1 **Abstract**

2 The Dead Sea desertification-threatened region is affected by continual lake level
3 decline and occasional, but life-endangering flash-floods. Climate change has
4 aggravated such issues in the past decades. In this study, the impact on local
5 conditions leading to heavy precipitation of the drying out of the Dead Sea is
6 investigated. Sensitivity simulations with the high-resolution convection-permitting
7 regional climate model COSMO-CLM and several numerical weather prediction (NWP)
8 runs on an event time scale are performed over the Dead Sea area. A reference
9 simulation covering the 2003 to 2013 period and a twin sensitivity experiment, in which
10 the Dead Sea is dried out and set to bare soil, are compared. NWP simulations focus
11 on heavy precipitation events exhibiting relevant differences between the reference and
12 the sensitivity decadal realization to assess the impact on the underlying convection-
13 related processes.

14 The drying out of the Dead Sea is seen to affect the atmospheric conditions leading to
15 convection in two ways: (a) the local decrease in evaporation reduces moisture
16 availability in the lower boundary layer locally and in the neighbouring, directly affecting
17 atmospheric stability. Weaker updrafts characterize the drier and more stable
18 atmosphere of the simulations where the Dead Sea has been dried out. (b) Thermally
19 driven wind system circulations and resulting divergence/convergence fields are altered
20 preventing in many occasions convection initiation because of the omission of
21 convergence lines. On a decadal scale, the difference between the simulations
22 suggests a decrease in evaporation, higher air temperatures and less precipitation.

32 **1. Introduction**

33 The Eastern Mediterranean and the Middle East is a sensitive climate change area
34 (Smiatek et al. 2011). The anticipated warming in the 21st century combined with the
35 general drying tendency, suggest important regional impacts of climate change, which
36 should be investigated to assess and mitigate local effects on society and ecosystems.
37 The Dead Sea basin is dominated by semi-arid and arid climates except by the north-
38 western part that is governed by Mediterranean climate (Greenbaum et al. 2006). It is
39 an ideal area to study climate variation in the Near East. It was already discussed by
40 Ashbel (1939) the influence of the Dead Sea on the climate of its neighbouring regions.
41 The change in the climate of the Dead Sea basin caused by the drying of the Dead Sea
42 has also been evidenced in the last decades (Alpert et al. 1997; Cohen and Stanhill
43 1996; Stanhill 1994). The Dead Sea is the lowest body of water in the world (~ -430 m)
44 surrounded by the Judean Mountains (up to ~ 1 km amsl) to the west and to the east
45 by the Maob Mountains (up to ~ 3 km amsl). The area in between is rocky desert. The
46 complex topography of the area favours the combined occurrence of several wind
47 regimes in addition to the general synoptic systems, namely valley and slope winds,
48 Mediterranean breezes and local lake breezes (e.g. Shafir and Alpert 2011). These
49 wind systems are of great importance for the living conditions in the region since they
50 influence the visibility and the air quality (e.g. Kalthoff et al. 2000; Corsmeier et al.
51 2005) as well as the atmospheric temperature and humidity. Since the Dead Sea is a
52 terminal lake of the Dead Sea Valley, no natural outflow exists; evaporation is the main
53 loss of water. The wind velocity and vapour pressure deficit are identified as the main
54 governing factors of evaporation throughout the year (Metzger et al. 2017). Through
55 the high evaporation the lake level declines and results in a desertification of the
56 shoreline and a changing fraction of water and land surface in the valley. The
57 documented Dead Sea water level drop of about 1 m/y in the last decades (Gavrieli et
58 al. 2005) is mainly due to the massive water consumption at its upstream having
59 climate changes a small contribution to the lake level decrease (Lensky and Dente
60 2015). This situation severely affects agriculture, industry and the environmental
61 conditions in the area, thus, leading to substantial economic losses (Arkin and Gilat
62 2000).

63 The Jordan River catchment and Dead Sea-exhibit in the north, annual precipitation in
64 the order of 600-800 mm, whereas in the south, there is an all year arid climate with an
65 annual precipitation of <150 mm (Schaedler and Sasse 2006). Rain occurs between
66 October and May and can be localized or widespread (Dayan and Sharon 1980)
67 (Sharon and Kutiel 1986). Rainfall varies seasonally and annually, and it is often

68 concentrated in intense showers (Greenbaum et al. 2006) caused mainly by severe
69 convection (Dayan and Morin 2006). Flash floods are among the most dangerous
70 meteorological hazards affecting the Mediterranean countries (Llasat et al 2010), thus,
71 knowledge about the processes shaping these events is of high value. This is
72 particularly relevant in arid climates, where rainfall is scarce, and often, local and highly
73 variable. In flood-producing rainstorms, atmospheric processes often act in concert at
74 several scales. Synoptic-scale processes transport and redistribute the excess sensible
75 and latent heat accumulated over the region and subsynoptic scale processes
76 determine initiation of severe convection and the resulting spatio-temporal rainfall
77 characteristics. The main responsible synoptic weather patterns leading to heavy
78 rainfall in the region are in general well known and described in previous publications
79 (e.g. Belachsen et al. 2017; Dayan and Morin 2006). Belachsen et al. (2017) pointed
80 out that three main synoptic patterns are associated to these heavy rain events: Cyprus
81 low accounting for 30% of the events, Low to the east of the study region for 44%, and
82 Active Read Sea Trough for 26%. The first two originate from the Mediterranean Sea,
83 while the third is an extension of the Africa monsoon. Houze (2012) showed that
84 orographic effects lead to enhanced rainfall generation; rain cells are larger where
85 topography is higher. Sub-synoptic scale processes play a decisive role in deep
86 convection generation in the region. Convection generated by static instability seems to
87 play a more important role than synoptic-scale vertical motions (Dayan and Morin
88 2006). The moisture for developing intensive convection over the Dead Sea region can
89 be originated from the adjacent Mediterranean Sea (Alpert und Shay-EL 1994) and
90 from distant upwind sources (Dayan and Morin 2006).

