

23 crustal ions (i.e., Ca^{2+} , Mg^{2+}), Na^+ , and Cl^- showed the highest concentrations in the semi-arid
24 regions and the coastal cities, respectively. The statistical methods confirmed that the mean
25 anthropogenic contribution ratios to SO_4^{2-} , F^- , NO_3^- , and NH_4^+ at a national scale were 46.12%,
26 71.02%, 79.10%, and 82.40%, respectively. However, Mg^{2+} (70.51%), K^+ (77.44%), and Ca^{2+}
27 (82.17%) were mostly originated from the crustal source. Both Na^+ (70.54%) and Cl^- (60.42%) were
28 closely linked to the sea-salt aerosols. On the basis of the stepwise regression (SR) analysis, it was
29 proposed that most of the secondary ions and F^- were closely related to gross industrial production
30 (GIP), total energy consumption (TEC), vehicle ownership, and N fertilizer use, but the crustal ions
31 (Ca^{2+} and K^+) were mainly controlled by the dust events. The influence of dust days, air temperature,
32 and wind speed on ions increased from Southeast China (SEC) to Central China, and then to
33 Northwest China (NWC), whereas the influence of socioeconomic factors on acid ions (SO_4^{2-} and
34 NO_3^-) displayed the higher value in East China.

35 **Keywords:** Water-soluble ions; precipitation; spatiotemporal variation; source identification; China

36 **1. Introduction**

37 Atmospheric wet deposition generally removes efficiently the aerosol particles and dissolved
38 gaseous pollutants from the atmosphere (Garland, 1978; Al-Khashman, 2005; Migliavacca et al.,
39 2005). However, in some regions with severe air pollution, the scavenging of substantial aerosol
40 particles alters the chemical compositions of precipitation and even aggravates the acid deposition
41 (Kuang et al., 2016). Some inorganic ions (i.e., SO_4^{2-} , NO_3^- , NH_4^+ , Ca^{2+}) play significant roles on
42 the terrestrial and aquatic ecosystem via wet deposition; for instance, leading to severe soil (lake)
43 acidification (alkalization), inhibiting the plant growth, and changing the regional climate (Liu et
44 al., 2011; Yan et al., 2010; Larssen and Carmichael, 2000; Larssen et al., 1999). In the past decades,

45 China has been suffered from the severe air pollution along with the population growth and
46 industrialization (Liu et al., 2016a). Therefore, the investigation of the wet deposition status of
47 inorganic ions is of great interest to the public and policy makers (Négrel et al., 2007).

48 A large amount of studies mainly focused on the spatiotemporal variation of the S and N
49 deposition around the world due to their adversely ecological effects in the past decades (Gerson et
50 al., 2016; Clemens 2006; Zhang et al., 2010). Okuda et al. (2005) showed that the SO_4^{2-}
51 concentration in the precipitation exhibited a slight decrease coupling with the decrease of the SO_2
52 concentration in Tokyo during 1990-2012. Hunová et al. (2014) reported that the averagely S
53 deposition flux decreased from 181 kg/ha/year to 100 kg/ha/year in Czech during 1995 and 2011 on
54 the basis of the data in 15 cities. Du et al. (2012) estimated that the wet deposition flux of inorganic
55 nitrogen reached 3.5 kg N/ha/year according to the average of 151 monitoring in the United States
56 during 1985-2012, which were significantly lower than that of China during the same period (11.11-
57 13.87 kg/ha/yr) (Jia et al., 2014).

58 Many researches about the S and N deposition have been extensively performed to date in China
59 in the recent years (Jia et al., 2014; Xu et al., 2015). In the past decades, the anthropogenic emissions
60 of SO_2 , NO_2 , and NH_3 displayed the remarkable increase along with the dramatic increase of fossil
61 fuel and fertilizer consumption in China (Jia et al., 2014; Kuribayashi et al., 2012). It was well
62 documented that the gaseous precursors containing S and N could be transformed into sulfates
63 (SO_4^{2-}), nitrates (NO_3^-), and ammonium (NH_4^+) during ageing in the atmosphere, thereby
64 contributing to the formation of airborne fine particles, of which were considered to be the main
65 reason for the persistent fog and haze pollution in China (Wang et al., 2016a; Qiao et al., 2015). At
66 a city level, Huang et al. (2008) observed that the wet deposition fluxes of SO_4^{2-} , NH_4^+ , and Ca^{2+}

67 displayed the slight decrease from 1986 to 2006 in the urban of Shenzhen, whereas the wet
68 deposition of NO_3^- increased rapidly during the same period. Very recently, Pu et al. (2017) reported
69 that the SO_4^{2-} concentration in the wet deposition of Shangdianzi (a regional background station of
70 Beijing) showed slight decrease during 2003-2014, but the NO_3^- concentration showed an opposite
71 trend. At a regional scale, Pan et al. (2013) observed that the highest S wet deposition was
72 concentrated in the urban and industrial region of Tianjin among of ten sites of North China (NC).
73 Song et al. (2017) suggested that the bulk deposition fluxes were in the order of Chengdu (urban) >
74 Yanting (agricultural area) > Gongga mountain (natural reserve). At a national scale, Jia et al. (2014)
75 firstly found that the wet deposition of N in Southeast China (SEC) showed a significant decrease,
76 whereas it increased slightly in the western of China on the foundation of the data (620 monitoring
77 sites) collected from 120 cities across China during 1990 and 2010. Following this work, Liu et al.
78 (2016) further observed that the serious S deposition (79 monitoring sites) on SEC and Southwest
79 China (SWC). In these studies, the spatial distributions of both S and N were determined using the
80 spatial interpolation method, which generally required substantial monitoring sites (city > 150, and
81 monitoring site > 300). However, these conclusions were obtained based on a small quantity of
82 monitoring sites, which increased the uncertainties of the results. Meanwhile, the monitoring sites
83 in these studies were mainly located on some remote regions such as mountain or rural site rather
84 than the mixture of urban, suburban, and rural sites, which cannot accurately reflect the spatial
85 variations of inorganic ions in China. Moreover, the spatiotemporal variations of other inorganic
86 ions (i.e., K^+ , Ca^+ , Mg^{2+}) remained unclear to date, which were also linked to the acid deposition,
87 as well as the haze pollution in China (Mikhailova et al., 2013; Aloisi et al., 2017; Müller et al.,
88 2015).

89 Based on these field measurements, the ion levels in the deposition across China were believed
90 to be underestimated due to the few ion species measured by previous studies (Liu et al., 2016a),
91 which was closely associated with various emission sources (Kuang et al., 2016). Thus, the source
92 identification should be performed to assess accurately their contributions to the wet deposition
93 (Larssen et al., 1999). Liu et al. (2015b) identified that the Cl^- and NH_4^+ in the precipitation of Tibet
94 were both originated from the marine and crustal source using the geochemical index method. On
95 the basis of the positive matrix factorization (PMF) model, Qiao et al. (2015) showed that fossil fuel
96 combustion and agriculture were the main sources of SO_4^{2-} and NO_3^- in Jiuzhaigou (Sichuan
97 province). In a newly work reported by Leng et al. (2018), they supposed that the combustion of
98 fossil fuels, domestic sewages, and fertilizers were the main sources of the N-bearing ions on the
99 basis of the N isotope analysis. To date, some methods, including geochemical index method,
100 multivariate analyses, and isotope signatures have been utilized to identify the anthropogenic versus
101 natural sources of the inorganic ions in the precipitation. However, these methods suffered from
102 some weaknesses from different standpoints (AlKhatib and Eisenhauer 2017; Shi et al., 2014). For
103 instance, the geochemical index methods cannot estimate the contribution ratios of multiple sources
104 to Ca^{2+} and Na^+ at a spatial scale (Liu et al., 2015b). Despite the advances of multivariate analyses
105 lowering the associated uncertainties, the multi-collinearity still disturbed the predictions of these
106 models (Shi et al., 2014). The isotope signature method was costly and complex, especially for the
107 unconventional stable isotopes (i.e., K, Ca) (AlKhatib and Eisenhauer 2017), which restricted its
108 application at a large scale. Therefore, multiple source apportionment methods should be combined
109 in order to enhance the reliability of the results. Liu et al. (2015) also demonstrated that the
110 geochemical index method coupled with multiple statistics decreased the uncertainties of results.

111 Apart from the source apportionment, the key factor identification for the ions in the wet
112 deposition is also of great importance to reduce the acid deposition. At an early study, Singh and
113 Agrawal (2008) revealed that the significant increase of vehicle emissions contributed to the
114 accumulation of NO₂, which might be an important precursor of acid rain. Allen et al. (2015)
115 observed that some inland cities in arid and semi-arid regions were generally subjected to dust
116 events, which could increase the Ca²⁺ and K⁺ concentrations in the wet deposition. Following this
117 work, Yu et al. (2017a) found that considerable energy consumption, gross domestic production
118 (GDP), and emitted substantial pollutants made China as major regions of acid rain around the world
119 using path analysis and correlation analysis. However, these researches only assessed the limited
120 factors for the inorganic ions in the wet deposition (Yu et al., 2016; Yu et al., 2017a), ignoring the
121 contributions of other socioeconomic and natural factors. Moreover, these researches mainly
122 focused the whole effects of the influential factors on inorganic ions at a national scale, while they
123 did not consider the spatial heterogeneity of the influential factors, resulting possibly in the great
124 deviation of the inorganic ions in the wet deposition for the different regions.

125 Here, the data of nine water-soluble ions in the precipitation including Ca²⁺, Cl⁻, F⁻, K⁺, Mg²⁺,
126 Na⁺, NH₄⁺, NO₃⁻, and SO₄²⁻ in the 320 cities across the whole China were collected during 2011-
127 2016 to examine the characteristics of the main water-soluble ions in the precipitation. Specifically,
128 the objectives of our study were (1) to reveal the spatiotemporal patterns of water-soluble ions in
129 the precipitation recently in China at a national scale; (2) to identify quantitatively the source of the
130 water-soluble ions in the precipitation based on the multiple statistical methods; and (3) to seek out
131 the key factors for the inorganic ions at a spatial scale. This study supplied the systematical data for
132 comprehensive understanding on the inorganic composition in the precipitation based on the long-

133 term field measurement, at a national scale (the 1282 monitoring sites distributed in the 320 cities
134 across the whole China), which was beneficial to the implementation of appropriate strategies to
135 promote environmental protection in China.

