}^3 N_i(D_p)}, \quad (1)$$

166 where  $\kappa_i$  refers to the  $\kappa$  of the  $i$ th mode, and  $N_i(D_p)$  refers to the number concentration of particles in  
167 the  $i$ th mode. According to  $\kappa$ -Köhler theory (Petters and Kreidenweis, 2007),  $\kappa$  at a certain diameter  
168 ( $D_d$ ) can be calculated as

$$169 \quad \kappa(D_d) = (\text{GF}^3 - 1) \cdot \left[ \frac{1}{\text{RH}} \exp\left(\frac{4\sigma_{s/a}M_w}{RT\rho_w D_d \text{GF}}\right) - 1 \right], \quad (2)$$

170 where RH is the control value by the humidifier in the H-TDMA system,  $T$  is the mean room  
171 temperature of the container set to 293 K,  $\sigma_{s/a}$  is the surface tension of the solution/air interface assumed

172 to be the same as the surface tension coefficient between water and air (about  $0.0728 \text{ N m}^{-1}$  at  $293 \text{ K}$ ),  
173  $M_w$  is the molecular weight of water,  $R$  is the universal gas constant,  $\rho_w$  is the density of water, and  $D_d$   
174 is the diameter of the dry particles. The GF at a given RH is defined as the ratio of the humidified  
175 diameter [ $D_p(\text{RH})$ ] to  $D_d$ :

$$176 \quad \text{GF} = D_p(\text{RH})/D_d . \quad (3)$$

177 The known  $\kappa$  of each mode derives the size-resolved  $\kappa$  at 90 % RH using Eq. (1). Substituting the size-  
178 resolved  $\kappa$  into Eq. (2) results in size-resolved GFs at various RHs. Finally, the volume of ALWC at  
179 ambient RH is equal to the increased aerosol volume due to water uptake, i.e., ALWC can be calculated  
180 as

$$181 \quad \text{ALWC}_{\text{HTDMA}} = \left[ \frac{1}{6} \sum_i n_i D_{p,i}^3 \left( \text{GF}(D_{p,i}, \text{RH})^3 - 1 \right) \right] \cdot \rho_w , \quad (4)$$

182 where  $n_i$  refers to the particle number concentration of dry particles for the corresponding particle size  
183 range in the  $i$ th mode, and  $D_{p,i}$  refers to the particle diameter for the corresponding particle size range.

### 184 3.2. ALWC simulations based on the ISORROPIA II model

185 The thermodynamic equilibrium model ISORROPIA II developed by Fountoukis and Nenes  
186 (2007) using aerosol chemical composition information from the HR-AMS can simulate ALWC  
187 ( $\text{ALWC}_{\text{ISO}}$ ). However, the ISORROPIA II model only considers the contribution of inorganic species  
188 ( $\text{Ca}^{2+}$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{NH}^+$ ,  $\text{Na}^+$ ,  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{Cl}^-$  and  $\text{H}_2\text{O}$ ) on ALWC and neglects the contribution of  
189 organics. In this study, the phase state was assumed to be stable in the model calculation, and the model  
190 was set up to reverse mode due to the lack of measurements of gaseous ammonia.

191 According to the model assumptions that the aerosol curvature effect in Köhler theory is ignored,  
192 and the aerosol water uptake has no effect on ambient vapor pressure, the water activity ( $a_w$ ) defined  
193 as the effective mole fraction of water is equal to the ambient RH in this model (Seinfeld and Pandis,  
194 2006):

$$195 \quad a_w = \text{RH} \quad (5)$$

196 The ALWC can be calculated using the Zdanovskii–Stokes–Robinson (ZSR) mixing rule (Stokes and  
197 Robinson, 1966),

$$198 \quad \text{ALWC}_{\text{ISO}} = \sum_i \frac{M_i}{m_{0i}(a_w)}, \quad (6)$$

199 where  $M_i$  is the mole concentration of the  $i$ th species ( $\text{mol m}^{-3}$  in air), and  $m_{0i}(a_w)$  is the corresponding  
200 molality of the binary solution of the  $i$ th species under the same  $a_w$  with complex solution. Finally,  
201 with measured ambient RH and  $T$  values as input  $\text{ALWC}_{\text{ISO}}$  values under different RH and  $T$  conditions  
202 can be derived.

### 203 3.3. Inferring the contribution of organics to ALWC

204 According to the  $\kappa$ -Köhler theory and the ZSR mixing rule,  $\kappa$  can also be expressed as the sum of  
205 the contributions of each aerosol component:

$$206 \quad \kappa = \sum_i \varepsilon_i \kappa_i, \quad (7)$$

207 where  $\varepsilon_i$  and  $\kappa_i$  are the volume fraction and hygroscopicity of the  $i$ th species, respectively. Submicron  
208 aerosols mainly consist of organic and inorganic species (Carbone et al., 2013; Zieger et al., 2017). As  
209 mentioned in section 2.2, the HR-AMS measures the mass concentrations of organics and inorganics,  
210 including  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{NH}_4^+$ , and  $\text{Cl}^-$ . The volume fraction of inorganic species can be calculated based  
211 on the ion-pairing scheme given by the following equations (Gysel et al., 2007):