91 In this study, the sensitivity of the local conditions in the Dead Sea region to the drying
92 out of the Sea is investigated focusing on the conditions leading to heavy precipitating
93 convection in the region. The relevance of the Dead Sea as a local source of moisture
94 for precipitating convection as well as the impact of the energy balance partitioning
95 changes and related processes caused by the drying of the Dead Sea are investigated.
96 With this purpose, a sensitivity experiment with the high-resolution regional climate
97 model COSMO-CLM [Consortium for Small scale Modelling model (COSMO)-in
98 Climate Mode (CLM); Böhm et al. 2006] is conducted. The high horizontal grid spacing
99 used (~ 2.8 km) resolves relevant orographic and small-scale features of the Dead Sea
100 basin, which is not the case when coarser resolution simulations are performed.
101 Moreover, at this resolution convection is explicitly resolved instead of being
102 parametrized, which has been already extensively demonstrated to be highly beneficial
103 for the simulation of heavy precipitation and convection-related processes. The benefit

104 of employing high-resolution convection permitting simulations is mainly in sub-daily
105 time-scales, (e.g., Prein et al., 2013; Fosser et al., 2014; Ban et al., 2014), however,
106 daily precipitation is also positively affected, particularly in winter time (Fosser et al.,
107 2014). Previous studies in the area applying high-resolution modelling agree with the
108 beneficial impact of finer resolution against coarser ones (e.g. *Rostkier-Edelstein et al.*
109 *2014; Hochman et al. 2018; Kunin et al. 2019*).

110 A decadal simulation and several event-based Numerical Weather Prediction (NWP)
111 runs covering the eastern Mediterranean are carried out. A process understanding
112 methodology is applied to improve our knowledge about how sub-synoptic scale
113 processes leading to severe convection are affected by the drying of the Dead Sea.
114 The article is organized as follows. Section 2 provides an overview of the data and the
115 methodology used. Then, in section 3, the climatology of the region based on the high-
116 resolution convection-permitting decadal simulation is presented and the impact of
117 drying out the Dead Sea is examined across scales. Finally, conclusions are discussed
118 in section 4.

119

120 **2. Data and methodology**

121 **2.1 The COSMO-CLM model**

122 In this investigation, the regional climate model (RCM) of the non-hydrostatic COSMO
123 model, COSMO-CLM (CCLM), is used (Version 5.0.1). It has been developed by the
124 Consortium for Small-scale modeling (COSMO) and the Climate Limited-area Modeling
125 Community (CLM) (Böhm et al., 2006). It uses a rotated geographical grid and a
126 terrain-following vertical coordinate. The model domain covers the southern half of the
127 Levant, centred around the Dead Sea, with a horizontal resolution of 7 km and 2.8 km,
128 60 vertical levels and a time step of 60 and 20 seconds, respectively. Using IFS
129 (Integrated Forecasting System) analysis, the spectral weather model of ECMWF
130 (European Centre for Medium-Range Weather Forecast) as driving data for the
131 simulations, a double nesting procedure was employed. The coarsest nest at 0.0625°
132 resolution (about 7 km) covers 250 grid points in x direction and 250 grid points in y
133 direction. The size and location of the 7 km domain has been considered large enough
134 to take into consideration all possible synoptic situations relevant for the development
135 of extreme phenomena in the study area as well as the influence of the Mediterranean
136 Sea. The finest nest at 0.025° (circa 2.8 km) covers 150 x 150 grid points, thus a total

137 area of 22500 grid points and includes the study area (72 grid point in x direction and
138 92 in y direction) centred around the Dead Sea.

139 A Tiedtke (1989) mass-flux scheme is used for moist convection in the 7 km, and
140 reduced Tiedtke mass-flux scheme for shallow convection. Contrary to the CCLM-7 km
141 simulation, where convection is parameterized, in the CCLM-2.8 km convection is
142 explicitly resolved (Doms and Baldauf, 2015), so only the reduced Tiedtke mass-flux
143 scheme is used for shallow convection. The model physics includes a cloud physics
144 parameterization with 5 types of hydrometeors (water vapor, cloud water, precipitation
145 water, cloud ice, precipitation ice), a radiative transfer scheme based on a delta-two-
146 stream solution (Ritter and Geleyn, 1992) and a roughness-length dependent surface
147 flux formulation based on modified Businger relations (Businger et al., 1971).

148 Orography data from GLOBE (Global Land One-km Base Elevation Project) of NOAA
149 (National Oceanic and Atmospheric Administration) and soil data from HWSD
150 (Harmonized Worlds Soil Database) TERRA is used. HWSD is a global harmonization
151 of multiple regional soil data sets with a spatial resolution of 0.008° (FAO, 2009),
152 resulting in 9 different soil types in the model, namely 'ice and glacier', 'rock / lithosols',
153 'sand', 'sandy loam', 'loam', 'loamy clay', 'clay', 'histosols', and 'water'.

154 Multiple model runs have been performed. A 7 km run from 2003 to 2013 with daily
155 output is used as nesting for two 2.8 km runs over the same time span. The Dead Sea
156 is dried out and replaced with soil types from the surrounding area in one of them
157 (SEN), the other one is used as reference (CLIM). For the detailed investigation of
158 convective events on 14.11.2011 and 19.11.2011, sub-seasonal simulations have been
159 performed with the same settings as the decadal simulation, but with additional hourly
160 output.

161 **2.2 Methodology**

162 A decadal simulation covering the 2003 to 2013 time period was carried out with the
163 convection permitting 2.8 km COSMO-CLM model. Lateral boundary conditions and
164 initial conditions are derived from the European Centre for Medium-Range Weather
165 Forecasts (ECMWF) data. The COSMO-CLM 7 km is used as nesting step in between
166 the forcing data and the 2.8 km run. This reference simulation will be hereafter referred
167 to as REF^{CLIM} simulation. Parallel to this, a sensitivity experiment (hereafter SEN^{CLIM}) is
168 carried out in which the Dead Sea is dried out and set to bare soil on -405 m level
169 (depth of the Dead Sea in the external data set, GLOBE (Hastings and Dunbar, 1999)).