136 **2. Materials and methods**

137 2.1 Site description

138 The spatial distribution of field stations in National Acid Deposition Monitoring Network
139 (NADMN) is illustrated in Fig. 1. The selected 1282 monitoring sites are distributed in the 320 cities
140 across 31 provinces. These cities are classified into Northeast China (NEC), NC, SEC, Northwest
141 China (NWC), and Southwest China (SWC) (Tab. S1). Both of NEC and NC show typical
142 temperature monsoon climate, while SEC presents the subtropical monsoon climate. The SWC
143 region suffers from the combined effects of subtropical monsoon climate and tropical monsoon
144 climate. NWC suffers from the temperate continental climate and displays minor rainfall amount.
145 NEC and NC are filled with temperate deciduous forest, whereas SEC is mainly occupied by the
146 subtropical evergreen forest. The subtropical evergreen forest and tropical evergreen forest spread
147 out the SWC region. The NWC is generally filled with expansive grasslands and desert. The
148 latitudes and longitudes of all of 1282 monitoring sites range from 18.25 to 50.78° *N*, and from 79.57
149 to 129.25° *E*, respectively. Annual mean rainfall ranges from 10 to 1853 mm and the annual mean
150 air temperature varies between -6.9 and 24.3 °C. The monitoring sites were designed as a mixture
151 of urban and background sites. 850 monitoring sites are concentrated in urban region, and 432 sites
152 in suburban and rural areas are considered as the background sites.

153 2.2 Sampling and chemical analysis

154 The real-time precipitation was collected by monitors in the field stations as a routine procedure

155 of NADMN. Samples from each monitoring site were collected using wet deposition automatic
156 collectors (diameter 30 cm) installed at 1.5 m above ground level. The cover of the collection
157 instrument opened automatically without delay when the precipitation sensor was activated and
158 closed automatically when precipitation ceased and no water remained on the sensor surface. The
159 sample in each rain event was collected and these samples were collected in all of the monitoring
160 sites simultaneously. Each sample was properly collected during the precipitation event when the
161 wet-only deposition instrument was under the normal condition. After the sampling, the pH and EC
162 values of the samples were measured immediately. The sample pH was measured using a pH meter
163 (MP-6p, HACH, USA) at 20–25°C. The EC value of the precipitation samples was determined by
164 an EC meter (CyberScan, CON1500, USA). After the analysis of pH and EC, all of the samples
165 were contained in the pre-cleaned polyethylene plastic bottles at -18°C in order to prevent the
166 possible transformation by microbes. All of the plastic buckets and the polyethylene plastic bottles
167 were cleaned with deionized water for more than three times and then air-dried in clean room prior
168 to use.

169 All of the precipitation samples were used to analyze the concentrations of the water-soluble
170 ions including NO_3^- , Cl^- , Ca^{2+} , K^+ , F^- , NH_4^+ , Mg^{2+} , SO_4^{2-} , and Na^+ . The microporous membranes
171 (0.45 μm) were employed to remove all of insoluble particulates ($< 0.45\mu\text{m}$) from the precipitation
172 samples before the analysis. The ion concentrations were determined through ion chromatography
173 (Dionex ICS-900) equipped with a conductivity detector (ASRS-ULTRA). The CS12A column and
174 AS11-HC column were applied to determine the cations and anions, respectively. Each sample was
175 measured for more than three times and the relative standard deviation was less than 5% for each
176 ion. Analysis of the blank samples once a month confirmed that the cross contamination in the

177 present research was negligible. For each ion, the analysis of simulated precipitation suggested that
178 the relative bias was lower than 10%.

179 2.3 Data calculation

180 The monthly and annual volume-weighted mean (VWM) concentrations were calculated based
181 on the concentrations of specific ions and precipitation. The monthly and annual VWM
182 concentrations were obtained as follows:

$$183 \quad C_x = \frac{\sum_{i=1}^n (C_i(x) \times P_i)}{\sum_{i=1}^n P_i} \quad (1)$$

184 where C_x denoted the monthly and annual VWM concentration of the given ion; $C_i(x)$ was the
185 concentration of the given ion in the precipitation ($\mu\text{eq/L}$); P_i was the precipitation in individual
186 sample. The monthly and annual VWM pH values were obtained based on the corresponding VWM
187 concentrations of H^+ via Eq. (1).

188 The wet deposition flux of the given ion was calculated using the following Eq. (2)

$$189 \quad D_w = P_t C_w / 100 \quad (2)$$

190 where D_w was the wet deposition flux of the given ion (kg N ha^{-1}); P_t was the total amount of the
191 precipitation events (mm); C_w was the VWM concentration of each ion (mg/L); and 100 was a unit
192 conversion factor.

193 In order to obtain the contributions of various alkaline species to acid neutralization in the
194 precipitation, the neutralization factor (NF) was calculated using the following Eq. (3)-(5)
195 (Kulshrestha et al., 1995):

$$196 \quad NF_{\text{NH}_4^+} = \frac{\text{NH}_4^+}{\text{NO}_3^- + \text{SO}_4^{2-}} \quad (3)$$

197
$$NF_{Ca^{2+}} = \frac{Ca^{2+}}{NO_3^- + SO_4^{2-}} \quad (4)$$

198
$$NF_{Mg^{2+}} = \frac{Mg^{2+}}{NO_3^- + SO_4^{2-}} \quad (5)$$

199 2.4 Source apportionment of ionic species in wet deposition

200 The enrichment factor (EF) has been widely applied to estimate the contribution ratios of the
 201 various sources to the major ions in the previous studies (Lawson and Winchester 1979; Cao et al.,
 202 2009; Lu et al., 2011). In the present study, an ion EF in the precipitation relative to the ion in the
 203 sea was calculated using Na as a reference element as follows:

204
$$EF_{sea} = \frac{(X / Na^+)_{precipitation}}{(X / Na^+)_{sea}} \quad (6)$$

205 where EF_{sea} was the enrichment indicator of a given ion in the precipitation relative to the ion in the
 206 sea; X was the ion in the precipitation; $(X/Na^+)_{precipitation}$ represented the ratio of components in the
 207 precipitation; $(X/Na^+)_{sea}$ denoted the ratio of components in the sea (Keene et al., 1986; Turekian,
 208 1968).

209 The EF value of an ion in the precipitation relative to the corresponding ion in the soil was
 210 calculated following Eq. (7):

211
$$EF_{soil} = \frac{(X / Ca^{2+})_{precipitation}}{(X / Ca^{2+})_{soil}} \quad (7)$$

212 where EF_{soil} represented the EF value of an ion in the precipitation relative to the corresponding ion
 213 in the soil; X denoted an ion in the precipitation; $(X/Ca^{2+})_{precipitation}$ was the ratio of components in
 214 the precipitation; $(X/Ca^{2+})_{soil}$ denoted the ratio of components in the soil (Wei et al., 1991; Wei et al.,
 215 1992; Shi et al., 1996; Zhang et al., 2012; Chen et al., 1992).

216 In order to quantify the anthropogenic source versus natural one of ionic species in the

217 precipitation. The fractions of anthropogenic, marine, and crustal source contributed to the ions in
218 the precipitation were calculated as follows:

$$219 \quad SSF = \frac{(X / Na^+)_{sea}}{(X / Na^+)_{precipitation}} \times 100\% \quad (8)$$

$$220 \quad CF = \frac{(X / Ca^{2+})_{soil}}{(X / Ca^{2+})_{precipitation}} \times 100\% \quad (9)$$

$$221 \quad AF = 100\% - SSF - CF \quad (10)$$

222 where *SSF* represented the fraction of sea salt; *CF* denoted the crustal contribution; and *AF* denoted
223 the anthropogenic fraction. *SSF* was recalculated as the difference between 1 and *CF* when *SSF* was
224 greater than 1; *CF* was recalculated as the difference between 1 and *SSF* when *CF* was higher than
225 1.

226 Factor analysis (FA) has been widely employed to determine the contribution ratios of natural
227 and anthropogenic source to ionic species in the precipitation. First of all, FA was applied to reduce
228 the dimension of original variables (measured ion concentrations in samples) and to extract a small
229 number of principal components to analyze the relationships among the observed variables. All of
230 the factors with eigenvalues over 1 were extracted based on the Kaiser-Meyer-Olkin (KMO) test
231 and the Bartlett's test of sphericity, and were rotated using the Varimax method. The FA factor scores
232 and each ion concentration were treated as independent and dependent variables, respectively. The
233 resultant regression coefficients were employed to convert the absolute factor scores and then to
234 calculate the contribution of each PC source (Luo et al., 2015).

235 2.5 The geographical weight regression (GWR) method

236 Although the relationships between the independent variables and the dependent variables could
237 be calculated using correlation analysis and multiple linear regression analysis (MLR), these

238 methods cannot show the spatial variability of regression coefficients. Thus, the GWR method was
239 applied to explore the effects of socioeconomic factors on wet deposition of inorganic ions in
240 consideration of the spatial correlation. As an indicator to reflect the impacts of socioeconomic
241 factors on inorganic ion depositions, local regression coefficients were obtained using weighted
242 least squares with the following weighting function (Brunsdon et al., 1996):

$$243 \quad \beta(u_i, v_i) = (X^T W(u_i, v_i) X)^{-1} X^T W(u_i, v_i) Y \quad (11)$$

244 where $\beta(u_i, v_i)$ represented the local regression coefficient at city i ; X was the matrix of the
245 influential factors; Y denoted the matrix of the wet deposition fluxes of the water-soluble ions; and
246 $W(u_i, v_i)$ was an n order matrix that the diagonal elements were the spatial weighting of the influential
247 factors. The spatial weight function was calculated via the exponential distance decay form:

$$248 \quad W(u_i, v_i) = \exp(-d^2(u_i, v_i) / b^2) \quad (12)$$

249 where $d(u_i, v_i)$ represented the distance between the location i and j , and b was the kernel bandwidth.

250 2.6 Data source and statistical analysis

251 The data of GDP, gross industrial production (GIP), N fertilizer use, vehicle ownership, urban
252 green space (UGS) during 2011-2016 were collected from China City Statistical Book. Total energy
253 consumption (TEC) during the period were obtained from China Energy Statistical Yearbook, which
254 consisted of the consumption of coal, crude oil, and natural gas. The daily meteorological factors
255 including precipitation, maximum and minimum air temperature, wind speed, air pressure, relative
256 humidity (RH) during 2011-2016 were collected from China Meteorological Data Network. The
257 daily visibility data during 2011-2016 was collected from National Centers for Environmental
258 Prediction (NCEP). The data of dust days were calculated based on the horizon visibility data. The
259 days with the visibility lower than 1 km were treated as the dust days. The daily data of $PM_{2.5}$, PM_{10} ,

260 SO₂, and NO₂ were downloaded from the National Environmental Monitoring Platform
261 (<https://www.aqistudy.cn/historydata/>). These data at a national scale were open access since
262 January 2014. To match the meteorological data at a national scale, the data of air pollutants during
263 2014-2016 were applied to investigate the relationships of the water-soluble ions, meteorological
264 factors, and the air pollutants in the atmosphere (Tab. S2). In addition, the SR analysis was employed
265 to determine the key factors regulating the wet deposition fluxes of the water-soluble ions. All of
266 the statistical analysis were performed by the software package of ArcGIS 10.2, SPSS 21.0, and
267 Origin 8.0 for Windows 10.