$$\begin{aligned} 212 \quad n_{\text{NH}_4\text{NO}_3} &= n_{\text{NO}_3^-}, \\ 213 \quad n_{\text{NH}_4\text{HSO}_4} &= \min(2n_{\text{SO}_4^{2-}} - n_{\text{NH}_4^+} + n_{\text{NO}_3^-}, n_{\text{NH}_4^+} - n_{\text{NO}_3^-}), \\ 214 \quad n_{(\text{NH}_4)_2\text{SO}_4} &= \max(n_{\text{NH}_4^+} - n_{\text{NO}_3^-} - n_{\text{SO}_4^{2-}}, 0), \\ 215 \quad n_{\text{H}_2\text{SO}_4} &= \max(0, n_{\text{SO}_4^{2-}} - n_{\text{NH}_4^+} + n_{\text{NO}_3^-}), \\ 216 \quad n_{\text{HNO}_3} &= 0, \end{aligned} \quad (8)$$

217 where  $n$  represents the mole numbers, and “min” and “max” are minimum and maximum values,

218 respectively. The  $\kappa$  values of the inorganic species sulfuric acid, ammonium sulfate, ammonium  
219 hydrogen sulfate, and ammonium nitrate are 1.19, 0.48, 0.56, and 0.58, respectively (Topping et al.,  
220 2005; Petters and Kreidenweis, 2007). So the ZSR model can be used to estimate the contribution of  
221 inorganic species to the  $\kappa$  value. The hygroscopicity parameter of organics ( $\kappa_{\text{Org}}$ ) can be calculated  
222 using the volume fraction of organics and the total  $\kappa$  value derived from the H-TDMA, according to  
223 Eq. (7). Finally, the ALWC contributed by organic species ( $\text{ALWC}_{\text{Org}}$ ) can be calculated as (Petters  
224 and Kreidenweis, 2007)

$$225 \quad \text{ALWC}_{\text{Org}} = \frac{m_{\text{Org}} \rho_{\text{W}}}{\rho_{\text{Org}}} \frac{\kappa_{\text{Org}}}{\left(\frac{1}{\text{RH}} - 1\right)}, \quad (9)$$

226 where  $m_{\text{Org}}$  is the organic mass concentration from the AMS (Xu et al., 2015), and  $\rho_{\text{Org}}$  is the density  
227 of organics, taken as  $1.4 \text{ g cm}^{-3}$  (Moore et al., 2011; Latham et al., 2013; Cerully et al., 2014).

## 228 4. Results and discussion

### 229 4.1. Comparison of calculated and simulated ALWC

230 The trends in ALWC calculated based on the hygroscopic growth factor and PNSD  
231 ( $\text{ALWC}_{\text{HTDMA}}$ ) and simulated from ISOPPOPIA II model ( $\text{ALWC}_{\text{ISO}}$ ) are generally consistent (Fig.  
232 S1). However, the difference between  $\text{ALWC}_{\text{HTDMA}}$  and  $\text{ALWC}_{\text{ISO}}$  is large at low RH, especially at  
233 ultra-low RH ( $< 30\%$ ). Figure 1a shows that  $\text{ALWC}_{\text{HTDMA}}$  and  $\text{ALWC}_{\text{ISO}}$  agree well and that their  
234 coefficient of determination ( $R^2$ ) is 0.89. The correlation is especially strong for RH over 90%.  
235 However, for RH below 60%,  $\text{ALWC}_{\text{ISO}}$  is less than  $\text{ALWC}_{\text{HTDMA}}$  and even close to 0 in some cases.  
236 Bian et al. (2014) and Tan et al. (2017) observed a similar phenomenon in northern and southern China.  
237 There are two possible explanations for these results. H-TDMA samples were humidified to 90% RH  
238 during the field campaign, thereby leading to the neglect of the deliquescence process in the  
239  $\text{ALWC}_{\text{HTDMA}}$  calculation. This may lead to overestimation of  $\text{ALWC}_{\text{HTDMA}}$  for RH below the  
240 deliquescence relative humidity (DRH). Second, the ISORROPIA II model ignores the effect of  
241 aerosol shape and complex organic species on the DRH. Previous studies have suggested that the

242 particle spherical assumption and simplified aerosol chemical species in this model can overestimate  
243 the DRH (Seinfeld and Pandis, 2006; Sjogren et al., 2007). So for RH below the simulated DRH  
244 (~60 %), particles may still be dry in the ISORROPIA II model, but may have been hydrated in the  
245 real atmosphere. Therefore, this model underestimates ALWC. The ambient aerosol deliquescent  
246 phenomenon is rare in the North China Plain (Kuang et al., 2016). In addition, the ISORROPIA II  
247 model cannot simulate water uptake by organics, which can lead to some bias between simulated and  
248 calculated ALWCs. As described in section 3.3,  $ALWC_{Org}$  can be inferred and used to discuss  
249 differences between  $ALWC_{ISO}$  and  $ALWC_{HTDMA}$ . Figure 1b shows that adding  $ALWC_{Org}$  to  $ALWC_{ISO}$   
250 leads to a stronger correlation with  $ALWC_{HTDMA}$  ( $R^2 = 0.92$ ). The correlation improves significantly  
251 for RH below 60 %. This demonstrates that (1) organic species contribute significantly to ALWC, and  
252 (2) the underestimation of ALWC by the ISORROPIA II model is also related to the neglect of organic  
253 species in the model.