170 After examination of the results, the first year of simulations is considered spin-up time,
171 thus, our analysis covers the 2004-2013 period.

172 The precipitation field has been validated using the EOBS dataset (resolution of 0.1°
173 and available for the period 1980-2011; Haylock et al. 2008), and the APHRODITE's
174 (Asian Precipitation - Highly-Resolved Observational Data Integration Towards
175 Evaluation: Yatagai et al. 2008, 2012) daily gridded precipitation, resolution of 0.25°
176 and available for 1980-2007. The APHRODITE data shows generalized lower
177 precipitation values than EOBS, but still higher than our simulation particularly close to
178 the northern Mediterranean shoreline, over coastal-flat terrain, whereas the best
179 agreement is at areas dominated by complex terrain. Despite these biases the
180 comparison of the temporal areal-mean of the model simulations at 7 km and 2.8 km
181 and the APHRODITE dataset demonstrates that in general the model quite well
182 captures the precipitation events. An improvement is seen at the finer resolution.

183 Regional dry and wet periods are identified and quantified in the simulations by means
184 of the Effective Drought Index (EDI; Byun and Wilhite 1999; Byun and Kim 2010). The
185 EDI is an intensive measure that considers daily water accumulations with a weighting
186 function for time passage normalizing accumulated precipitation. The values are
187 accumulated at different time scales and converted to standard deviations with respect
188 to the average values. Here we use an accumulation period of 365 days. EDI dry and
189 wet periods are categorized as follows: moderate dry periods $-1.5 < \text{EDI} < -1$, severe dry
190 periods $-2 < \text{EDI} < -1.5$, and extreme dry periods $\text{EDI} < -2$. Normal periods are revealed by
191 $-1 < \text{EDI} < 1$ values.

192 Based on daily mean values, precipitation and evapotranspiration distribution and
193 possible tendencies in the 10-year period are assessed. To further assess the most
194 affected areas in our study area, this is divided in four subdomains surrounding the
195 Dead Sea and trying to respect the orographic pattern in the area (Figure 3). Annual
196 cycles are thus separately investigated to take into consideration the relevant
197 differences in orography, soil types, and distance to the coast among others (Figure1),
198 which are known to have a significant impact in the precipitation distribution in the
199 region (e.g. Belachsen 2017; Houze 2012). . Differences in the annual cycle and
200 temporal evolution of precipitation and evapotranspiration between the REF^{CLIM} and
201 SEN^{CLIM} are discussed. Also, differences in the near-surface and boundary layer
202 conditions and geopotential height patterns are examined. Geographical patterns of
203 mean evapotranspiration and precipitation and differences with respect to the reference
204 simulation are assessed. Probability distribution functions (PDFs), and the Structure,

205 Amplitude and Location (SAL: Wernli et al. 2008) analysis methodologies are used to
206 illustrate differences in the mean and extreme precipitation between the reference and
207 the sensitivity experiments. The SAL is an object-based rainfall verification method.
208 This index provides a quality measure for the verification of quantitative precipitation
209 forecasts considering three relevant aspects of precipitation pattern: the structure (S),
210 the amplitude (A), and the location (L). The A component measures the relative
211 deviation of the domain-averaged rainfall; positive values indicate an overestimation of
212 total precipitation, negative values an underestimation. The component L measures the
213 distance of the center of mass of precipitation from the modelled one, and the average
214 distance of each object from the center of mass. The component S is constructed in
215 such a way that positive values occur if precipitation objects are too large and/or too
216 flat and negative values if the objects are too small and/or too peaked, quantifying the
217 physical distance between the centres of mass of the two rainfall fields to be compared.
218 Perfect agreement between prediction and reference are characterized by zero values
219 for all components of SAL. Values for the amplitude and structure are in the range (-2,
220 2), where ± 0.66 represents a factor of 2 error. The location component ranges from 0
221 to 2, where larger values indicate a greater separation between centres of mass of the
222 two rainfall fields. This is done by selecting a threshold value of 1/15 of the maximum
223 rainfall accumulation in the domain (following Wernli et al. 2008). The structure and
224 location components are thus independent of the total rainfall in the domain.

225

226 Differences in the temporal evolution of precipitation between the REF^{CLIM} and SEN^{CLIM}
227 are identified. In Table 1, those events in which an area-mean (study area, Figure 1)
228 difference between both simulations higher than ± 0.1 mm/d exists are selected as
229 potential heavy precipitation events and classified attending to their synoptic scale
230 environment and atmospheric stability conditions (Table 1).

231 Although Dayan and Morin (2006) discuss that in general large-scale vertical motions
232 do not provide the sufficient lifting necessary to initiate convection, it was demonstrated
233 by Dayan and Sharon (1980) that a relationship exists between the synoptic-scale
234 weather systems and deep moist convection, being those systems responsible for the
235 moisturizing and destabilization of the atmosphere prior to convective initiation. They
236 pointed out that indices of instability proved the most efficient determinants of the
237 environment characterizing each rainfall type in the region. Thus, two indicators of the
238 atmospheric degree of stability/instability, namely the Convective Available Potential
239 Energy (CAPE; Moncrieff and Miller 1976) and the KO-index (Andersson et al. 1989),
240 are examined in this study. The CAPE is a widely known index indicating the degree of

241 conditional instability. Whereas, the KO-index, which is estimated based on the
242 equivalent potential temperature at 500, 700, 850 and 1000 hPa (following the
243 recommendations by Bolton 1980), describes the potential of deep convection to occur
244 as a consequence of large-scale forcing (Andersson et al. 1989; Khodayar et al. 2013).
245 Generally, regions with KO-index < 2 K and large-scale lifting are identified as
246 favourable for deep convection. Parcel theory (50 hPa ML (Mixed Layer) parcel) and
247 virtual temperature correction (Doswell and Rasmussen 1994) are applied to these
248 calculations.