268 **3 Results and discussion**

269 3.1 The pH and EC values in the precipitation

270 To obtain the preliminary knowledge about the precipitation characteristics, the basic
271 physiochemical properties including pH and EC of the precipitation samples are presented in Fig.
272 2. The annually pH during 2011 and 2016 ranged from 5.45 ± 0.27 (mean \pm standard deviation) to
273 5.94 ± 0.46 and the mean value was 5.76 (Fig. 2a). Seinfeld (1986) estimated that the precipitation
274 with pH lower than 5.60 was considered as acid rain because the pH value of natural water in
275 equilibrium with atmospheric CO₂ was 5.60. However, the CO₂ level has been increasing in recent
276 years and thus the equilibrium pH has changed (McGlade and Ekins 2015) Therefore, the average
277 CO₂ concentration during 2011-2016 (396.83 ppm) around the world was applied to the present
278 study (<http://www.ipcc.ch/>). The ionization equation of CO₂ include CO₂+H₂O=H₂CO₃ and
279 H₂CO₃=HCO₃⁻+H⁺. The dissociation constant of two equations are 3.47×10^{-2} (K₀) and 4.4×10^{-7} (K₁),
280 respectively. The $(c(H^+))^2 = K_0 \times K_1 \times P_{CO_2} = 6.06 \times 10^{-12}$. Therefore, the equilibrium pH was 5.61,
281 which was slightly higher than the current value (pH = 5.60). Herein, 41% of the samples during

282 the measurement showed the pH value below 5.61. Compared with the pH value of the precipitation
283 during 1980-2000 (Wang and Xu 2009), the pH value of the precipitation showed a remarkable
284 increase in recent years. For instance, the pH value in the precipitation of SWC increased from 3.5-
285 4.0 (the mean value of 1980-2000) to 5.87 during 2011-2016. Although some cities in Hunan and
286 Hubei province (e.g., Chengzhou, Erzhou) still suffered from the severe acid deposition, the mean
287 pH values (4.46) of the two provinces during 2011-2016 were slightly higher than those in 1980-
288 2000 (3.5-4.0). It was well known that precipitation pH was associated with the SO₂ and NO_x
289 emissions (Pu et al., 2017). Due to the implementation of SO₂ control measurements since the 11th
290 Five-year Plan, the SO₂ column concentration over China displayed a marked decrease after 2007
291 based on Global Ozone Monitoring Experiment (GOME), reported by Gottwald and Bovensmann
292 (2011). Based on the bottom-up method, Lu et al. (2010) also supposed that SO₂ emission began to
293 decrease since 2007, in good agreement with the results obtained from the remote sensing. Besides,
294 nearly all of the power plants built newly and the in-use plants have been required to be equipped
295 with advanced selective catalytic reduction (SCR) or selective non-catalytic reduction (SNCR) since
296 2010 (Tian et al., 2013; Lu et al., 2011), resulting in a gradual decrease of the NO_x emission after
297 2010 (China Statistical Yearbook, <http://data.stats.gov.cn/easyquery.htm?cn=C01>). Based on the
298 result of correlation analysis (Tab. S2), the pH value showed the significantly negative correlation
299 with SO₂ and NO₂ in the ambient air especially with the increased RH. Thus, it could be proposed
300 that the pH value of the precipitation in most of the regions of China during 2011 and 2016 were
301 significantly higher than those before 2000 because the SO₂ and NO_x emissions during 2011-2016
302 were lower than those before 2000.

303 The pH value in the precipitation at a national scale exhibited significantly seasonal variation

304 with the highest value in summer (6.57), followed by autumn (5.64), spring (5.49), and the lowest
305 one in winter (5.32) (Fig. 2b). The seasonal variation of pH values in wet deposition was supposed
306 to be linked with the wash-out effect of precipitation on atmospheric particular matters (Xing et al.,
307 2017), which was supported by the positive relevance between pH and precipitation ($p < 0.01$).
308 Besides, the scavenging atmospheric SO₂ by precipitation may also play an important role in the
309 seasonal variation of the pH values (Wu and Han, 2015). The atmospheric SO₂ concentration was
310 the lowest in summer and the highest in winter. The highest atmospheric SO₂ and sulfate
311 concentrations in winter of the north part of China were partially ascribed to the intensive domestic
312 coal combustion for heating (Liu et al., 2016b; Liu et al., 2017).

313 At a spatial scale across the whole China (Fig. 3a), the pH value of the precipitation presented a
314 gradual increase from SEC to NC and NWC. The relatively low pH values in the precipitation were
315 usually observed in YRD (i.e., Huzhou, Ningbo, and Shanghai), Hunan province (i.e., Changde,
316 Changsha, and Loudi), Hubei province (i.e., Wuhan), and Jiangxi province (i.e., Nanchang, Yichun,
317 and Jingdezhen), but the relatively high pH values occurred in NC and NWC, especially in Xinjiang
318 autonomous region (i.e., Changji, Altai, Urumqi and Aksu). Among of the 320 cities, the lowest one
319 and the highest one were located in Huzhou, (3.20, Zhejiang province), and Altai, (6.82, Xinjiang
320 autonomous region), respectively (Fig. 3). Compared with high acidity in some cities of SEC, the
321 acidity of the precipitation in many cities of NC could be largely neutralized by some alkaline ions
322 because the saline-alkali soils were widely distributed in NC (Wang et al., 2014). Some city
323 atmosphere (i.e., Urumqi and Altay) in Xinjiang autonomous region were frequently attacked by
324 local continental dust particles, diluting the precipitation acidity (Rao et al., 2015).

325 The annually mean EC varied from $10.18 \pm 3.21 \mu\text{S cm}^{-1}$ to $13.33 \pm 3.75 \mu\text{S cm}^{-1}$ during the

326 period (Fig. 2a). The EC value was mainly affected by total water-soluble ions in the precipitation
327 and rainfall amount, of which indirectly reflected the cleanliness of the precipitation and the air
328 pollution status. The decrease of EC in recent years suggested that air pollution in China has been
329 mitigated due to the implementation of special air pollution control measures (Wang et al., 2017;
330 Yang et al., 2016). The EC value also presented distinctly seasonal variation and showed the highest
331 value in spring (Fig. 2c), followed by ones in summer and autumn, and the lowest one in winter,
332 which was apparently different from the seasonal pH variation. Among all of the inorganic ions,
333 only Ca^{2+} displayed notable relationship with EC ($p < 0.01$). It was supposed that many crustal ions
334 such as Ca^{2+} could be lifted up and transported to East China by frequent dust storms in spring and
335 summer, thereby leading to the high EC value in the precipitation (Fu et al., 2014). The mean EC
336 value exhibited a significantly spatial variation with the higher ones in Shizuishan ($36.60 \mu\text{S cm}^{-1}$)
337 and Yinchuan ($24.79 \mu\text{S cm}^{-1}$) (Ningxia autonomous region), Wuwei ($60.01 \mu\text{S cm}^{-1}$) (Gansu
338 province), Edors ($28.72 \mu\text{S cm}^{-1}$) (Inner Mongolia autonomous region), and Aksu ($22.06 \mu\text{S cm}^{-1}$)
339 (Xinjiang autonomous region) and the lower one in some remote regions such as Lhasa ($3.42 \mu\text{S cm}^{-1}$)
340 (Tibet autonomous region), Aba ($2.20 \mu\text{S cm}^{-1}$) (Sichuan province) and Diqing ($2.46 \mu\text{S cm}^{-1}$) (Yunnan
341 province) (Fig. 3b). The lowest and highest EC were observed in Aba ($2.20 \mu\text{S cm}^{-1}$) and Wuwei
342 ($60.01 \mu\text{S cm}^{-1}$), respectively (Fig. 3). The cities in the western and northern of Sichuan province,
343 and the southern of Tibet autonomous region presented the lower EC values due to the sparse
344 population and minimal industrial activity. Although TB has received the effects of the industrial
345 emissions and biomass burning from South Asia via a long-range atmospheric transport, most of the
346 pollutants tended to be deposited on the South of Himalayas except persistent organic pollutants
347 (POPs) (Yang et al., 2016b; Dong et al., 2017). The cities with higher EC was generally close to the

348 Taklamakan and Gobi deserts. Strong winds in these deserts stirred a large amount of dusts, and
349 then caused many dust events, resulting in high loading of Ca^{2+} and Mg^{2+} (Wang et al., 2016d). The
350 positive relationship between wind speed and EC also revealed that strong wind promoted the
351 accumulation of crustal ions over China (Tab. S2).

352 3.2 Chemical composition in the precipitation

353 3.2.1 The inter-annual variation of the water-soluble ions

354 The inter-annual variation of the ionic constituents of the precipitation in China during 2011-2016
355 are summarized in Fig. 4. The concentrations of Na^+ , NO_3^- , and SO_4^{2-} increased from 7.26 ± 2.51 ,
356 11.56 ± 3.71 , and 33.73 ± 7.59 $\mu\text{eq/L}$ to 11.04 ± 4.64 , 13.59 ± 2.63 , and 41.95 ± 8.64 $\mu\text{eq/L}$ during
357 2011 and 2014, respectively (Fig. 4a). However, Na^+ , NO_3^- , and SO_4^{2-} concentrations decreased
358 from the highest ones in 2014 to 9.75 ± 2.89 , 12.29 ± 4.02 , and 30.57 ± 7.43 $\mu\text{eq/L}$ in 2016. The
359 concentrations of Ca^{2+} , NH_4^+ , and Mg^{2+} increased from 31.59 ± 8.29 , 14.84 ± 4.63 , and 8.77 ± 2.42 ,
360 to 58.84 ± 10.31 , 41.33 ± 10.26 , and 10.49 ± 3.07 during 2011-2013 (Fig. 4a), whereas they
361 decreased from the peak values in 2013 to 31.20 ± 8.48 , 18.13 ± 4.84 , and 8.93 ± 2.92 $\mu\text{eq/L}$ in
362 2016, respectively. The F^- concentration exhibited gradual decrease from 3.63 to 2.96 $\mu\text{eq/L}$ during
363 2012-2016. However, the K^+ and Cl^- concentration fluctuated during 2011 and 2016 and did not
364 display regularly annual variation.