254

## 255 4.2. Impact of different factors on ALWC

### 256 4.2.1. Impact of aerosol chemical species on ALWC

257 Figure 2 shows the characteristics of seven heavy pollution events selected for examination.  
258 Figures 2a and 2c display the time series of WS, WD, and ambient RH. The prevailing wind during  
259 the haze episodes was a weak southerly wind that was favorable for bringing in pollutants from the  
260 highly populated and industrialized neighboring regions to the sampling site. This is beneficial to the  
261 formation and accumulation of SA (T. Wang et al., 2010; Y. Wang et al., 2017). However, the prevailing  
262 winds during the clean events were strong northerly winds that always carried in a clean air mass,  
263 resulting in pollutants being quickly removed (Figure 2c). Note that the  $PM_{10}$  mass concentration  
264 decreases somewhat in the evening during haze episodes, following the short-term change of WD from  
265 southerly to northerly. This is related to mountain-valley breezes in Beijing (Wehner et al., 2008; Gao

266 et al., 2011; Y. Wang et al., 2017). These results demonstrate that heavy haze episodes have a strong  
267 correlation with local wind direction in Beijing.

268 Figures 2a and 2d show the time series of ambient RH and mass concentrations of aerosol chemical  
269 species in  $PM_{10}$ . These figures suggest that the increase in inorganic and organic aerosols is  
270 synchronous with the increase in ambient RH during the heavy pollution periods (P1-P7). This is likely  
271 because of a positive feedback mechanism driven by Henry's law and thermodynamic equilibrium (Z.  
272 Wu et al., 2018). Figure 2b also shows that ALWC continuously increases during the pollution  
273 accumulation period. On average, ALWC increases from 8 to  $89 \mu\text{g m}^{-3}$  as ambient RH increases from  
274 15 to 80 %, and the inorganic and organic aerosol mass concentrations increase from 15 to  $120 \mu\text{g m}^{-3}$   
275 and from 12 to  $78 \mu\text{g m}^{-3}$ , respectively. These results imply that the increase in ambient RH and  
276 aerosol mass concentration are all important for the increase in ALWC.

277 Equation (4) also suggests that the absolute value of ALWC is dependent on the value of ambient  
278 RH and aerosol chemical composition (i.e., the GF value). To further investigate the impact of  
279 chemical composition on ALWC, the impact of RH on ALWC should be accounted for. Previous  
280 studies suggest there is an exponential relationship between ALWC and RH (e.g., Z. Wu et al., 2018).  
281 Here, we define the relative ALWC as the ratio of  $ALWC_{HTDMA}$  and the function of ambient RH ( $e^{bRH}$ ).  
282 Figure 3a shows the relationship between relative ALWC and primary aerosols (PA) or SA mass  
283 concentrations. PA consists of primary organic aerosols (POA) and black carbon (BC), and SA consists  
284 of SOA, sulfate, and nitrate. The relative ALWC is highly correlated with SA mass concentrations ( $R^2$   
285 = 0.94) but poorly correlated with PA mass concentrations ( $R^2 = 0.69$ ). High relative ALWCs  
286 coincident with high SA mass concentrations suggest that SA plays a key role in the increase in ALWC.  
287 This is likely because SA is mainly generated from photochemical reactions in the daytime or reactions  
288 at night, making SA highly aged with a hygroscopicity stronger than that of PA (Ervens et al., 2011;  
289 Sareen et al., 2017). SA can, therefore, absorb more water vapor than PA in the atmosphere. The  
290 enhanced aerosol liquid water induced by SA is further favorable for the formation of SA by speeding

291 up the atmospheric chemical reaction rate and serving as the medium for gas-particle heterogeneous  
292 reactions (G. Wang et al., 2016; Cheng et al., 2016). This further increases the bulk aerosol  
293 hygroscopicity. This is also the reason why inferred  $\kappa$  based on the ZSR model continuously increases  
294 during haze episodes (Figure 2c).

295 Secondary aerosols are mainly composed of nitrate, sulfate, and SOA. To determine which species  
296 is the driver for ALWC in Beijing, Figure 3b shows the correlation analysis between relative ALWC  
297 and the mass concentrations of different aerosol chemical species. Relative ALWC and all SIA agree  
298 well [ $R^2$  equal to 0.66 (sulfate) and 0.56 (nitrate)]. It has been reported that ALWC is driven by  
299 inorganic salts with both nitrate and sulfate playing key roles in determining ALWC (Z. Wu et al.,  
300 2018). ALWC also agrees well with SOA ( $R^2 = 0.60$ ) in our study. This is unexpected because the  
301 hygroscopicity of SOA is relatively lower than that of nitrate and sulfate. Some studies have also  
302 suggested that the water uptake of aged organics accounts for only a few percent of the total aerosol  
303 water uptake (e.g., Gysel et al., 2007; Engelhart et al., 2011). In our study, the contribution of  $ALWC_{Org}$   
304 to total ALWC is significant, accounting for  $30 \% \pm 22 \%$ . Studies of ALWC in Beijing, therefore,  
305 cannot neglect  $ALWC_{Org}$ . This is different from the studies in other regions such as in the Po Valley in  
306 Italy (Hodas et al., 2014) and the eastern U.S. (Carlton et al., 2013) where the ALWC was found to be  
307 only driven by nitrate and sulfate respectively.