249 Based on the above criteria, a separation was made between events with widespread
250 rainfall and those more localized. Among the latter, we selected two events to illustrate
251 the local impacts on the boundary layer conducive to deep moist convection.
252 Particularly, differences in the amount, structure and location of precipitation are
253 assessed by examining the spatial patterns and the SAL verification method. The two
254 selected events for detail analysis in this study are those showing the larger SAL
255 deviations. Those two cases occur close in time, but they are not the same event. No
256 differences in the soil and atmospheric conditions have been found in the period
257 between the events when the REF and SEN simulations are compared. Even though
258 a more detail analysis is provided for the two selected cases, all convective-events
259 listed in Table 1 have been examined to assess the main impacts on the mechanisms
260 leading to convection. High-resolution simulations with the NWP COSMO 2.8 km model
261 are performed with hourly output temporal resolution and covering a 3-day period
262 (including 48-h prior to the day of the event, from 00 UTC) to capture atmospheric pre-
263 conditions conducive to deep moist convection. For this, a reference simulation,
264 REF^{NWP} , and a sensitivity experiment, SEN^{NWP} , are carried out for each event.

265 We have to point out that the external data sets commonly employed describing
266 relevant features of the Dead Sea region, such as the depth, shape and orography of
267 the Dead Sea, as well as Dead Sea water characteristics at the reference run, do not
268 accurately represent the reality. In the same direction, biases in relation to different
269 variables such as the precipitation field and evaporation over the Dead Sea have to be
270 considered.

271

272 **3. Results and discussion**

273 **3.1 Climatology of the Dead Sea region**

274 *Annual cycle*

275 To assess the climatology of the study region (Figure 1) the annual evaporation and
276 precipitation cycles based on daily means of the respective quantities are investigated
277 (Figure 2). Additionally, we examine the evolution of specific humidity ($Q_{v_{2m}}$) and
278 temperature at 2 m (T_{2m}) as well as total column integrated water vapour (IWV) and
279 low-boundary layer (< 900 hPa) equivalent potential temperature (Θ_e). Possible
280 changes in the atmospheric stability conditions are evaluated by examination of the
281 CAPE and KO-index. In Figure 2, all grid points over the study region (Figure 1) and
282 the time period 2004-2013 are considered. Differences between the REF^{CLIM} and the
283 SEN^{CLIM} simulations are also discussed.

284 The annual cycle of evaporation shows minimum values in the autumn season (around
285 October, ~ 0.1 mm/d) and maximum evaporation in spring (around March, ~ 0.4 mm/d).
286 The dependency with the precipitation cycle is clear with maximum values of the latter
287 around March and rain occurring between October and May (Figure 2a) in agreement
288 with observations in the area (Dayan and Sharon 1980). The difference between the
289 evaporation in the REF^{CLIM} and the SEN^{CLIM} simulations indicates a mean decrease in
290 the order of 0.02 (February) to ~ 0.1 (August) mm/d in the absence of the Dead Sea
291 water (SEN^{CLIM}). The largest difference is in the dry period (May to October) when
292 water availability is less dependent on precipitation, and evaporation is higher over the
293 Dead Sea in contrast to the minimum values over land (Metzger et al. 2017). In
294 general, there is a decrease of about 0.5 % in mean precipitation in the SEN^{CLIM}
295 simulation. In contrast to the differences in evaporation, precipitation differences
296 between the reference and the sensitivity experiment occur in both directions during
297 the rain period, from October to May. Examining the total number over the whole
298 decadal simulation it is seen that the number of dry or wet days (> 0.1 mm/d) or heavy
299 precipitation events is not largely affected in the sensitivity experiment. In general, the
300 number of dry days increases (fewer wet days) in the SEN^{CLIM} simulation, whereas the
301 number of high intensity events show almost no variation. For each simulation, the
302 difference between precipitation and evaporation is negative mainly in spring and
303 summer contributing to the dryness in the region. Furthermore, the difference between
304 the REF^{CLIM} and SEN^{CLIM} simulations indicates that PREC-EVAP is higher in the
305 SEN^{CLIM} simulation probably in relation to the reduced evaporation over the dry sea
306 area and the general decrease in the precipitation amount in the region.

307 In addition to the reduced evaporation and precipitation (about 0.5 %) in the whole
308 domain in the SEN^{CLIM} simulation a drier and warmer lower-troposphere is identified
309 (Figure 2b) in agreement with the observational assessment by Metzger et al. (2017) of
310 the cooling effect of evaporation on air temperature in the region. The annual cycle of

311 IWV and $\Theta_{e<900hPa}$ in Figure 2c show that the impact of the dry Dead Sea resulting
312 evaporation is less pronounced when a deeper atmospheric layer is considered.
313 Indeed, $\Theta_{e<900hPa}$ evolution evidences that the warming effect due to the decreased
314 evaporation in the SEN^{CLIM} simulation is restricted to the near surface.

315 In Figure 2d, the annual cycle of areal mean CAPE displays larger values in the period
316 from August to November, being this the period more favourable for convection.
317 Negative CAPE differences between the REF^{CLIM} and the SEN^{CLIM} simulations are
318 presumably in relation to the identified distinct lower-atmospheric conditions, being
319 these more favourable and consequently CAPE values higher in the REF^{CLIM}
320 simulation. In the same period, the KO-index indicates a more potentially unstable
321 atmosphere, i.e. prone to deep convection because of large-scale forcing, and larger
322 differences between simulations.

