Abstract. This study underlines the important role of transported black carbon (BC) mass concentration in the West-African Monsoon (WAM) area. BC was measured with a micro aethalometer integrated in the payload bay of the unmanned research aircraft ALADINA (Application of Light-weight Aircraft for Detecting IN situ Aerosol). As part of the DACCIWA (Dynamics-Aerosol-Chemistry-Cloud Interactions in West Africa) project, 53 measurement flights were carried out at Savè, Benin, in 2–16 July 2016. A high variability of BC (1.79 to $2.42 \pm 0.31 \mu\text{g m}^{-3}$) was calculated along 155 vertical profiles that were performed below cloud base in the atmospheric boundary layer (ABL). In contrast to initial expectations of primary emissions, the vertical distribution of BC was mainly influenced by the stratification of the ABL during the WAM season. The article focuses on an event (14 and 15 July 2016), which showed distinct layers of BC in the lowermost 900 m above ground level (a.g.l.). Low concentrations of NO_x and CO were sampled at Savè supersite near the aircraft measurements and suggested marginal impact of local sources during the case study. The lack of primary BC emission was verified by a comparison of the measured BC with the model COSMO-ART (Consortium for Small-scale Modelling–Aerosols and Reactive Trace gases) that was applied for the field campaign period. The modelled vertical profiles of BC led to the assumption that the measured BC was already altered, as the size was mainly dominated by the accumulation mode. Further, calculated vertical transects of wind speed and BC presume that the observed BC layer was transported from south with maritime inflow, but was mixed vertically after the onset of a nocturnal low-level jet at the measurement site. This report contributes to the scope of DACCIWA by linking airborne BC data with ground observations and model and it illustrates the importance of a more profound understanding of the interaction between BC and the ABL in the WAM region.

1 Introduction

BC is one of the major contributors affecting the Earth's climate system. Freshly emitted BC caused by incomplete combustion, is insoluble in water and it strongly absorbs the solar radiation in the visible spectrum (Bond et al., 2013). Once BC is emitted into the atmosphere, ongoing physical and chemical reactions, like secondary aerosol formation influence the composition and mixing state of aerosol particles. Aged BC can act as cloud condensation nuclei after hygroscopic growth in the atmosphere (Zhang et al., 2008), which ultimately contributes to the indirect aerosol effect. The understanding of BC life cycle is still poor, as monitoring of type and source of combusted products, ageing processes in the atmosphere and the current knowledge of wet deposition differ in used measurement methods, and simulations show a high discrepancy (e.g., Li et al., 2017).

The role of BC emission is of special interest in regions with dense population. For instance, the population in southern West Africa is proposed to grow to more than 800 million by the middle of the century (Knippertz et al., 2015a), consequently a degradation of air quality and human health is expected by ongoing anthropogenic pollutions. Lioussé et al. (2014) compared three different future scenarios for the African emissions in the year 2030, if no regulations for the combustions will be carried out. The calculated BC emission factors varied between 2 and 4 in comparison with 2005, meaning a possible emission of more than 2.5 Tg BC y^{-1} that would be comparable with 20–30 % of the BC emissions worldwide.

Investigating the impact of growing air pollution on the southern West Africa area at a regional and global-scale is one subject of the DACCIIWA project (see Knippertz et al., 2015b). DACCIIWA aims at understanding complex interactions between aerosols, clouds and their impact on climate and weather in South West Africa. The study combines in-situ and aircraft observations that are further compared with satellite data and models. The intensive field experiment of DACCIIWA was carried out in June–July 2016 during the WAM (e.g., Knippertz et al., 2017; Flamant et al., 2018; Kalthoff et al., 2018). The aerosol composition in the WAM region is mainly influenced by the large-scale synoptic pattern (Mari et al., 2008). During July and September, biomass burning smokes from southern Africa are the dominant contributors during WAM season and were proposed as a major source for BC, retrieved by satellite data and simulations (Huang et al., 2009). Horizontal transects were performed with aircraft at the coastal site of South West Africa and the results of PM_{10} concentration were shown in Brito et al. (2018). Interestingly, the observed BC fraction of the aerosol composition varied only minimal (6 %) above in-plume flights in comparison with background concentrations of BC with $0.34 \mu\text{g m}^{-3}$ in the lowermost 2 km. The observations are in agreement with simulations by Huang et al. (2009), showing that BC concentration is more likely dominated by long range transport triggered by the WAM instead of local biomass burning emissions.