308 An interesting phenomenon is frequently observed at the initial stage of heavy haze episodes (e.g.,  
309 P4, P5, P6, and P7).  $ALWC_{ISO}$  is almost close to 0, but both  $ALWC_{HTDMA}$  and  $ALWC_{Org}$  are always  
310 larger than 0, and the organic aerosol mass fraction is high at this stage. These observations reveal that  
311 at the initial stage of heavy haze episodes, the ALWC is mostly contributed by organic species.  
312 Meanwhile,  $\kappa$  is not very low and increases markedly as the  $PM_{10}$  mass concentration increases, which  
313 is unexpected because of the lower hygroscopicity of organic aerosols compared to SIA. Therefore,  
314 some highly hygroscopic substance (i.e., SA) must be generated through multiphase chemical reaction  
315 at this stage. We propose that the liquid water contributed by organic species provides a reactor for the

316 transformation of gaseous precursors to SA at the initial stages of heavy haze episodes, increasing the  
317 uptake of more liquid water by more SA and further accelerating the formation of heavy haze. Section  
318 4.3 provides a case study to demonstrate this.

#### 319 4.2.2. Impact of PNSD on ALWC

320 In addition to aerosol chemical composition, ALWC also depends on PNSD (Bian et al., 2014).  
321 As described in section 3.1, the nucleation mode ( $< 30$  nm), the Aitken mode (30–110 nm), and the  
322 accumulation mode (110 nm to 1  $\mu$ m) (Whitby, 1978; Birmili et al., 2001) are considered in this study.  
323 Particles with diameters greater than 1  $\mu$ m are not considered because most of these large particles are  
324 composed of hydrophobic species (e.g., dust or mineral substances) that contribute little to ALWC  
325 (Hussein et al., 2004; S. Liu et al., 2008; Bian et al., 2014; Tan et al., 2017).

326 Figure S2 in the supplement shows that the contributions of nucleation mode, Aitken mode, and  
327 accumulation mode particles to ALWC are  $< 1.0$  %, 18.0 %, and 82.0 %, respectively. Figure 4 shows  
328 the correlations between  $ALWC_{HTDMA}$  and the volume concentrations of different mode particles, and  
329 the average contribution of different mode particles to  $ALWC_{HTDMA}$  ( $f_{ALWC}$ ) under five different RH  
330 conditions. The  $R^2$  and  $f_{ALWC}$  of the nucleation mode particles (left column in Figure 4) are all less than  
331 0.1 and 1 %, respectively, under all RH conditions. This is likely because the volume concentration of  
332 nucleation mode particles is very low, and most of these small particles are composed of hydrophobic  
333 chemical species such as BC and POA. Similarly, the number concentration of Aitken mode particles  
334 also shows weak correlations with  $ALWC_{HTDMA}$  ( $R^2 < 0.2$ ) under  $RH < 90$  % conditions, but their  
335 correlation ( $R^2 = 0.25$ ) is enhanced significantly under  $RH > 90$  % conditions (middle column of Figure  
336 4). This is because there are more aged particles in the Aitken mode which can absorb much more  
337 water when the ambient RH is higher than 90 %. However, the contribution of the Aitken mode to  
338 ALWC ranges from 14 % to 21 % and decreases as RH increases.  $ALWC_{HTDMA}$  is strongly correlated  
339 to the volume concentration of accumulation mode particles, with  $R^2$  and  $f_{ALWC}$  greater than 0.6 and  
340 75 %, respectively, under all RH conditions (right column of Figure 4). Figure 4 also shows that ALWC

341 increases slightly as the volume concentration of accumulation mode particles increases under RH <  
342 70 % conditions (slope < 0.001), but increases strongly under higher RH conditions, especially under  
343 RH > 90 % conditions (slope = 0.0041). This is likely because there are more accumulation mode SA  
344 formed due to multiphase chemical reactions under high ambient RH conditions. Swietlicki et al.  
345 (1999) have suggested that the contribution of accumulation mode particles to ALWC is largest for all-  
346 mode particles.

347 In summary, the contribution of nucleation mode particles to ALWC is very low. The contribution  
348 of Aitken mode particles is much higher than nucleation mode particles and decreases with increasing  
349 ambient RH. The contribution of accumulation mode particles to ALWC is largest under all RH  
350 conditions and increases with increasing ambient RH, thus playing a key role in determining ALWC.

#### 351 4.2.3. Impact of RH on ALWC

352 As discussed in 4.2.1, the absolute value of ALWC has an exponential relationship with ambient  
353 RH. Figure 5 shows the relationship between ALWC and RH for different PM<sub>1</sub> mass concentration  
354 ranges. ALWC increases slowly as RH increases under lower ambient RH conditions then sharply  
355 increases when RH exceeds a critical RH value. This critical RH value is different for different PM<sub>1</sub>  
356 mass concentrations. This is because the low RH conditions cannot provide enough water for aerosol  
357 particles, even though the PNSD is dominated by accumulation mode particles with higher  
358 hygroscopicity (Tan et al., 2016). This demonstrates the important influence of RH on ALWC. The  
359 lower critical RH value for higher PM<sub>1</sub> mass concentrations (~80 %) suggests that ALWC is easily  
360 formed under heavily polluted conditions. This is likely because there are more SA and accumulation  
361 mode particles during pollution periods (Sun et al., 2016a; Y. Wang et al., 2017).