323 In agreement with the well-known precipitation distribution in the region most of the
324 events occur in A1 (north-west) and A2 (north-east). Also, in these subdomains larger
325 differences between the REF^{CLIM} and SEN^{CLIM} simulations are identified pointing out the
326 relevance of the Dead Sea evaporation in the pre-convective environment for rainfall
327 episodes over the study area (Figure3a). Considering only land grid points almost no
328 difference between simulations is found in the evaporation annual cycle of A1 and A2
329 (Figure3b) suggesting the distinct amount of moisture advected towards A1 and A2
330 from the Dead Sea in REF^{CLIM} and SEN^{CLIM} as responsible for the differences in the
331 boundary layer conditions conducive to convection. Also, in these subdomains the
332 dryer and warmer lower boundary layer and the reduced instability in the SEN^{CLIM} are
333 recognized

334 *Inter-annual variability*

335 In Figures 4 we discuss the inter-annual variability (based on monthly-daily areal mean
336 values) of evaporation, precipitation as well as drought evolution.

337 The reduced evaporation in the annual cycle of the SEN^{CLIM} simulation for the whole
338 investigation domain, resulting from the drying of the Dead Sea and affected
339 evaporation, remains from year to year (Figure 4a). Larger differences between the
340 simulations occur in the May to November months in agreement with the annual cycle
341 in Figure 2a. This, and the time period of the maximum/minimum is constant over the
342 years. A tendency towards lower evaporation at each simulation and higher differences
343 between both at the end of the period are identified. An inter-annual fluctuation is
344 observed in both REF^{CLIM} and SEN^{CLIM} simulations. The yearly rate of evaporation

345 shows, for example, in REF^{CLIM} maximum values of about 7 mm in 2011 and around 17
346 mm in 2012. This is in agreement with the positive correlation expected between
347 precipitation and evaporation, a trend towards decreased precipitation and a
348 correspondence between drier years such as the 2011-2012 period and lower annual
349 evaporation are seen in Figure 4b. Year to year EDI calculations in Figure 4c help us
350 identify the regional extreme dry and wet periods. The EDI range of variation from
351 about -1 to 2 for the whole period of simulation indicates that the dry condition is the
352 common environment in the area, while the wet periods, EDI up to 6, could be
353 identified as extreme wet periods (relative to the area), in this case in the form of heavy
354 precipitation events. Maximum positive EDI values are in the first months of the year in
355 agreement with the precipitation annual cycle in Figure 2, whereas minimal EDI values
356 occur in summer and autumn indicative of the dry conditions in these periods.
357 Differences in the EDI calculations from both simulations reveal distinct precipitation
358 evolutions and denote timing differences in the occurrence of the precipitation events.
359 When the regional climate evolution is examined in combination with the impact on the
360 number of heavy precipitation events (Table 1) the impact is stronger in the dry period
361 of 2011 (Figure 4a). About six events show relevant differences in this period, contrary
362 to the average 3 episodes per year.

363 *Spatial distribution*

364 The geographical patterns of evaporation and precipitation are presented in Figure 5.
365 Over the Dead Sea, the simulated average annual evaporation for the period under
366 consideration is in the order of 1500-1800 mm/y, in contrast to the values in the deserts
367 east and south, where the evaporation is less than 20 mm/y. Observed annual
368 evaporation of this lake is known to be about 1500 mm and to vary with the salinity at
369 the surface of the lake and freshening by the water inflow (Dayan and Morin 2006;
370 Hamdani et al. 2018). Over land, higher evaporation is seen over the Judean
371 Mountains and the Jordanian Highlands. High correlation with the orography and soil
372 types is seen (Figure 1). Evaporation is probably correlated with rainfall which in turn is
373 correlated with topography. Particularly, in the Jordanian Highlands where maximum
374 evaporation is around 200 mm/y, the complex topography coincides with sandy loam
375 soils, whereas most of the soil in study region is defined as loamy clay or clay (Figure
376 1). The evaporative difference field between simulations in Figure 5a shows a highly
377 inhomogeneous patchiness not evidencing any relationship with orography or soil type,
378 but rather with changes in the precipitation pattern in the SEN^{CLIM} simulation as seen in
379 Figure 5b.

380 In agreement with the temporal series of areal mean precipitation in Figure 3 higher
381 annual precipitation are in the north-west and -east, with respect to the southern
382 regions. Topographic features exert a large impact on precipitation distribution with
383 maxima of about 175 to 300 mm/y over the Judean Mountains and the Jordanian
384 Highlands. To the northern end of the Dead Sea valley, the largest precipitation
385 difference between the REF^{CLIM} and the SEN^{CLIM} simulations is identified, rather than
386 directly over the Dead Sea area noting the importance of advected moisture from the
387 Dead Sea evaporative flux upslope and along the Dead Sea valley as well as the
388 indirect effects of a different spatial distribution of low-tropospheric water vapour in the
389 occurrence of precipitating convection.

390 Regarding the impact on the large-scale conditions, differences in the spatial pattern
391 and strength of the 500 hPa geopotential height field are identified over the Dead Sea
392 (not shown). In the 10-year mean, differences up to 0.002gpdm higher in SEN than in
393 REF are observed. Around the Dead Sea area, the differences are smaller and more
394 irregular. Generally, the differences are higher in the east of the Dead Sea than in the
395 west.

396 *Precipitation probability distribution function*

397 While the probability for lower intensity precipitation is very similar in the REF^{CLIM} and
398 the SEN^{CLIM} simulations differences are recognized in the higher precipitation
399 intensities, from about 150 mm/d (Figure 6a). Particularly, above 180 mm/d extreme
400 precipitation values occur less frequent at the SEN^{CLIM} simulation where a drier,
401 warmer and more stable atmosphere is identified (Figure 2).