365 It was well documented that the SO_4^{2-} concentration was closely associated with the SO_2
366 emissions because SO_2 in the ambient air could be transformed into SO_4^{2-} during aging in the
367 atmosphere (Qiao et al., 2015). In the present study, SO_4^{2-} in the precipitation exhibited a marked
368 correlation with SO_2 in the ambient air ($p < 0.01$), especially with the increased RH (Tab. S2). The
369 total SO_2 emissions in China decreased dramatically due to the installation of the flue gas

370 desulfurization (FGD) systems and the closure of less efficient power plants in China since 2012
371 (Li et al., 2017b). At a national scale, the remarkable decrease of the SO_4^{2-} concentration was
372 observed since 2014, which lagged behind the decrease of the SO_2 emission. Such scenario was
373 widely observed in some developed countries such as Japan (Okuda et al., 2005). However, some
374 cities (i.e., Beijing and Baoding) in NC showed the notable decreases since 2012, which
375 corresponded to the decrease of the total SO_2 emission. It was supposed that the electrostatic
376 precipitators (ESP) and fabric filters (FFs) for the sulfates removal were more widely applied to
377 steel and iron plants, and cement production process, both of which were widely distributed in NC
378 (Hua et al., 2016; Wang et al., 2016b). Moreover, coal has been gradually replaced by natural gas
379 for domestic heating in Beijing, resulting in the less SO_2 emission and thus decreasing the SO_2
380 concentration in the ambient air (Pu et al., 2017). Based on the open data downloaded from National
381 Environmental Monitoring Platform, the annually mean SO_2 concentration in Beijing decreased
382 from $22.0 \mu\text{g}/\text{m}^3$ to $9.29 \mu\text{g}/\text{m}^3$ during 2014-2016, in good agreement with the temporal variation of
383 SO_4^{2-} in the precipitation.

384 The NO_x emission decreased rapidly after the upgrading of oil product quality standards, the
385 import denitrification facilities, and the implementation of low- NO_2 burner technologies (Li et al.,
386 2016; Liu et al., 2017). However, the NO_3^- concentration in the precipitation over China only
387 displayed slight decrease during this period, which was in good agreement with the slight decrease
388 of national NO_2 concentration in the atmosphere (Zhan et al., 2018). It suggested that stricter
389 controls on NO_x emissions from power plants might be counteracted by the increase of power plants
390 and energy consumption (Liu et al. 2015a; Wang et al. 2018). Besides, it was assumed that the high
391 NO_3^- in the precipitation resulted from the increase of motor vehicles (Link et al., 2017). Based on

392 the bottom-up method, the estimated NO_x emissions from vehicle exhausts in China linearly
393 increased by 75% since 1998 (Wu et al., 2016). Shandong suffered from the highest vehicle
394 emissions among all of the provinces, of which the NO_x released from vehicle exhausts in Shandong
395 province increased from 477.6 Gg to 513.8 Gg during 2011-2014 (Sun et al., 2016), corresponding
396 to the annual variation of NO_3^- in the precipitation of Jinan and Linyi. The $\text{NO}_3^-/\text{SO}_4^{2-}$ value was
397 recognized as an important index to determine the relative importance of nitrate (mobile) vs. sulfate
398 (stationary) emission in the atmosphere (Arimoto et al., 1996). The value of $\text{NO}_3^-/\text{SO}_4^{2-}$ at the
399 national scale was still lower than 1, suggesting that the contribution of sulfate to the acidity of the
400 precipitation was still higher than that of NO_3^- . Nevertheless, the ratio in the precipitation showed a
401 gradual increase from 0.33 to 0.40 during this period, indicating that the precipitation type in China
402 has evolved from sulfuric acid type to a mixed type controlled by sulfuric and nitric acid.

403 The NH_4^+ level in the precipitation was closely linked to the NH_3 emission because NH_3 tended
404 to be neutralized to form $(\text{NH}_4)_2\text{SO}_4$ and NH_4NO_3 in the atmosphere (Zhang et al., 2016). The
405 anthropogenic emission of NH_3 was mainly derived from fertilizer use, livestock manures, vehicle
406 exhausts, and industrial processes (Kang et al., 2016). Wherein, livestock manures and synthetic
407 fertilizer application were considered as two major source of the NH_3 emission, accounting for 80-
408 90% of total emission (Kang et al., 2016; Xu et al., 2016). The nitrogen fertilizer consumption has
409 decreased since 2013 (<http://www.stats.gov.cn/>), which was in good agreement with the variation of
410 the NH_4^+ concentration in the precipitation. Therefore, the fertilizer consumption could be treated
411 as an important factor for the NH_4^+ level in the precipitation. However, the NH_3 emission from
412 livestock manures estimated by Kang et al. (2016) showed an opposite variation to the NH_4^+ level
413 in the precipitation collected herein. It was probably attributed to the slight decrease of air

414 temperature in the major cities of China during 2011-2013 because the actual NH_3 emission to the
415 atmosphere was sensitive to air temperature (Kang et al., 2016), which has been proved by the
416 correlation analysis (Tab. S2). Apart from the contribution source mentioned above, soil served as
417 major natural sources of the NH_3 emissions (Sun et al., 2014). Teng et al. (2017) demonstrated that
418 urban green space made a great contribution to the NH_3 amount in the atmosphere. In the present
419 study, the urban green space in some cities such as Lianyungang (Jiangsu province) and Qingdao
420 (Shandong province) showed the marked correlation with the NH_4^+ level in the wet deposition.

421 The long-range transport of dust aerosol was considered as the major source of Ca^{2+} and Mg^{2+}
422 in the atmosphere (Fu et al., 2014). Song et al. (2016) reported that the magnitude of dust emissions
423 in spring generally decreased in the past decades. The dust deposition and ambient PM_{10}
424 concentration in the Xinjiang autonomous region also decreased dramatically during 2000-2013
425 (Zhang et al., 2017a). Here, Ca^{2+} and Mg^{2+} in the wet deposition of some cities such as Aksu in
426 Xinjiang autonomous region decreased from 32.37 to 4.80 $\mu\text{eq/L}$ and from 15.80 to 4.81 $\mu\text{eq/L}$
427 during 2011-2016, respectively, corresponding to the decrease of dust deposition. However, the
428 decrease of Ca^{2+} and Mg^{2+} over China significantly lagged behind the reduction of dust deposition.
429 It was well known that the increase of soil particles and dusts due to urbanization might induce the
430 high level of Ca^{2+} and Mg^{2+} in the wet deposition (Lyu et al., 2016). The road mileage in China
431 increased by 25% from 2011 to 2013, while it only showed slight increase (2.52%) during 2013-
432 2016 (<http://www.stats.gov.cn/>). Padoan et al. (2017) also demonstrated that the resuspension of
433 road dust generally showed the highest impact on the emission of the Ca and Mg elements among
434 non-exhaust sources (i.e. tire wear, brake wear, road dust).

435 Both of K^+ and Cl^- were identified as the important tracers for biomass burning and fireworks

436 (Cheng et al., 2014). Nevertheless, the K^+ and Cl^- concentration in the precipitation did not reflect
437 the contribution of biomass burning because biomass burning usually occurred in dry seasons (Zhou
438 et al., 2017b). Furthermore, the K^+ concentration in the precipitation showed significantly
439 relationship with crustal ions (Ca^{2+} ($r = 0.40$, $p < 0.01$) and Mg^{2+} ($r = 0.49$, $p < 0.01$)) (Tab. S2),
440 suggesting that other sources could play important role on the accumulation of K^+ and Cl^- . Chen et
441 al. (2017b) recommended that fugitive dust to be the main source of K^+ when the mitigation
442 measures were seriously implemented. The minor F^- in the wet deposition served as an indicator of
443 coal combustion because fluorine was generally released from coal combustion (Chen et al., 2013).
444 Recently, the F^- emission displayed remarkable decrease because more coal-fired power plants were
445 equipped with FGD and dust removal equipment (Zhao and Luo, 2017), which explained the
446 decrease of F^- in the precipitation of some industrial cities such as Baoding (3.22 to 1.65 during
447 2012-2016), Shijiazhuang (3.18 to 2.73), and Handan (3.88 to 3.53) in Hebei province. Na^+ was
448 generally originated from the transport of sea salt aerosols, fugitive dusts, and the incineration of
449 wastes and fossil fuels (Zhao et al., 2011). The Cl^-/Na^+ value in the precipitation of some coastal
450 cities (i.e. Lishui (1.15), Jiaxing (1.20), Dandong (1.18), Wenzhou (1.18)) were similar to the marine
451 equivalent Cl^-/Na^+ ratio (1.17) (Wang et al., 2015a), suggesting that Na^+ in the precipitation of these
452 coastal cities might be derived from ocean. However, the Cl^-/Na^+ ratios in the precipitation of some
453 regions far from the ocean were significantly higher than marine equivalent Cl^-/Na^+ ratio due to the
454 contribution of coal combustion (Liu et al., 2016b; Liu et al., 2017).