362 Figure 6a shows the diurnal variations of ALWC<sub>HTDMA</sub> and ambient RH during the sampling  
363 period. The extreme ALWC<sub>HTDMA</sub> values appear at night and during the day respectively, likely related  
364 to the diurnal variations of ambient RH. The elevated ambient RH at night not only increases ALWC  
365 through water uptake of particles directly, but also facilitates the formation of hydrophilic particulate

366 nitrate through the speeding up of the uptake coefficient of  $\text{N}_2\text{O}_5$  (Thornton et al., 2003; Bertram et  
367 al., 2009). This can further enhance ALWC. However, although the diurnal variations of  $\text{ALWC}_{\text{HTDMA}}$   
368 and ambient RH are similar, the peak and nadir of  $\text{ALWC}_{\text{HTDMA}}$  (0300 LT and 1100 LT, respectively)  
369 appear three hours earlier than the peak and nadir of ambient RH (0600 LT and 1400 LT, respectively).  
370 This time difference is likely related to changes in PNSD. The diurnal variation of PNSD (Figure 6b)  
371 shows that the number concentrations of Aitken and accumulation mode particles begin to decrease  
372 quickly at 0300 LT. ALWC also begins to decrease, although the ambient RH increases slightly at that  
373 time. In the morning, ALWC decreases sharply following the ambient RH and PNSD changes due to  
374 the lifting planetary boundary layer height. ALWC decreases to its minimum value at ~1100 LT then  
375 begins to increase quickly. However, ambient RH still decreases at that time and reaches its minimum  
376 value at ~1400 LT. The increase in ALWC is likely associated with changes in aerosol chemical species  
377 and PNSD. Figure 6b and 6c show that there are many newly formed Aitken and accumulation mode  
378 particles and that the fraction of SA increases at noon, likely because of strong photochemical  
379 reactions. Y. Wang et al. (2017, 2018) have suggested that daytime photochemical reactions are  
380 efficient enough to enhance aerosol hygroscopicity and change the aerosol mixing state from external  
381 to internal in North China through the formation of hydrophilic chemical species. All this suggests that  
382 ambient RH is not the only determining factor for ALWC. PNSD and aerosol chemical composition  
383 are also important for ALWC.

#### 384 4.3. A case study of the impact of $\text{ALWC}_{\text{Org}}$ on SA formation

385 As discussed in section 4.2.1, a hypothesis is proposed that  $\text{ALWC}_{\text{Org}}$  maybe provide a reactor for  
386 the formation of secondary species. To verify this hypothesis, the P4 case shown in Figure2 is selected  
387 to further analyze the influence of  $\text{ALWC}_{\text{Org}}$  on the formation of secondary aerosols (Figure 7). Figure  
388 7a shows the time series of  $\text{ALWC}_{\text{HTDMA}}$ ,  $\text{ALWC}_{\text{ISO}}$ , and  $\text{ALWC}_{\text{Org}}$  during this case. On 27 November  
389 2017,  $\text{ALWC}_{\text{ISO}}$  was close to 0 all day long because of the low ambient RH, but both  $\text{ALWC}_{\text{HTDMA}}$  and  
390  $\text{ALWC}_{\text{Org}}$  were always larger than 0, increasing with increasing  $\text{PM}_{10}$  mass concentration (Figure 7a).

391 Figure 7a also shows that the fraction of  $ALWC_{Org}$  in  $ALWC_{HTDMA}$  was high at the initial stage of this  
392 pollution case, but this fraction decreased as haze increased. This case was further divided into three  
393 periods (Figure 7b). Organics were the most abundant chemical species during the first period (64 %),  
394 which explains the high fraction of  $ALWC_{Org}$  in  $ALWC_{HTDMA}$  at the initial stage of this haze case. The  
395 pie charts in Figure 7b also show that both SOA and SIA (sulfate, nitrate, and ammonium) increases  
396 from the first to third periods but POA decreases, likely related to multiphase reactions (i.e., aqueous-  
397 phase reactions) due to the enhanced ALWC. Time series of  $f_{44}$  and the fraction of sulfate in total sulfur  
398 ( $F_{SO_4^{2-}}$ ) are also shown to further illustrate the influence of aqueous-phase reactions on aerosol  
399 chemical species. The  $m/z$  44 signal intensity  $f_{44}$  (mostly contributed by the  $CO_2^+$  ion) measured by the  
400 AMS can be used as an indicator of the oxidation level in organic species (Mei et al., 2013). The sulfur  
401 oxidation ratio  $F_{SO_4^{2-}}$  (Sun et al., 2006) is defined as

$$402 \quad F_{SO_4^{2-}} = \frac{n[SO_4^{2-}]}{n[SO_4^{2-}] + n[SO_2]}, \quad (10)$$