However, previous data showed only the large-scale variability of BC instead of columns on smaller-scales of a few square kilometres above one particular measurement field. Especially the relationship between the ABL and BC distributions needs more profound investigations. Liu et al. (2018) studied the ABL height for 347 days depending on the classification of polluted ($\text{BC} > 5 \mu\text{g m}^{-3}$) and non-polluted events ($\text{BC} < 5 \mu\text{g m}^{-3}$) in Wuhan, China. The ABL height was suppressed on polluted days, which ultimately leads to poorer air quality. The reduction of the ABL height can be explained by the increase of absorption due to enhanced particulate matter originating from pollution (e.g., Petäjä et al., 2016). The growing absorption heats up the upper part of the ABL which further results in an increase of stability. As cause of weaker turbulence and mixing

in more stable conditions, the ABL height decreases. But in most investigations, BC is solely measured at ground. Further, Liu et al. (2018) calculated the top of the ABL from lidar measurements neglecting cases with low clouds. So that studies are missing with non-clear sky days like during monsoon seasons.

Therefore, a large benefit can be expected by using unmanned aerial systems (UAS) for investigating the small-scale variability of BC in the ABL. Relating to BC measurements, optical methods based on light-absorbing principle are common. The development of miniaturised BC instrumentation is essential, as reduced size and limitation of weight are the main challenges of new sensor integration on airborne platforms. Wilcox et al. (2016) presented vertical profiles of BC, measured with a miniaturised three wavelength absorption photometer (Corrigan et al., 2008) on UAS, during the winter monsoon over the northern Indian Ocean. BC loads were higher in the lowermost 3 km on polluted days in comparison with days of minor pollution observed at the surface. A lower ABL height was estimated during polluted days, supporting the current understanding of feedback mechanisms, like it was summarised in Petäjä et al. (2016). However, the observations showed an increase of humidity in the surface mixed layer that might favour cloud formation that is in contrast to the understanding of a lower instability and minor turbulence due to absorption of aerosols in the ABL. Thus, further studies are essential to better understand the role of BC in the ABL and to consider potentially other impacts on the vertical distribution in a broader range.

The objective of the current study is to investigate the small-scale vertical variability of BC and its relation with the ABL, by using the UAS ALADINA at a remote site in West Africa. To the authors' knowledge, there is no study of the vertical distribution of BC obtained by unmanned research aircraft in the WAM region so far. Subsequently, BC distribution within the ABL is presented in general for the whole observation period (2–16 July 2016), and in particular for an event (14–15 July 2016). In order to quantify the small-scale vertical BC distribution and to assess the role of small-scale local emissions, the airborne data was compared with ground monitoring and the COSMO-ART model of the DACCWA framework. More precisely, observations of wind profiler, ceilometer and gas concentrations are taken into account that were installed 4 km away from the research flights in order to characterise the current weather situation and possible sources for BC. The COSMO-ART model is used as indicator of particle size and distribution.

The article is structured as follows: The UAS ALADINA and its instrumentations are introduced in Sect. 2. The model set up of COSMO-ART is provided in Subsect. 2.4 and the measurement sites are presented in Subsect. 2.5. The results are discussed in Sect. 3 and the outcome of the study is summarised in Sect. 4.

2 Instrumentation, Model, and Measurement Site

2.1 The Unmanned Aerial System ALADINA

There is a wide range of airborne platforms, including UAS operating with batteries and fuel engines, both fixed wings and multicopters that are applied for atmospheric research on a various sampling locations (e.g., Mayer et al., 2010; Marino et al., 2015; Renard et al., 2016; Jiménez et al., 2016; Cuxart et al., 2016; Båserud et al., 2016; Brosy et al., 2017). The different systems have advantages and shortcomings. In terms of ALADINA, the aircraft is electrically powered, so that any contamination of the measured air probe can be prevented. Thus, a qualitative analysis of aerosol particles is guaranteed by sampling in short

periods of time, like it was done in previous studies using ALADINA (Platis et al., 2016; Altstädter et al., 2018) in Melpitz, Germany.

ALADINA was designed at the Technische Universität Braunschweig for atmospheric research and it was steadily improved regarding current technical requirements. The Carolo P360 has a maximum take off weight of 25 kg and a wing span of 3.6 m.

- 5 The modular payload bay offers the capacity for a payload weight of approximately 4 kg. The pusher aircraft has an electrical propulsion and enables a flight endurance of 40–50 min at a cruising speed of $28\text{--}30\text{ m s}^{-1}$ in the current configuration. ALADINA is operated manually during take off and landing, whereas controlled automatically during measurement flights via autopilot. Flight time, accurate position, altitude and attitude of the aircraft are given by the installed GPS (Global Positioning System) and IMU (Inertial Measurement Unit). A precision of $\pm 1.5\text{ m}$ in constant height is provided by the autopilot system.
- 10 The flight track follows predefined waypoints that are sent before take off or during flight to the on board computer and can be changed according to the current scientific goals during measurement flights. Observed data and flight path can be monitored via live transfer at a temporal resolution of 1 Hz.