455 3.2.2 The seasonal variation of the inorganic ions in the wet deposition

456 Overall, the mean concentrations of SO_4^{2-} , NO_3^- and F^- in the wet deposition were in the order
457 of winter (SO_4^{2-} , NO_3^- and F^- : 45.74, 19.44 and 6.10 $\mu eq/L$) > spring (42.61, 13.83, and 3.45 $\mu eq/L$) >

458 autumn (28.85, 9.73, and 2.67 $\mu\text{eq/L}$) > summer (19.26, 7.66, and 2.04 $\mu\text{eq/L}$) (Fig. 4b). However,
459 the seasonal variation of inorganic ions still showed the slight difference between North China and
460 South China. The mean concentrations of SO_4^{2-} , NO_3^- and F^- in the precipitation of North China
461 displayed the highest in winter (47.88, 13.79, and 5.24 $\mu\text{eq/L}$), followed by those in spring (47.02,
462 10.18, and 3.64 $\mu\text{eq/L}$), autumn (32.20, 10.08, and 2.73 $\mu\text{eq/L}$), and summer (22.75, 6.29, and 1.69
463 $\mu\text{eq/L}$). However, NO_3^- in South China showed the highest level in spring (27.66 $\mu\text{eq/L}$). It was well
464 known that SO_4^{2-} and NO_3^- were usually generated via the oxidation of SO_2 and NO_2 in the
465 atmosphere, respectively (Yang et al., 2016). The combustion of fossil fuels for domestic heating in
466 winter probably promoted the accumulations of SO_2 and NO_2 in the atmosphere (Liu et al., 2017;
467 Lu et al., 2010). The cities in North China showed the higher SO_4^{2-} and NO_3^- levels in the
468 precipitation of winter compared with those in summer, which were in agreement with the seasonal
469 variations of SO_2 and NO_2 concentrations in the ambient air. It reflected that the combustion of
470 fossil fuels for domestic heating contributed to the accumulation of SO_4^{2-} and NO_3^- and these ions
471 deposited via the rainfall. Nevertheless, the acidic ions in the cities of South China were not always
472 in agreement with those in North because coal combustion for heating in winter was not widespread.
473 The NO_3^- level in South China showed the highest one in spring due to the effects of meteorological
474 factors. The stagnant meteorological conditions including shallow mixing layers, high atmospheric
475 pressure, low precipitation, and low wind speed occurred frequently in winter, thereby trapping
476 more pollutants and elevating the concentrations of SO_2 and NO_2 in the atmosphere (Tai et al., 2010).
477 In contrast, strong solar radiation and turbulent eddies from ocean in summer could promote the
478 dispersion of these pollutants (Antony Chen et al., 2001). For instance, some coastal cities such as
479 Beihai (Guangxi autonomous region) and Haikou (Hainan province) were generally exposed of

480 strong solar radiation and high wind speed, which significantly decreased the SO_4^{2-} and NO_3^-
481 concentrations in the precipitation of summer (Beihai: SO_4^{2-} (6.06) and NO_3^- (7.37); Haikou: SO_4^{2-}
482 (5.33) and NO_3^- (4.96)), whereas they usually displayed the higher value in spring due to the scarce
483 rainfall amount. The F^- concentration in the precipitation displayed the similarly seasonal variation
484 to SO_4^{2-} and NO_3^- , which was likely associated with the higher coal consumption for domestic
485 heating in some industrial cities of NC, NWC, and NEC (Ding et al., 2017).

486 The concentrations of Cl^- , Ca^{2+} , K^+ , NH_4^+ , Mg^{2+} , and Na^+ exhibited the highest values in summer,
487 followed by those in spring and autumn, and the lowest one in winter. The higher concentration of
488 NH_4^+ in the precipitation collected in summer was probably linked to agricultural activities. The
489 widespread utilization of fertilizer in summer have been observed over China (Zhang et al., 2011;
490 Tao et al., 2016), which could increase the NH_3 emission. In addition, the NH_3 emission was
491 sensitive to the air temperature and generally increased with the temperature (Kang et al., 2016).
492 The NH_3 released from agricultural activities could transform to NH_4^+ , especially under the
493 condition of high RH (Li et al., 2013). Thus, the high NH_3 emission and rapid photochemical
494 reaction contribute to the higher NH_4^+ in the precipitation in summer. However, K^+ , Ca^{2+} , and Mg^{2+}
495 displayed higher concentrations in spring and summer, which was probably related to the high
496 loading of fugitive dusts (Zhang et al., 2017c). Lyu et al. (2016) demonstrated that the high
497 temperature coupled with strong wind caused the lower water content in the road, leading to higher
498 tendency of dust re-suspension in the Wuhan summer. In the present study, these crustal ions in the
499 precipitation also showed the higher values in the summer of Wuhan. The high concentration of Na^+
500 and Cl^- in spring and summer was probably attributed to the evaporation of sea salt under the
501 condition of high air temperature (Grythe et al., 2014). It was found that Na^+ in summer were 5.1-

502 10.3 times of those in winter in some coastal cities such as Qingdao (5.96) (Shandong province),
503 Qinhuangdao (9.65) (Hebei province), and Sanya (6.83) (Hainan province).

504 3.2.3 Spatial distribution of the water-soluble ions across the whole China

505 At a spatial scale, the annual mean concentrations of NO_3^- , Cl^- , Ca^{2+} , K^+ , F^- , NH_4^+ , Mg^{2+} , SO_4^{2-} ,
506 and Na^+ ranged from 0.20 to 47.98 $\mu\text{eq/L}$, from 0.27 to 80.86 $\mu\text{eq/L}$, from 0.59 to 157.15 $\mu\text{eq/L}$,
507 from 0.15 to 23.43 $\mu\text{eq/L}$, from 0.11 to 11.64 $\mu\text{eq/L}$, from 0.20 to 84.24 $\mu\text{eq/L}$, from 0.28 to 39.30
508 $\mu\text{eq/L}$, from 0.29 to 191.95 $\mu\text{eq/L}$, and from 0.15 to 39.50 $\mu\text{eq/L}$ during 2011-2016, respectively.

509 All of these water-soluble ions displayed significantly spatial variation, as shown in Fig. 5 and Fig.
510 6.

511 The mean concentrations of the secondary ions (NO_3^- , NH_4^+ , and SO_4^{2-}) showed the highest
512 values in YRD (Changzhou (34.53, 73.40, and 80.47 $\mu\text{eq/L}$) (Fig. 5a-c) and Nanjing (35.62, 17.12,
513 and 49.51 $\mu\text{eq/L}$) and SB (Chengdu (38.08, 65.19, and 57.16 $\mu\text{eq/L}$) and Leshan (25.32, 38.99, and
514 61.24 $\mu\text{eq/L}$), followed by ones in NC (Jinan (11.67, 16.57, and 58.28 $\mu\text{eq/L}$) and Anyang (20.46,
515 41.32, and 22.01 $\mu\text{eq/L}$), and the lowest ones in TB (0.50, 0.91, and 1.44 $\mu\text{eq/L}$) (Lhasa). Many
516 secondary ions exhibited the high concentrations in YRD because of intensive energy consumption
517 and industrial activities (Zhou et al., 2017a). For instance, the total energy consumption of the
518 Jiangsu province was second to Hebei province among all of the provinces in China (Wang 2014).
519 The SO_2 and NO_x emissions from cement plants and iron and steel industries in Jiangsu and Zhejiang
520 province were significantly higher than those in other provinces (Hua et al., 2016; Wang et al.,
521 2016b), which was in coincident to the spatial agglomeration of the SO_2 and NO_2 concentrations in
522 the ambient air of these provinces It has been reported that the acid deposition pattern have moved
523 from SWC to SEC since 2000s (Yu et al., 2017a). However, SB still possessed high concentrations

524 of secondary ions in the precipitation because of high S content in the local consumed coals (Ren et
525 al., 2006). Besides, the unique topographic conditions and unfavorable diffusion conditions
526 facilitated the deposition of regionally transported pollutants stuck by Qinling mountains and Daba
527 mountain (Kuang et al., 2016), although the energy consumption of Sichuan province was much
528 less than those in other provinces (Tian et al., 2013). Moreover, the steady increase use of fertilizer
529 and livestock manures coupled with high air temperature made SB to be one of the NH₃ emission
530 hotspots (Li et al., 2017a). Nevertheless, some remote areas in NWC and SWC such as Lhasa and
531 Abo showed the lower secondary ions due to sparse population and anthropogenic activities (Li et
532 al., 2007). In these regions, these secondary ions were mainly derived from crustal source, and then
533 deposited concurrently in the rainfall events (Niu et al., 2014). Besides, relatively extensive
534 anthropogenic activities such as increased vehicle exhaust might promote the emissions of
535 secondary ions in the tourist season (Qiao et al., 2017). For instance, the number of tourists in Lhasa
536 have been increasing to 11 million until 2015 ([http://www.xinhuanet.com/fortune/2016-
537 01/13/c_1117763885.htm](http://www.xinhuanet.com/fortune/2016-01/13/c_1117763885.htm)), which could boost the slight increase of secondary ions in the wet
538 deposition.

539 F⁻ showed the higher concentrations in NC, YRD, and SB because many coal-fired power plants
540 and iron and steel industries were mainly concentrated in the Hebei and Jiangsu province (Liu et al.,
541 2015a) (Fig. 6a). Besides, Hebei and Jiangsu were two provinces with much higher coal
542 consumptions (Li et al., 2017), which could release large quantity of F⁻ to the atmosphere. Although
543 the power plants and iron and steel industries were relatively scarce in SB, many large phosphorite
544 mines might increase the F⁻ concentration in the precipitation (Wu et al., 2014). As one of the largest
545 phosphorite mine over China, Jinhe phosphorite mine was close to Chengdu, which significantly

546 increased the F⁻ concentration in the precipitation of Chengdu (9.21 µeq/L). Moreover, the high
547 abundance of F⁻ in the local coal (Mianyang: 269.25 µg/g, Guangan: 1061 µg/g) also contributed to
548 the F⁻ emissions (Dai and Ren, 2006; Wang et al., 2016c; Ren et al., 2006). In addition, the F⁻ in the
549 precipitation showed remarkable relevance with T_{max} based on the correlation analysis ($r = 0.12$, p
550 < 0.05). The annually mean air temperature in SB (17.2 °C) were slightly higher than that in Hebei
551 (14.3 °C) and Jiangsu (16.4 °C) province, thereby boosting the F⁻ emission.

552 The high concentrations of Cl⁻ were mainly concentrated on coastal cities such as Shanghai,
553 Lianyungang (Jiangsu province) and Qingdao (Shandong province) (Fig. 6b), indicating the effect
554 of sea-salt sourced from the ocean (Gu et al., 2011; Allen et al., 2015; Grythe et al., 2014). The high
555 Na⁺ concentration not only focused on these coastal cities (Fig. 6c), but also enrich in some arid and
556 semi-arid cities such as Jinchang (35.08 µeq/L) and Gannan (25.51 µeq/L) (Gansu province). It was
557 assumed that the windblown dust originated from Taklimakan Desert could play a vital role on the
558 enrichment of Na⁺ in Inner Mongolia and Hexi corridor because these regions were located on the
559 downwind direction of dust (Engelbrecht et al., 2016). Meanwhile, the evaporation of salt lakes in
560 West China might promote the Na⁺ enrichment in the precipitation (Bian et al., 2017). Besides, the
561 dust event also promoted the elevation of Ca²⁺, especially in Jiayuguan and Guyuan (Gansu province)
562 (Fig. 6d), both of which were located in the Hexi corridor (Allen et al., 2015). The Mg²⁺ presented
563 higher value in some cities (Handan: 36.63 µeq/L, Liupanshui: 39.30 µeq/L) in the Hebei province
564 and Guizhou province (Fig. 6e). The soil in the Guizhou province possessed the highest Mg
565 concentration (843.33 mg/kg) in China (Li et al., 1992), where the Mg²⁺ stored into the soils could
566 be lifted into the atmosphere by strong wind coupled with severe stony desertification (Jiang et al.,
567 2014). Although the Mg concentration in the soil of Hebei province was slightly lower compared

568 with those of Guizhou province, the bioavailable Mg concentration peaked in Hebei province (Hao
569 et al., 2016), which could be inclined to re-suspend into the atmosphere and then deposit with the
570 rainfall in the warm season.