403 where  $n[SO_4^{2-}]$  and  $n[SO_2]$  refer to the molar concentrations of  $SO_4^{2-}$  and  $SO_2$ , respectively. Figure 7b  
404 suggests that  $f_{44}$  and  $F_{SO_4^{2-}}$  both increase gradually with increasing  $ALWC_{HTDMA}$  and  $PM_{10}$  mass  
405 concentration from 27 November to 30 November 2017. This is likely because the increase in ALWC  
406 is beneficial to the oxidation of organics and the transformation of  $SO_2$  to  $SO_4^{2-}$ , implying the  
407 importance of aqueous-phase chemical reaction on haze formation in Beijing. The production of  
408 secondary organic and inorganic species can further enhance aerosol hygroscopicity, increasing ALWC  
409 in the atmosphere. This positive feedback is the reason behind the rapid formation of heavy haze events  
410 in Beijing (G. Wang et al., 2016). A rapid increase in  $f_{44}$  and  $F_{SO_4^{2-}}$  was seen during the first period at  
411 night on 27 November (shown by green and red arrows in Fig. 7) when organics contributed the most  
412 to ALWC. This suggests that ALWC contributed by organics may have played an important role in the  
413 formation of secondary species at the initial stage of the pollution event.

414

## 415 5. Conclusions

416 In this study, the aerosol liquid water content (ALWC) was calculated using the size-resolved  
417 aerosol hygroscopic growth factor and the particle number size distribution (PNSD) measured at a  
418 Beijing urban site during the APHH winter campaign (8 November to 15 December 2017). Also done  
419 were simulations using the ISORROPIA II model with measured aerosol chemical composition data  
420 as input data. During the sampling period, seven heavy haze episodes were selected to investigate the  
421 influence of different factors (PNSD, ambient RH, and aerosol chemical composition) on ALWC.

422 The calculated and simulated ALWC ( $ALWC_{HTDMA}$  and  $ALWC_{ISO}$ ) agree well (correlation of  
423 determination  $R^2$  equal to 0.89). However,  $ALWC_{ISO}$  is much lower than  $ALWC_{HTDMA}$  for RH below  
424 60 %, even approaching zero many times. This deviation is in part attributed to the neglect of the  
425 contribution of organics to ALWC ( $ALWC_{Org}$ ) in the ISORROPIA II model, contradicting with  
426 previous studies ignoring this contribution. The aerosol hygroscopicity of organics was also derived  
427 in this study for use in calculating  $ALWC_{Org}$ . The sum of  $ALWC_{ISO}$  and  $ALWC_{Org}$  has a higher  
428 correlation ( $R^2 = 0.92$ ) with the calculated ALWC (i.e.,  $ALWC_{HTDMA}$ ), especially for RH below 60 %.  
429 This implies that organic aerosols are also an important contributor to ALWC.

430 PNSD, ambient RH, and aerosol chemical composition are all found to affect ALWC significantly.  
431 Nucleation mode and Aitken mode particles have little influence on ALWC. Accumulation mode  
432 particles play a key role in determining ALWC and dominate among all aerosol modes. ALWC is  
433 highly related to the relative humidity (RH) when RH exceeds a critical RH value that is different for  
434 different  $PM_{10}$  mass concentrations. ALWC varies diurnally with its extreme values appearing at night  
435 and during the day respectively. The diurnal variation of ambient RH explains this. However, there is  
436 a three-hour difference between when the extreme ALWC and RH values occur, caused by the diurnal  
437 variations in PNSD and aerosol chemical composition.

438 On average,  $ALWC_{Org}$  accounts for  $\sim 30 \% \pm 22 \%$  of the total aerosol liquid water during the  
439 sampling period. This shows the significant contribution of organic species to ALWC. Our results

440 suggest that ALWC is not only driven by inorganic salts but also driven by organics in Beijing. This is  
441 different from the results obtained in the Po Valley in Italy (Hodas et al., 2014) and the eastern U.S.  
442 (Carlton et al., 2013) where the ALWC is driven by nitrate and sulfate respectively. Finally, one case  
443 study was used to study the importance of ALWC<sub>Org</sub> on multiphase chemical reactions. ALWC<sub>Org</sub> was  
444 found to play an important role in the formation of secondary aerosols by speeding up aqueous-phase  
445 reactions at the initial stage of heavy haze. Our study is important for investigating the contribution of  
446 organics to ALWC and its importance on haze formation in Beijing.

701  
 702 **Figure 1.** Comparison between  $ALWC_{HTDMA}$  and (a)  $ALWC_{ISO}$  and (b) the sum of  $ALWC_{ISO}$  and  $ALWC_{Org}$ .  
 703  $ALWC_{HTDMA}$  refers to calculated ALWC based on the measured growth factor and PNSDs,  $ALWC_{ISO}$  refers to  
 704 simulated ALWC from the ISORROPIA II model, and  $ALWC_{Org}$  refers to the inferred ALWC contributed by  
 705 organic species. The coefficient of determination  $R^2$  is given in each panel. The color of the dots denotes the ambient  
 706 RH; the solid line denotes the 1:1 line.  
 707

708  
 709 **Figure 2.** Time series of (a) wind speed (WS, left y-axis), ambient relative humidity (RH, right y-axis), and wind  
 710 direction (WD, colored dots), (b)  $ALWC_{HTDMA}$  (in blue),  $ALWC_{ISO}$  (in red), and  $ALWC_{Org}$  (in green), (c)  $PM_1$  mass  
 711 concentration (left y-axis) and hygroscopicity parameter ( $\kappa$ , right y-axis) calculated using the ZSR model described  
 712 by Eq. (7), and (d) mass concentrations of aerosol species in  $PM_1$  (left y-axis) and organic aerosol mass fraction