402 *SAL*

403 The use of the SAL method in this study differs from the approach frequently presented
404 in literature since it is here not our purpose to examine differences between the
405 simulated field and observations (adequate observations for this comparison are not
406 available in the area), but to compare changes regarding the structure, amount and
407 location of the precipitation field between our reference and sensitivity experiments.
408 Figure 6b shows that when the mean precipitation over the whole simulation period is
409 considered all three SAL components are close to zero, meaning that very small
410 differences are found. However, when single precipitation events in the REF^{CLIM}
411 simulation are compared with the same period at the SEN^{CLIM} simulation, larger
412 differences regarding structure, amount and location of rainfall events are found. For
413 further examination of this issue two exemplary heavy precipitation events (indicated by

414 boxes in Figure 6b) are analysed in detail. In both cases, a negative A-component is
415 recognized, that is, less precipitation falls in the SEN^{CLIM} simulation. The S-component
416 also evidences the change in the structure of the convective cells. The L-component is
417 low meaning that the convective location does not change significantly in the SEN^{CLIM}
418 simulation, in contrast to the intensity and structure of the cells.

419

420 **3.2 Sensitivity of atmospheric conditions to the Dead Sea drying: episodic** 421 **investigation**

422 Among those events exhibiting differences in the precipitation field between both
423 simulations (Table 1 and Figure 6b) two situations occurring in the time period of the 14
424 to 19 November 2011 are investigated in the following.

425 In this term, the synoptic situation is characterized by a Cyprus low and its frontal
426 system located over the Dead Sea at about 00 UTC on the 15 November 2011 and at
427 12 UTC on the 18 November 2011. The low-pressure system and its frontal system
428 induced strong south-westerly to westerly winds with mean wind velocities up to 15
429 m/s.

430 In the first situation (hereafter CASE1), in association with the western movement of
431 the cold front a convective system develops over the Jordanian Highlands with
432 precipitation starting at about 21 UTC on the 14 November 2011. This convective
433 system is of high interest because of the large difference in its development between
434 the REF^{14.11} and the SEN^{14.11} simulations.

435 In Figure 7a the 24-h accumulated precipitation, from 14.11 09 UTC to 15.11 08 UTC,
436 in the investigation area is shown for the REF^{14.11} and the SEN^{14.11} simulations. Two
437 precipitation areas are seen, on the north-western and north-eastern of the Dead Sea.
438 Larger difference between models is on the north-eastern region (24-h accumulated
439 precipitation > 100 mm/d in REF^{14.11}, while < 50 mm/d in SEN^{14.11}), which is the focus of
440 our analysis.

441

442 The REF^{14.11} simulation shows that in the 6 hours period prior to the initiation of
443 convection the pre-convective atmosphere and more specifically the lower boundary
444 layer exhibit a moist (IWV ~ 24-30 mm, qvPBLmax ~ 7-10 g/kg) and unstable (CAPE ~
445 1100 J/kg; KO-index ~ -8 K; not shown) air mass on the western side of the
446 investigation area, particularly close to the western Mediterranean coast, and drier
447 (IWV~ 8-16; qvPBLmax ~ 4-6 g/kg) and more stable conditions (CAPE< 200 J/kg; KO-

448 index $\sim 0-2$ K) on the eastern side of the domain (Figure 7b). A maximum difference of
449 about 5 g/kg from west to east is established in the lower boundary layer.

450 Main differences between both simulations are over the Dead Sea (IWV difference up
451 to 2 mm and qv_{PBL} up to 1.5 g/kg) and north and north-east of it, but almost similar
452 conditions everywhere else. In our target area (subdomain of investigation where the
453 convection episode takes place (red box in Figure 7)), north-east of the Dead Sea, a
454 drier and a more stable atmosphere is identified at the SEN^{14.11} simulation.

455 The evolution of the wind circulation systems in the area is similar in both simulations
456 (Figure 7c). The 700 hPa, 850 and 950 hPa winds dominantly blow from the south
457 south-west during the pre-convective environment advecting the moist unstable air
458 mass towards the Dead Sea valley and north-east of it, directly affecting the
459 atmospheric conditions at the target area (for a comparison with a climatology of the
460 wind conditions in the region please see Metzger et al. 2017). In both simulations, the
461 passage of the cold front over the Dead Sea establishes a strong southerly wind from
462 about 10 UTC on the 14 November 2011.

463 Prior to this time, dry air was advected below about 850 hPa towards the target area
464 from the east. The turning of the low-level winds and the resulting moistening of the
465 atmosphere is well and equally captured by both simulations (Figure 8a). Furthermore,
466 at the near-surface, from about 16 UTC, ~ 5 h prior to convection initiation in the target
467 area, a near-surface convergence line forms at the foothills of the northern part of the
468 Jordanian Highlands, which is also well and equally captured by both simulations
469 (Figure 8b). The lifting provided by the convergence line triggers convection in the
470 area. However, the drier and more stable atmosphere in the SEN^{14.11} simulation results
471 in less intense convection, weaker updrafts, and reduced precipitation at the eastern
472 slope of the valley.

473

474 In the second case, CASE2, we address an episode of localized convection taking
475 place on the north-western edge of the Dead Sea in the REF simulation, whereas no
476 convection develops in the SEN simulation. The isolated convection in the REF
477 simulation left about 50 mm rain in 3 h starting at about 03 UTC on the 19 November
478 2011 (Figure 9).

479 In contrast to CASE1, the modification of the pre-convective environment relevant for
480 convective initiation is in this case dominated by dynamical changes in the mesoscale
481 circulations. Differences in the evolution and strength of the Mediterranean Sea Breeze
482 (MSB), the Dead Sea breeze and orographic winds influence atmospheric conditions in
483 the target area leading to the assistance to or to the absence of convection. The most

484 significant difference observed between the simulations is in the development of a
485 strong near-surface convergence line in the REF simulation (which is not present in the
486 SEN simulation hindering convection in the area), which forms about 2 h before
487 convective initiation (Figure 10).