571 3.2.4 Neutralization capacity of the alkaline ions

572 In order to reveal the most important ion for neutralization (Ca^{2+} , NH_4^+ , and Mg^{2+}) in the
573 precipitation, the relative proportion of three NFs in all of the cities are summarized in Fig. 7. The
574 triangular diagram showed that the contribution of three ions were in the order of Ca^{2+} (51.84%) >
575 NH_4^+ (34.14%) > Mg^{2+} (14.02%). The NF ratios of NH_4^+ and Ca^{2+} in China displayed the highest
576 values in summer, followed by ones in spring and autumn, and the lowest one in winter (Fig. 7a). It
577 was supposed that strong acid neutralization were mainly brought about by the alkaline ions via
578 high rainfall. Besides, the neutralization capacity of the alkaline ions reached higher in spring due
579 to the effects of dust events (Wang et al., 2015b). In the present study, the NFs of NH_4^+ and Ca^{2+} in
580 Beijing (NH_4^+ : 0.57, Ca^{2+} : 0.17) and Baoding (NH_4^+ : 0.56, Ca^{2+} : 0.19) showed the markedly higher
581 values in spring. Zhai and Li (2003) also observed that most frequent dust storms generally occurred
582 in NC in spring. However, the NFs of Mg^{2+} (0.70) showed the highest one in winter. Aside from the
583 temporal difference of neutralization, the NFs presented a significantly spatial variation in China
584 (Fig. 7b). The high NFs of Ca^{2+} were mainly concentrated on some cities in NWC such as
585 Bayingolin (0.57) because these arid and semi-arid regions were exposed of periodic Asian dust
586 intrusions (Yu et al., 2017b). In the case of the typical dust events, the content of crustal species
587 such as Ca increased substantially (Chen et al., 2015). Compared with the other regions, the NFs of
588 NH_4^+ showed the higher value in some cities of SWC such as Chengdu (0.55). Kang et al. (2016)
589 demonstrated that the NH_3 emissions in Sichuan province were significantly higher than those in

590 other provinces of China, accounting for more than 10 % of the total emission from livestock
591 manures. The NFs of Mg^{2+} peaked in NC, which was in good agreement with the higher
592 concentration of Mg^{2+} in the wet deposition of NC. The higher concentration of bioavailable Mg^{2+}
593 in the soil was beneficial to increase the neutralization capacity of Mg^{2+} in the wet deposition (Hao
594 et al., 2016), although the SO_2 and NO_2 emissions in NC were significantly higher than those in
595 other regions (Fu et al., 2016).

596 3.3 Comparisons of pH, EC, and the inorganic ion concentrations with the previous studies

597 The annual mean pH, EC and the inorganic ion levels in the precipitation of some metropolitans
598 across China are summarized in Tab. 1. The mean pH values of the most cities in SEC and SWC
599 (i.e., Shanghai: 4.39 and Wuhan: 4.68) were lower than those in some remote areas such as
600 Jiuzhaigou (5.95) and Yulong mountain (5.94) (Qiao et al., 2018; Niu et al., 2014), while the average
601 pH values of some cities in NC and NWC such as Zhengzhou (6.09) and Urumqi (6.13) were slightly
602 higher than those in remote areas. It was assumed that the remote areas were less affected
603 anthropogenic source except local tourist activities, while high aerosol emissions were mainly
604 centered on some metropolitans of SEC and SWC. The pH of the precipitation in Zhengzhou (pH =
605 6.09) (Henan province) and Urumqi (pH = 6.13) (Xinjiang autonomous region) showed high value
606 compared with some remote regions because of the strong neutralization capacity of alkaline ions
607 (Wang et al., 2014). Besides, the pH values in the wet deposition of most metropolitans in China
608 were also lower than those in some developing countries (e.g., Guaiba: 5.92, Petra: 6.80) (Tab. 1).
609 It was supposed that SO_2 and NO_x emitted from industrial and vehicle emissions in China could be
610 higher than those in some countries such as Brazil and Jordan (Wu and Han 2015). In addition,
611 higher abundance of the neutralizing components in Jordan tended to increase pH of the

612 precipitation. On the other hand, the pH values of the wet deposition in most cities of China were
613 significantly higher than those in some cities of developed countries such as Sardinia (pH = 5.18)
614 (Italy) and Adirondack (pH = 4.50) (United States). It was assumed that many Western countries
615 were faced up with severe acid issue due to the rapid industrialization before 2002 (Sickles II and
616 Shadwick 2015). In addition, the annually mean rainfall amount in some cities of East China were
617 higher than those in Sardinia and Adirondack, which could dilute the acidity of the precipitation
618 (Tsai et al., 2011). The mean EC in the wet deposition of most cities over China were approximate
619 to those in some remote regions (i.e., Yulong Mountain, Jiuzhaigou), and some foreign cities such
620 as Guaiba, Brazil. However, Lanzhou (EC = 58.06 $\mu\text{S cm}^{-1}$) (Gansu province) and Petra (EC = 160
621 $\mu\text{S cm}^{-1}$) (Jordan) showed remarkably higher value than other cities, suggesting that the dust
622 cyclones from Taklamakan and Khamaseen played vital roles on the EC and chemical composition
623 in the precipitation (Abed et al., 2009).

624 The concentrations of NO_3^- , SO_4^{2-} , and NH_4^+ in the most cities of China except Qingdao
625 (Shandong province) and Lhasa (Tibet autonomous region) were significantly higher than those in
626 some natural reserve areas such as Jiuzhaigou, Yulong Mountain, and Nam Co (Qiao et al., 2018;
627 Niu et al., 2014) (Tab. 1), suggesting the local point and non-point emissions in these cities played
628 important roles on the concentrations of inorganic ions in the precipitation. However, the
629 concentrations of these inorganic ions in the most cities were lower than those in foreign cities such
630 as Singapore, Petra (Jordan), Tokyo, and Newark (United States) (Balasubramanian et al., 2001; Al-
631 Khashman et al., 2005; Okuda et al., 2005; Song and Gao 2009), indicating the effects of restricting
632 emissions of air pollutants since Chinese 12th Five-Year Plan (Liu et al., 2016a). However, some
633 cities including Shenyang (Liaoning province) and Chengdu (Sichuan province) were still faced up

634 with severe acid deposition. On the whole, the concentrations of the crustal ions (Ca^{2+} and Mg^{2+})
635 were in the order of the arid and semi-arid cities/regions (Nam Co, Urumqi, Lanzhou, and Petra) >
636 the inland cities and natural reserve regions (Chengdu and Yulong mountain) > the coastal cities
637 (i.e., Guaiba, Singapore, and Tokyo). Kang et al. (2016) reported that Tibetan Plateau have been
638 frequently affected by dust events under the condition of climate change in the past decades, which
639 probably increased the Ca^{2+} and Mg^{2+} levels in Nam Co. However, it should be noted that some
640 coastal cities such as Patras (Greece) and Sardinia (Italy) possessed higher Ca^{2+} and Mg^{2+} levels,
641 which was probably attributed to the long transport of the dust from of the Sahara desert (Kabatas
642 et al. 2014). Cabello et al. (2016) demonstrated that African air masses mostly reached some coastal
643 cities of Mediterranean on the basis of back-trajectory analysis.

644 3.4 The source apportionment of the ions in the precipitation across China

645 3.4.1 EF and geochemical index method

646 The mean values of EFs (seawater and soil), SSF and CF in all of the cities are listed in Tab. 2.
647 The water-soluble ion was treated to be enriched relative to the reference source when the EF value
648 of the ion was significantly higher than 1.00, whereas it was considered to be diluted when the EF
649 value of the ion was not much higher than 1.00. In the present study, the mean EF_{sea} for Na^+ , Cl^- ,
650 SO_4^{2-} , NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , NO_3^- , and F^- over China were 1.00, 1.13, 7.22, 10.51, 16.16, 18.18,
651 231.56, 3507.49, and 5864.28, suggesting that Cl^- and Na^+ in the precipitation were enriched in the
652 marine origin at a national scale. The mean EF_{soil} of Mg^{2+} , K^+ , Ca^{2+} , Na^+ , SO_4^{2-} , F^- , NO_3^- , NH_4^+ , and
653 Cl^- reached 0.55, 0.83, 1.00, 1.83, 5.13, 9.96, 59.36, 86.31, and 169.88, indicating that Ca^{2+} , K^+ , and
654 Mg^{2+} were considered to be originated from the crustal source. Both of the EF_{sea} for SO_4^{2-} and NO_3^-
655 showed significantly spatial variability and they presented the higher ones in YRD and SB

656 (significantly higher than 1) (Fig. 8a-b), which suggested that both of the ions were not mainly
657 sourced from the sea source. However, EF_{sea} for SO_4^{2-} in some cities such as Nujiang (0.92) and
658 Nanchong (0.81) were lower than 1. It was assumed that the Indian monsoon played an important
659 role on the wet deposition of SO_4^{2-} (Gu et al., 2016). Except SO_4^{2-} and NO_3^- , EF_{sea} for other ions
660 showed relatively uniform distribution at a national scale. EF_{sea} for NH_4^+ , F^- , Ca^{2+} , K^+ , and Mg^{2+} in
661 most of the cities were higher than 1 (Fig. 8c and S1), indicating the effects of anthropogenic source
662 or crustal source. The EF_{sea} for Cl^- presented the lower value in many coastal cities such as Beihai
663 (0.53) and Haikou (0.52), while they were significantly higher than 1 in some inland cities such as
664 Daqing (13.11). The spatial variability of EF_{sea} for Cl^- confirmed the spatial difference of Cl^-/Na^+
665 between coastal cities and inland ones mentioned above. Compared with EF_{sea} , the EF_{soil} of ions
666 generally displayed remarkably spatial variation. The EF_{soil} of SO_4^{2-} , NO_3^- , F^- , and Cl^- showed
667 notably higher values in SEC, implicating the effects of industrial activity (Fig. 8a-b and S2a-b).
668 The EF_{soil} of NH_4^+ presented markedly higher value in the eastern region of Inner Mongolia and
669 Heilongjiang province such as Hegang (325.69) (Fig. 8c) because intensive grazing was beneficial
670 to the NH_3 emission (Kobbing et al., 2014). It was interesting to note that the EF_{soil} of Na^+ showed
671 higher value in some cities around Qinghai Lake and the evaporation of salt lake could contribute
672 to the higher EF_{soil} of Na^+ (Fig. S2c). The EF_{soil} of crustal ions such as Mg^{2+} and K^+ in NWC were
673 close to 1, reflecting the contributions of dust events and soils (Fig. S2e-f).