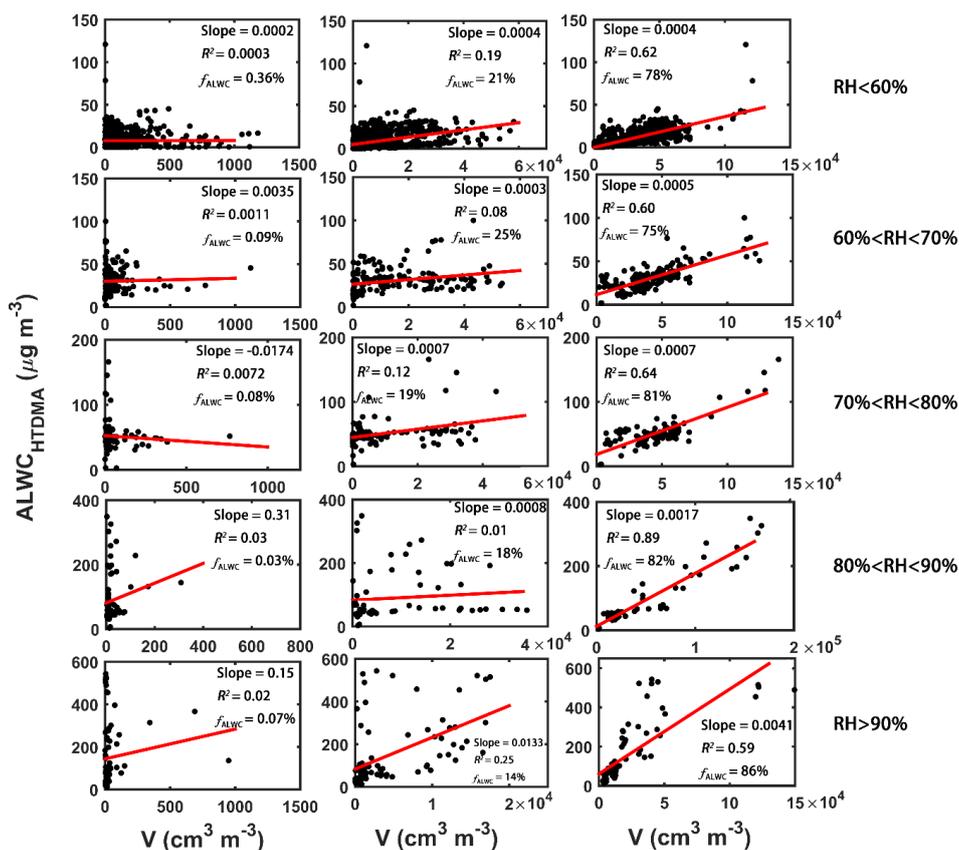

713 (right y-axis). Seven polluted episodes (segments of the time series with a purple background) are selected for  
714 examination.  
715

716  
717 **Figure 3.** The correlation analysis between relative ALWC and (a) primary (in black) and secondary (in red) aerosol  
718 mass concentrations, and (b) nitrate, sulfate, and secondary organic aerosol (SOA) mass concentrations. Panel (a)  
719 shows mean relative ALWCs (solid dots) with boxes showing the 25th, 50th, and 75th percentiles. The extremities  
720 show the 5th and 95th percentiles. The solid lines in (a) and the dashed lines in (b) both represent the corresponding  
721 best-fit lines from linear regression.

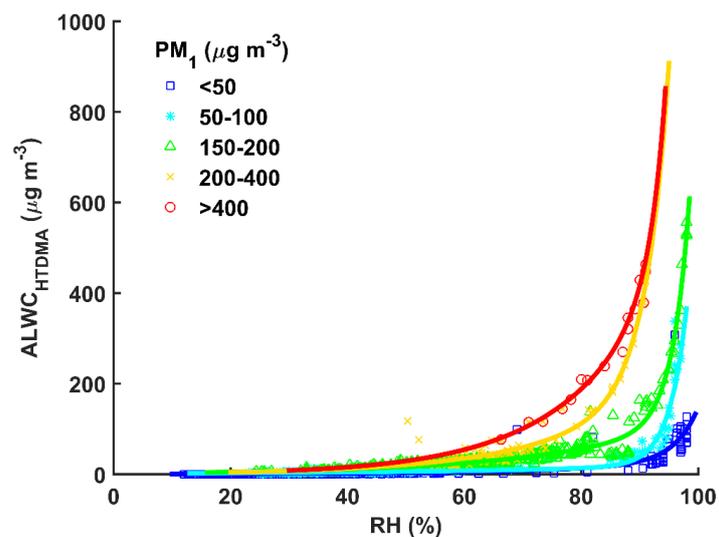

722

723

724 **Figure 4.** The correlation analysis between  $ALWC_{HTDMA}$  and the volume concentration of nucleation mode (left  
 725 column), Aitken mode (middle column), and accumulation mode (right column) particles under different ambient  
 726 relative humidity (RH) conditions. The average contribution of each mode particles to ALWC under different  
 727 ambient RH conditions is denoted by  $f_{ALWC}$ . The red lines represent the best-fit lines from linear regression.