488 Even in the first hours of the 18 November 2011 differences in the speed and direction
489 of the near-surface winds over the Dead Sea and on the eastern flank of the Jordanian
490 Highlands could be identified. A fundamental difference between simulations occurs
491 from about 17 UTC when strong westerly winds indicating the arrival of the MSB reach
492 the western shore of the Dead Sea. One hour later, in the REF^{19,11} run the MSB
493 strongly penetrates the Dead Sea valley reaching as far as the eastern coast in the
494 centre to south areas. However, in the SEN^{19,11} simulation the MSB does not penetrate
495 downward, instead strong northerly winds flow along the valley (Figure 10a). Numerous
496 observational and numerical studies carried out to investigate the dynamics of the MSB
497 (e.g. Naor et al. 2017; Vuellers et al. 2018) showed that the downward penetration of
498 the MSB results from temperature differences between the valley air mass, which is
499 warmer than the maritime air mass. An examination of temperature differences along a
500 near-surface north-south valley transect (positions in Figure 10a) indicates a decrease
501 of about 4 °C at the near-surface over the dried Dead Sea area in contrast to negligible
502 changes on a parallel transect inland, on the western coast of the Dead Sea. These
503 evidences the notorious impact of the absence of water in the valley temperature, thus,
504 gradients in the region. The colder valley temperatures do not favour the downward
505 penetration of the MSB, which strongly affects the atmospheric conditions in the valley.
506 Moreover, a north-easterly land breeze is visible from about 20 UTC on the eastern
507 shore of the Dead Sea in the REF^{19,11} simulation, but not in the SEN^{19,11} simulation
508 (Figure 10b). This situation reflects an interesting case different from the ones
509 generally presented in former investigations in the area (e.g. Alpert et al. 1997 ; and
510 Alpert et al. 2006b) in which due to the recent weakening of the Dead-Sea breeze,
511 mainly because of the drying and shrinking of the Sea, the Mediterranean breeze
512 penetrates stronger and earlier into the Dead-Sea Valley increasing the evaporation
513 because of the strong, hot and dry wind.

514 Mountain downslope winds develop in both simulations from about 22 UTC. One hour
515 later, strong northerly valley flow in the northern part of the Dead Sea contrasts with the
516 westerly flow in the SEN^{19,11} simulation (Figure 10c). As the valley cools down during
517 night time in the SEN simulation, T2m decreases about 1 K from 20 UTC to 03 UTC in
518 contrast with the 0.1 K decrease of the Dead Sea in the REF simulation, the
519 temperature gradient weakens and the northerly valley flow present in the REF

520 simulation is absent in the SEN simulation. During the night, the synoptic conditions
521 gain more influence than the local wind systems governing the conditions in the valley
522 during day time. South-easterly winds prevail in the valley in both simulations. Much
523 stronger wind velocities are reached in the REF simulation, confirming the sensitivity of
524 large-scale dynamics to near-surface climate change-induced impacts.

525 The encounter of the north north-westerly and south south-easterly winds over the
526 Dead Sea area in the REF^{19,11} simulation induces the formation of a convergence zone,
527 which intensifies and extends offshore over the next hours and determines the location
528 of convective initiation. Meanwhile, homogeneous south-easterly winds are observed in
529 the SEN simulation (Figure 10d).

530 The differences in the wind circulations contribute to a different distribution of the
531 atmospheric conditions in the target area, particularly, low-tropospheric water vapour
532 as seen in the vertical cross sections in Figure 11. The evolution of the atmospheric
533 conditions in the 3-h period prior to convective initiation evidences the deeper and
534 wetter boundary layer in the REF^{19,11} simulation at the north-western foothills of the
535 ridge at the Jordanian Highlands. Differences of IWV up to 2 mm, and of instability
536 (CAPE) close to 200 J/kg are found in this area (not shown). This is the location of the
537 convergence line where convective updrafts, which start close to the ground, are
538 triggered reaching a maximum vertical velocity of about 5 m/s above the convergence
539 zone in the REF^{19,11} simulation.

540

541 **4. Conclusions**

542 The drying and shrinking of the Dead Sea has been extensively investigated in the last
543 decades from different points of view. This process has been related to significant local
544 climate changes which affect the Dead Sea valley and neighboring regions. The
545 climate of the Dead Sea is very hot and dry. But occasionally the Dead Sea basin is
546 affected by severe convection generating heavy precipitation, which could lead to
547 devastating flash floods.

548 In this study, high-resolution COSMO model simulations are used to assess the
549 sensitivity of Dead Sea changes on the occurrence of convective precipitation in the
550 region. A set of high-resolution, ~ 2.8 km, climate simulations covering the period 2003
551 to 2013, and several numerical weather prediction (NWP) runs on an event time scale
552 (~ 48-36 h) are performed over the Dead Sea area. On a decadal time scale, two
553 simulations are carried out. The first “reference” run with the Dead Sea area, and a

554 second run “sensitivity” in which the Dead Sea is dried out and set to bare soil. The
555 NWP simulations focus on two heavy precipitation events exhibiting relevant
556 differences between the reference and the sensitivity decadal runs. A total of four
557 simulations are performed in this case.

558 As the energy balance partitioning of the Earth’s surface changes due to the drying of
559 the Dead Sea, relevant impacts could be identified in the region. From a climatological
560 point of view, the drying out of the Dead Sea results in less evaporation, higher air
561 temperatures and less precipitation. Reduced evaporation over the Dead Sea occurs
562 from May to October. The cooling effect of evaporation in the neighboring areas results
563 in an increase of T-2m. Atmospheric conditions, such as air temperature and humidity,
564 are mostly affected in the lower-tropospheric levels, which in turn influence
565 atmospheric stability conditions, hence, precipitating convection. In general, the
566 number of dry/wet days is not largely affected by the drying out of the Dead Sea,
567 although these differences could be larger for hourly precipitation; rather the structure
568 and intensity of the heavier precipitation events is changed. While a general and
569 homogeneous decrease in evaporation is seen at the SEN^{CLIM} simulation, precipitation
570 deviations occur in both directions, which could suggest and impact on the timing of the
571 events. A relevant year to year variability is observed in evaporation-precipitation which
572 indicates the need of long time series of observations to understand local conditions
573 and to validate model simulations.