674 Based on the EF_{sea} and EF_{soil} , the estimated SSF, CF, and AF of ions are depicted in Fig. 9, S3,
675 and S4. The mean SSF values of NO_3^- , F^- , Ca^{2+} , NH_4^+ , Mg^{2+} , K^+ , SO_4^{2-} , Cl^- , and Na^+ were 0%,
676 0.02%, 0.06%, 0.10%, 2.94%, 4.88%, 13.85%, 88.31%, and 100%, respectively. The average CF
677 values of NH_4^+ , NO_3^- , Cl^- , F^- , SO_4^{2-} , Na^+ , K^+ , Mg^{2+} , and Ca^{2+} reached 0.01%, 0.02%, 0.59%, 10.04%,

678 19.50%, 35.34%, 95.12%, 97.06%, and 99.94%, respectively. The AF value was considered to be
679 the contribution ratio of each ion except SSF and CF. The AF values of Ca^{2+} , K^+ , Mg^{2+} , Na^+ , Cl^- ,
680 SO_4^{2-} , F^- , NH_4^+ , and NO_3^- reached 0%, 0%, 0%, 0%, 11.10%, 66.65%, 89.94%, 99.89%, and 99.98%,
681 respectively. The results suggested that NO_3^- , SO_4^{2-} , NH_4^+ , and F^- were mainly sourced from
682 anthropogenic activities based on minor SSF and CF. It was well documented that the combustion
683 of fossil fuels, iron and steel industrial emission, and vehicle exhaust were main sources of SO_4^{2-}
684 and NO_3^- across China (Song et al., 2006; Yang et al., 2016). In the present study, the AF values of
685 NO_3^- in all of cities were higher than 90%, and those of SO_4^{2-} in half of the cities were higher than
686 60%. Besides, the utility of nitrogen fertilization, and human and livestock excretions were treated
687 as the main source of NH_4^+ emission over China (Cao et al., 2009). Herein, 82.5% of cities across
688 China showed the higher AF value of NH_4^+ (> 90%). Ca^{2+} , K^+ , and Mg^{2+} were mainly derived from
689 crustal origin based on the high CF values. Although the K^+ concentration in the fine particles was
690 usually sourced from biomass burning, the component in the coarse particles generally resulted from
691 the soil erosion and dust re-suspension (Cao et al., 2009). The higher CF values of K^+ in most of
692 cities in China such as Aksu (Xinjiang autonomous region) and Bayin (Gansu province) suggested
693 that the wet deposition has become the main removal mechanism for the K^+ in the coarse particles
694 (Lim et al., 1991). The Na^+ and Cl^- ions were mainly originated from sea source because they were
695 main components of sea-salt and sea-spray aerosol (Prather et al., 2013), which was also supported
696 by the higher SSF value.

697 At a spatial scale, the highest AF values of NO_3^- , SO_4^{2-} , NH_4^+ , and F^- were mainly concentrated
698 on East China and SWC (Fig. 9a-c, S3a-c), which was similar to the spatial variation of population.
699 The emissions of aerosols and their precursors released by human activities were mainly

700 concentrated on East China (Fu and Chen 2016), thereby leading to high AF values of these
701 secondary ions. Indeed, many cities in NC such as Handan and Shijiazhuang showed the higher AF
702 value, which revealed the effects of power plant, non-ferrous smelting, and coal mining. The SSF
703 value of Cl^- exhibited high value in Xinjiang and Qinghai province (i.e., Altay and Haibei), SWC
704 (i.e., Chengdu and Guangan) (Fig. S3d-e), and some coastal cities (i.e., Ningbo and Shanghai). The
705 higher SSF values of Cl^- in SWC and coastal cities of East China were mainly controlled by Indian
706 monsoon and East Asia monsoon driven atmospheric transport, respectively (Gu et al., 2016).
707 However, it was assumed that the higher SSF value of Cl^- in the region close to Qinghai Lake could
708 be linked to the evaporation of saline (Bian et al., 2017). However, the relatively higher CF value
709 of Cl^- was centered on Ningxia autonomous region and Shaanxi province, which was frequently
710 exposed of Aeolian dust especially under the process of wind erosion (Lyu et al., 2017). As the
711 typical crustal ions, K^+ and Mg^{2+} in the most regions of China generally showed high CF values,
712 especially in some cities of SWC (i.e., Guiyang, Zunyi, Zhaotong) (Fig. S4a-d). It was supposed
713 that the severe soil erosion and loss, and rocky desertification frequently observed in Yungui Plateau
714 contributed to the higher CF value in this region (Jiang et al., 2014). The SSF of K^+ and Mg^{2+}
715 showed high values in some coastal cities (i.e., Sanya and Ningbo), and some cities of NWC such
716 as Haibei (Qinghai). The evaporation of salt in East China Sea and Qinghai Lake could play a vital
717 role on the K^+ and Mg^{2+} in these areas (Bian et al., 2017).

718 It should be noted that the geochemical index method showed some uncertainties for the
719 estimation of SSF, CF, and AF. First of all, the background values of Na^+ in the sea and Ca^{2+} in the
720 soil displayed the higher uncertainty, which varied significantly with the study areas. Unfortunately,
721 the background values of Na^+ and Ca^{2+} over China were absent. Besides, the source classification

722 might be not very accurate because many other sources such as forest fire, volcanic eruption were
723 ignored.

724 3.4.2 The FA-MLR analysis

725 In order to enhance the reliability of source identification, the FA method was also utilized to
726 identify the source of chemical compositions in the precipitation. The FA results of four seasons are
727 summarized in Tab. 3. Three principal components were extracted from the rainwater samples, all
728 of which explained 85.6% of the total variance. The Kaiser-Meyer-Olkin indicator (0.85) was higher
729 than 0.7, suggesting that three factors extracted in the present study was reasonable. Factor 1
730 grouped NO_3^- , F^- , NH_4^+ , and SO_4^{2-} , accounting for 52.3% of the variance, which was generally
731 associated with dense anthropogenic activities (Nayebare et al., 2016; Zhang et al., 2017b). Factor
732 2 displayed high loadings of Na^+ and Cl^- , indicating the effects of sea-salt and sea-spray aerosol
733 (Gupta et al., 2015). The result was also in good agreement with the high SSF value of Na^+ and Cl^-
734 supported by geochemical index method. Factor 3 occupied 9.54% of the total variance and was
735 dominated by Ca^{2+} , Mg^{2+} , and K^+ . The former two ions were considered to be the important
736 indicators of crustal origin or windblown dust source, which were commonly stored in soils and
737 dusts (Kchih et al., 2015). K^+ was also observed in urban fugitive dusts, although it was generally
738 considered as an important fingerprint of biomass burning (Shen et al., 2016). As a whole, the result
739 of FA was in coincident with that obtained from the EF and geochemical index method.

740 Although the key origins were isolated via the FA method, the contribution ratio of these
741 sources to the water-soluble ions were still unknown. Thus, the FA-MLR method was further applied
742 to quantify the contribution ratio of several sources to these ions in the 320 cities over China (Fig.
743 10a-d). In four seasons, the mean contributions of the anthropogenic source (NO_3^- , SO_4^{2-} , NH_4^+ , and

744 F⁻: 79.10%, 46.12%, 82.40%, and 71.02%) were significantly higher than those of sea source
745 (13.76%, 31.71%, 11.09%, and 11.52%) and crustal origin (7.14%, 22.17%, 6.52%, and 17.46%)
746 for NO₃⁻, SO₄²⁻, NH₄⁺, and F⁻. Nevertheless, the contribution ratio was in the order of crustal origin
747 (K⁺, Ca²⁺, and Mg²⁺: 77.44%, 82.17%, and 70.51%) > anthropogenic source (13.91%, 10.20%, and
748 18.36%) > sea source (8.65%, 7.64%, and 11.14%) for K⁺, Ca²⁺, and Mg²⁺. The sea source was the
749 dominant factor for the accumulation of Na⁺ and Cl⁻ in the rainwater, followed by the crustal origin
750 and the anthropogenic source. In addition, the contribution ratios of three sources showed the slight
751 variation in different seasons (Fig. 10). For instance, the contribution ratio of sea source to most
752 inorganic ions especially Na⁺ and Cl⁻ displayed the highest one in summer, followed by ones in
753 spring and autumn, and the lowest one in winter because the intense evaporation of sea salt in
754 summer was inclined to release more ions to the atmosphere (Teinilä et al., 2014). The contribution
755 ratio of anthropogenic activities presented the notable increase from summer to winter for SO₄²⁻
756 because of dense coal combustion (20 kg coal/m²) for domestic heating in winter (Zhao et al., 2016).

757 3.5 The deposition flux of the water-soluble ions and their key factors

758 At a national scale, the annually mean deposition fluxes of NO₃⁻, Cl⁻, Ca²⁺, K⁺, F⁻, NH₄⁺, Mg²⁺,
759 SO₄²⁻, and Na⁺ over China were 13.25, 8.44, 13.80, 2.49, 1.15, 5.90, 2.27, 33.41, and 4.39 kg ha⁻¹
760 yr⁻¹ during 2011-2016. The deposition fluxes of NO₃⁻, Ca²⁺, K⁺, NH₄⁺, and Na⁺ increased from 13.67
761 to 14.83 kg ha⁻¹ yr⁻¹, 13.32 to 16.99 kg ha⁻¹ yr⁻¹, 2.47 to 2.79 kg ha⁻¹ yr⁻¹, 5.21 to 6.48 kg ha⁻¹ yr⁻¹,
762 and 4.17 to 5.74 kg ha⁻¹ yr⁻¹ from 2011 to 2013, respectively. However, they decreased to 13.65,
763 11.01, 2.52, 5.90, and 3.69 kg ha⁻¹ yr⁻¹ in 2016. The wet deposition fluxes of F⁻ and Mg²⁺ over China
764 decreased from 1.27 to 0.96 kg ha⁻¹ yr⁻¹ and 2.76 to 1.85 kg ha⁻¹ yr⁻¹ during 2012-2014, respectively.
765 However, they began to increase slightly to 1.17 and 2.15 in 2016, respectively. The wet deposition

766 fluxes of Cl^- and SO_4^{2-} showed gradual decrease from 9.80 and 38.87 $\text{kg ha}^{-1} \text{yr}^{-1}$ to 8.09 and 26.54
767 $\text{kg ha}^{-1} \text{yr}^{-1}$ during 2011-2016, respectively. On average, the wet deposition flux of NO_3^- were higher
768 by 2.25 times than that of NH_4^+ , which was in contrast to the results of the dry deposition reported
769 by Xu et al. (2015). All of the water-soluble ions showed the highest wet deposition fluxes in
770 summer, followed by ones in spring and autumn, and the lowest ones in winter, which was probably
771 attributed by the high washout effect due to rain in summer (Jia et al., 2014). Based on the results
772 of the correlation analysis, the precipitation showed the significant relationship with the deposition
773 fluxes of the water-soluble ions ($p < 0.05$). In addition, the wet deposition fluxes of the water-soluble
774 ions showed the significantly spatial variation, which were in good agreement with the spatial
775 distribution of the water-soluble ion concentrations except Ca^{2+} (Fig. S5).