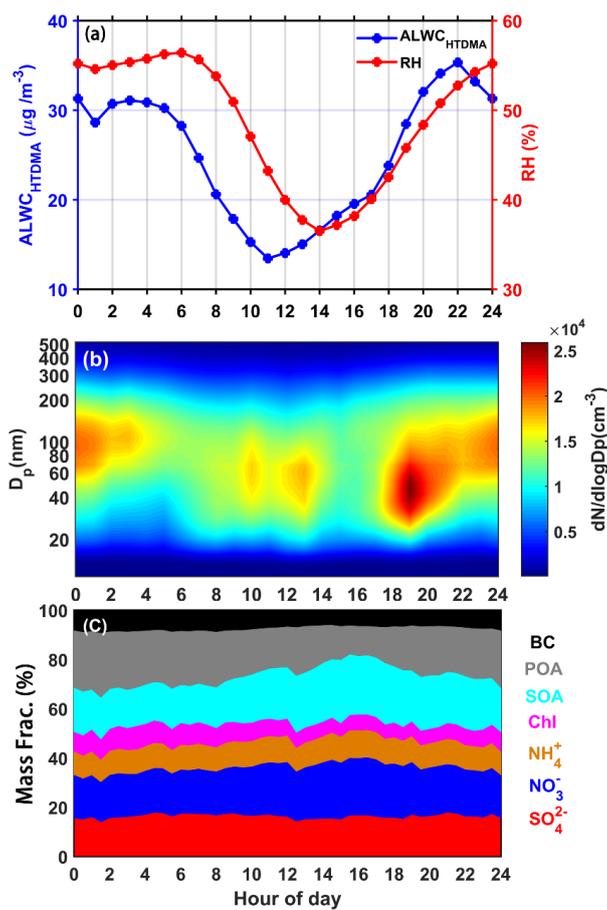

728

729

730 Figure 5. The dots show how  $ALWC_{HTDMA}$  varies with the ambient relative humidity (RH) for different  $PM_1$  mass  
731 concentration ranges (colored symbols). The colored curves represent the best-fit lines through the data using the  
732 fitting function  $y = ae^{bx}$ .

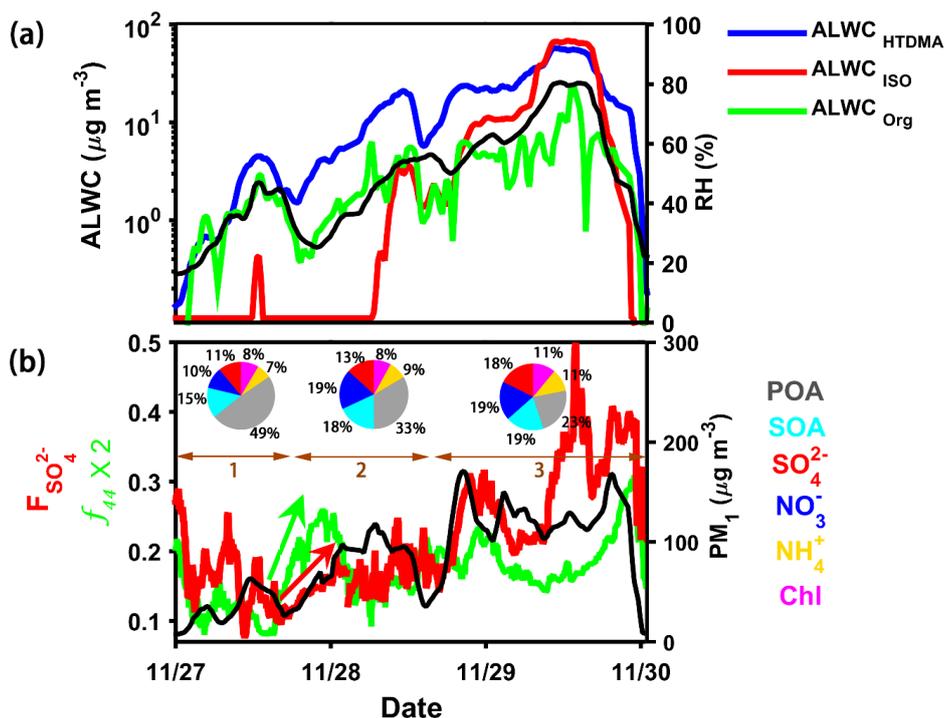

733

734

735 **Figure 6.** Diurnal variations of (a) ALWC<sub>HTDMA</sub> (in blue) and ambient RH (in red), (b) particle number size  
736 distribution, and (c) the mass fraction of different chemical species. The time is in Beijing time.

737

738

739 Figure 7. Time series of (a) ALWC<sub>HTDMA</sub> (in blue), ALWC<sub>ISO</sub> (in red), ALWC<sub>Org</sub> (in green), and RH (right y-axis), and  
 740 (b) the sulfur oxidation ratio ( $F_{SO_4^{2-}}$ ),  $f_{44}$ , and PM<sub>1</sub> mass concentration (right y-axis) during the P4 case in Figure 2.  
 741 The pie charts in (b) represent the average chemical compositions of PM<sub>1</sub> during three stages of the pollution event  
 742 (denoted by brown horizontal lines). The red and green arrows in (b) indicate the rapid increase in  $F_{SO_4^{2-}}$  and  $f_{44}$  at  
 743 the initial stage.