574 The detailed analysis of two heavy precipitation events allowed us to further assess the
575 possible causes and the processes involved regarding the decrease in precipitation
576 intensity or the total omission of convection with respect to the reference simulation in
577 the absence of the Dead Sea water. Two main components, strongly affected by the
578 drying out of the Dead Sea, are found to be highly relevant for the understanding of the
579 environmental processes in the Dead Sea region.

580 (a) First, the lower-atmospheric boundary layer conditions. Changes in the energy
581 balance affect the atmosphere through the heat exchange and moisture supply. The
582 drying of the Dead Sea in the SEN simulations and the resulting decrease in local
583 evaporation, impact the Dead Sea Basin conditions and the neighbouring areas. A
584 reduction in boundary layer humidity and an increase in temperature result in a general
585 decrease of atmospheric instability and weaker updrafts indicating reduced deep-
586 convective activity. Main differences on the atmospheric conditions are directly over the
587 Dead Sea, but these conditions are frequently advected to neighbouring areas by the

588 thermally driven wind systems in the region which play a key role for the redistribution
589 of these conditions and the initiation of convection.

590 (b) Secondly, wind systems in the valley. In the arid region of the Dead Sea Basin with
591 varied topography, thermally and dynamically driven wind systems are key features of
592 the local climate. Three different scales of climatic phenomena coexist: The
593 Mediterranean Sea Breeze (MSB), the Dead Sea breeze and the orographic winds,
594 valley-, and slope-winds, which are known to temper the climate in the Dead Sea valley
595 (Shafir and Alpert, 2011). The drying of the Dead Sea in the SEN simulation disturbs
596 the Dead Sea thermally driven wind circulations. The Dead Sea breezes are missing,
597 weaker wind speeds characterize the region and along valley winds are consequently
598 affected. Furthermore, the dynamics of the Mediterranean breeze penetration into the
599 Jordan Valley are affected.

600

601 Consequently, the impacts on convection initiation and development are twofold:

602 (i) Distinct redistribution of atmospheric conditions, locally or remotely, which yields to
603 different atmospheric conditions that in the absence of the Dead Sea result in a
604 reduced moisture availability in the lower atmospheric levels and increased stability
605 hindering convection or reducing the intensity of the events.

606 (ii) Modification of the divergence/convergence field. The absence of the Dead Sea
607 substantially modifies the wind circulation systems over the Dead Sea valley, which
608 leads to the omission of convergence lines which act as triggering mechanism for
609 convection.

610

611 We can conclude that in general the lack of sufficient low-atmospheric moisture in
612 relation to the drying out of the Dead Sea, the increase of atmospheric stability in
613 addition to an absence or reduction in the intensity of the convergence zones, works
614 against initiation or intensification of precipitating convection in the area. The relevance
615 of the small-scale variability of moisture and the correct definition and location of
616 convergence lines for an accurate representation of convective initiation illustrates the
617 limitation and the lack of adequate observational networks in the area and the need for
618 high-resolution model simulations of boundary layer processes to predict intense and
619 localised convection in the region.

620 These results contribute to gain a better understanding of the sensitivity of local
621 conditions in the Dead Sea valley and neighbouring areas to lake level decline. Energy
622 balance partitioning and wind circulation systems are determinant for local climatic
623 conditions, e.g. temperature and humidity fields as well as aerosol redistribution,

624 therefore, any change should be well understood and properly represented in model
625 simulations of the region. Our results point out, in agreement with past modelling
626 activities in the region, the need to further improve the representation of precipitation
627 fields in the area, particularly close to the Mediterranean coastline. More accurate
628 Mediterranean SST input fields have been suggested as relevant to reduce the model
629 inaccuracies. Furthermore, a more realistic representation of the lake shape, water
630 salinity and temperature, as well as Dead Sea abundance and depth must be
631 addressed to more accurately describe present and expected future conditions. In the
632 present study, limitations found in this direction in relation to model and external data
633 set descriptions, as well as identified biases regarding for example moisture sources
634 for HP in the region, MSB and Dead Sea evaporation, are expected to impact our
635 results, and have to be improved in future efforts in the region. In a further step, the
636 authors will investigate some of these issues in more detail, and will assess the impact
637 of model grid resolution on the horizontal and vertical flow field in the region across
638 scales, including the impact on large-scale dynamics. We will also put emphasis in
639 trying to better understand the dynamics of the MSB under lake level decline using
640 high-resolution modelling, especially the contrasting behaviour pointed out in this study.
641 Fine resolution simulations up to 100 m will be performed for this purpose.
642 Furthermore, we will provide a verification of the complex chain of processes in the
643 area using unique measurements in the framework of the interdisciplinary virtual
644 institute Dead Sea Research VEnue (DESERVE; Kottmeier et al., 2016).

645

646 **Author contribution**

647 SK wrote the manuscript, analysed the data, interpreted the results and supervised the
648 work. JH carried out data analysis, interpretation of results and prepared all the figures.

649

650 **Acknowledgements**

1061 Figure 7: Spatial distribution of (a) 24-h accumulated precipitation from 14.11 09 UTC
1062 to 15.11 08 UTC from the REF^{14.11} simulation (left) and the SEN^{14.11} simulation (right)
1063 and (b) specific humidity below 950 hPa, from the REF^{14.11} simulation (left) and the
1064 difference between the REF^{14.11} and SEN^{14.11} simulations, as a mean for the 6-h period
1065 prior to convection initiation in the target area (14 November 16 UTC to 21 UTC), and
1066 (c) wind conditions at 700 hPa, 850 hPa, and 950 hPa (no relevant differences with
1067 respect to the 10-m field) for the same time period. Wind roses are centred at about
1068 35.82°E-32.07°N in our target area.