776 In order to determine the dominant factors affecting the wet deposition fluxes of the water-
777 soluble ions across China, GDP, GIP, TEC, N fertilizer use, vehicle ownership, UGS, dust days,
778 many meteorological factors (i.e., T_{\max} , T_{\min} , WS), and air pollutants (i.e., SO_2 and NO_2) were
779 introduced as the explanatory variables. The SR analysis results are depicted in Tab. 4. GIP, vehicle
780 ownership, NO_2 , T_{\min} , and wind speed served as the key factors affecting apparently the wet
781 deposition of NO_3^- at a national scale. The atmospheric emission of NO_x from coal-fired power
782 plants was estimated about 7489.6 kt in 2010, although many newly built power plants were
783 equipped with advanced low NO_x burner (LNB) systems (Tian et al., 2013). Zhang et al. (2014)
784 estimated that NO_x from vehicle emissions reached 4570 kt in 2008, which was considered as the
785 second NO_x source only to industrial activities. The NO_x released from anthropogenic activity could
786 enhance the NO_2 concentration in the ambient air, which could be also transformed to NO_3^- via
787 oxidation in the atmosphere, especially under the condition of high temperature and low WS (Zhang

788 et al., 2016). The wet deposition of NH_4^+ were affected by N fertilizer use, UGS, and NO_2 over
789 China. Russel et al. (1998) recommended early that NH_4^+ in the precipitation was most likely
790 derived from the N fertilizer use via an isotope techniques coupled with back trajectory analysis.
791 Besides, Teng et al. (2017) demonstrated that the emission from UGS was identified to contribute
792 to the atmospheric NH_3 significantly during 60% of the sampling times, which could increase the
793 NH_4^+ concentration in the precipitation due to the photochemical reaction. The wet deposition flux
794 of SO_4^{2-} was closely associated with TEC in the 320 cities of China, respectively. It was supposed
795 that the SO_2 emission were dependent on the use of coal and petroleum (Lu et al., 2010). While
796 terrestrial petroleum emissions have declined in recent years, the emissions from international
797 shipping have offset the decrease of terrestrial petroleum (Smith et al., 2011). In the present study,
798 the deposition of some crustal ions were linked to the dust days because they were mainly derived
799 from the dust storm or soil (Deshmukh et al., 2011; Zhang et al., 2011). The F deposition was
800 associated with GIP due to the contributions of the coal-fired power plant fly ash and industrial raw
801 material (Kong et al., 2011).

802 The GWR method was used to calculate the local regression coefficients in order to determine
803 the dominant factor affecting the deposition of the water-soluble ions at the regional scale (Fig. 11
804 and S6). The mean R^2 of GWR method was 0.50 over China, and the p value was lower than 0.05,
805 which suggested that the GWR method could be applicable to the study. The local regression
806 coefficient of dust days for crustal ions including Ca^{2+} , Cl^- , K^+ , and Mg^{2+} increased from SEC to
807 NWC (Fig. S6a-e), suggesting that dust days played a significant role on the crustal ions in NWC
808 due to high intensity of dust deposition and extremely high WS (Zhang et al., 2017a). The influence
809 of GIP on the F and NO_3^- increased from West China to East China, and displayed the higher value

810 in some cities of YRD (i.e., Shanghai, Hangzhou) because many coal-fired power plants, cement
811 plants, and municipal solid waste incineration plants were located in YRD (Hua et al., 2016; Tian et
812 al., 2012; Tian et al., 2014) (Fig. S6f and 11a). The influence of N fertilizer use on NH_4^+ was
813 concentrated on some cities of NEC such as Jiamusi (Heilongjiang province) (Fig. 11b-c), Harbin
814 (Heilongjiang province), Changchun (Jilin province) because the largest commodity grain base were
815 located in Heilongjiang and Jilin province, leading to the higher N fertilizer use (Cheng and Zhang,
816 2005). In contrast to the effects of GIP, the TEC influence increased gradually from SEC to NWC,
817 and showed the highest value in Xinjiang autonomous region (i.e., Altay) (Fig. 11d). It has been
818 demonstrated that an inverted U-shaped curve (Environment Kuznets Curve) between per capita
819 GDP and energy consumption was generally observed during the development of economy (Song
820 et al., 2013; Yang et al., 2017). The Environment Kuznets Curve denoted that the energy
821 consumption displayed positive relationship with per capita GDP in the early stage of development.
822 However, the positive relationship tended to transform into the negative relevance with the
823 development of economy because the reliance on the energy-intensive industries would be reduced
824 in the developed stage (Yang et al., 2017). It was assumed that Xinjiang autonomous region kept at
825 the early stage of the inverted-U curve and largely rested on the energy-intensive industries as the
826 less-developed province (Yang et al., 2017). However, some developed provinces in SEC such as
827 Zhejiang and Jiangsu have sped up structural transformation of the economy and reduce the reliance
828 on the heavy industries. The influence of UGS and vehicle ownership peaked in Shandong province
829 (i.e., Qingdao, Jinan) and YRD (i.e., Shanghai, Hangzhou) (Fig. 11e-f). It was supposed that the
830 UGS and vehicle ownership in these cities showed higher values among all of the 320 cities
831 (National Bureau of Statistics of China). Apart from the effects of socioeconomic factors, the

832 meteorological factors also played significant roles on NO_3^- . The influences of air temperature and
833 WS both increased from East China to West China, and showed the highest values in Xinjiang
834 province (Fig. 11g-h). Zhang et al. (2017a) demonstrated that the strong dust events along with high
835 WS contributed to the neutralization of NO_3^- , although the NO_2 concentrations in some cities of
836 Xinjiang province were significantly higher than other regions of China.

837 **4. Conclusions**

838 This study newly reported spatiotemporal variation of nine water-soluble ions in the
839 precipitation across the whole China during 2011-2016. The mean pH and EC values varied
840 significantly compared with those during 1980-2000 because the implementation of special air
841 pollution control measures have mitigated the air pollution in China. The concentrations of Na^+ ,
842 NO_3^- , and SO_4^{2-} increased from 7.26 ± 2.51 , 11.56 ± 3.71 , and 33.73 ± 7.59 $\mu\text{eq/L}$ to 11.04 ± 4.64 ,
843 13.59 ± 2.63 , and 41.95 ± 8.64 $\mu\text{eq/L}$ during 2011 and 2014, while they decreased from the highest
844 ones in 2014 to 9.75 ± 2.89 , 12.29 ± 4.02 , and 30.57 ± 7.43 $\mu\text{eq/L}$ in 2016, respectively. The
845 concentrations of Ca^{2+} , NH_4^+ , and Mg^{2+} increased by 86.26%, 178.50%, and 19.71% from 2011 to
846 2013, whereas they decreased from 58.84 ± 10.31 , 41.33 ± 10.26 , and 10.49 ± 3.07 in 2013 to 31.20
847 ± 8.48 , 18.13 ± 4.84 , and 8.93 ± 2.92 $\mu\text{eq/L}$ in 2016, respectively. The concentration of F^- decreased
848 linearly by 5.58%/yr during 2012-2016. The mean concentrations of SO_4^{2-} , NO_3^- and F^- showed the
849 highest values in winter, followed by ones in spring and autumn, and the lowest ones in summer. It
850 was supposed that the dense anthropogenic activities such as domestic combustion for heating and
851 adverse meteorological conditions. The crustal ions (Ca^{2+} , Mg^{2+} , and K^+) peaked in spring and
852 summer, suggesting the contributions of fugitive dusts. The Na^+ and Cl^- were markedly affected by
853 evaporation of sea salt. All of the water-soluble ions in the precipitation exhibited notably spatial

854 variability. The secondary ions (SO_4^{2-} , NO_3^- and NH_4^+), and F^- peaked in YRD (i.e., Changzhou,
855 Hangzhou, and Nanjing) owing to the intensive energy consumption and industrial activities. The
856 higher S content in the coal and unfavorable diffusion conditions contributed to the higher
857 concentrations of secondary ions in SB (i.e., Chengdu, Leshan, and Dazhou). The crustal ions and
858 sea-salt ions showed the highest concentrations in semi-arid regions (i.e., Guyuan, Jiayuguan) and
859 coastal cities (i.e., Qingdao, Lianyungang), respectively.

860 The EF method, geochemical index method, and FA-MLR method consistently suggested that
861 NO_3^- , F^- , NH_4^+ , and SO_4^{2-} were dominated by anthropogenic activities. However, the Na^+ and Cl^-
862 were closely associated with sea-salt aerosol. Ca^{2+} , Mg^{2+} , and K^+ were mostly derived from crustal
863 source. The results of SR analysis and GWR method implied that GIP, TEC, vehicle ownership, and
864 N fertilizer use were main factors for SO_4^{2-} , NO_3^- , NH_4^+ , and F^- in the precipitation. However, the
865 crustal ions were significantly affected by dust events. The correlation between influential factors
866 and the ions in the wet deposition showed significantly spatial variability. The influence of dust days
867 on the crustal ions increased from SEC to NWC, whereas the influence of socioeconomic factors on
868 secondary ions showed the highest value in East China.

869 The present study validate the model estimations of the water-soluble ions deposition at a
870 national scale, and provide the fundamental data for the prevention and control of acid deposition
871 and air pollution. However, there were several plausible contributors to the uncertainty. First of all,
872 the monitoring sites were distributed unevenly and relatively scarce sites were located in Northwest
873 China. Moreover, the limited independent variables were included into the models. Thus, further
874 studies were required to establish more representative monitoring sites and incorporate more
875 variables to reduce the uncertainty associated with the ions deposition.

876 **Author contributions**

877 Rui Li analyzed the data and wrote the manuscript. Lulu Cui, Yilong Zhao, Ziyu Zhang, Tianming

878 Sun, Junlin Li, Wenhui Zhou, Ya Meng, and Kan Huang organized the campaign and analyzed data.

879 Hongbo Fu revised the manuscript.