- More information on the airplane itself can be found in Altstädter et al. (2015). The instrumentation was updated for DAC-CIWA and the set up is provided in Bärffuss et al. (2018). All UAS data derived during DACCIIWA are available from Bärffuss et al. (2017). Other aerosol sensors (optical particle counter and condensation particle counter) that are usually on ALADINA did
- 15 not work properly during DACCIIWA. One reason for this might be damage of optical parts after transportation. But adjusting and calibration was not possible at the research site due to missing laboratory, so that true causes could not be identified. Thus, the current study focuses explicitly on meteorology and BC and the instrumentations are explained in the following sections.

2.2 Meteorological Sensors for Turbulence Measurements

- 20 The meteorological sensor package is displayed in Fig. 1a. It consists of a multi hole probe (number 1), temperature sensors (number 2–4) and humidity sensors (number 4 and 5). The meteorological sensors are mounted at the tip of the aircraft nose in order to assure an undisturbed air flow.

- The three dimensional wind vector (\mathbf{V}) is derived via a multi hole probe manufactured by Institute of Fluid Dynamics (Technische Universität Braunschweig, Germany; e.g., Wildmann et al., 2014). The multi hole probe is combined with an
- 25 IMU/GPS system. The wind vector has a usable data rate of up to 100 Hz with an accuracy in wind speed components of $\pm 0.5\text{ m s}^{-1}$ and in wind direction of $\pm 10^\circ$. The methods for wind calculation are described in Bärffuss et al. (2018).

- The air temperature is calculated from three temperature sensors based on different measurement techniques. A finewire element was manufactured at Institute of Flight Guidance (Technische Universität Braunschweig, Germany) with a high temporal resolution of 30 Hz and an accuracy better than $\pm 0.05\text{ K}$ (see Fig. 1a, number 2). The sensor principle is comparable with a
- 30 system described in Wildmann et al. (2013), but it was additionally protected with a housing against direct solar radiation, dust particles and mosquitoes. In addition, a factory calibrated capacitive sensor of type TSYS01 (Measurement Specialties, USA) was used with a resolution of around 0.3 Hz and a given accuracy of $\pm 0.1\text{ K}$ (see Fig. 1a, number 3). These two sensors were fused together into a long term stable reading with an error of less than $\pm 0.1\text{ K}$ and used for this study. Further, air temperature was measured by an HMP110 (Vaisala, Finland) with lower resolution of 0.5 Hz and $\pm 0.2\text{ K}$ accuracy (Fig. 1a, number 4).

The relative humidity is measured with a Rapid P14 element (Innovative Sensor Technology, Switzerland) and a HMP110 (Vaisala, Finland), both based on capacitive measuring principle (Fig. 1a, number 4 and 5). The measurement range is from 0 to 95 % RH with an accuracy of ± 1.5 % RH in a temperature range between 0 and 40 °C, as specified by the manufacturer. The response time of 10 s resulted after combining the humidity sensors complementary.

5 2.3 Aethalometer for Detecting BC Mass Concentration

The one wavelength micro aethalometer (microAeth® model AE51, AethLabs, USA) is a light weight (around 280 g) and easy handling device for BC monitoring. It was implemented into the payload bay of ALADINA (see Fig. 1b). The aerosol inlet is installed at the front of the aircraft close to meteorological sensors (Fig. 1a, number 6). The air stream was run at a flow rate of 150 ml min⁻¹ and it was dried with silica gel before reaching the AE51 inlet in order to avoid strong influences of moisture on the filter stripe of the sensor.

Here, it has to be considered that different measurement methods (for instance optical or chemical) lead to different types of BC. A clear terminology is mandatory, as recommended by Petzold et al. (2013). In terms of the presented study, the equivalent black carbon (EBC) was calculated from the AE51. Only for the sake of simplicity, the term BC instead of EBC will be used hereafter.

The BC mass concentration is estimated from the attenuation coefficient (σ_{ATN}) at the wavelength of 880 nm on an aerosol loaded filter. In case of the AE51, a T60 Teflon-coated borosilicate glass fibre filter stripe is used that has to be manually changed after every measurement period. The measurement principle is based on the Lambert-Beer law and the attenuation (ATN) is defined as follows:

$$ATN = -100 \cdot \ln\left(\frac{I}{I_0}\right), \quad (1)$$

where the attenuation is calculated from the ratio of the light intensity (I) transmitted through the loaded filter with respect to the initial intensity of the transmitted light (I_0) on an aerosol-free filter stripe. Taken from Hansen et al. (1984), the attenuation is proportional to the surface concentration of BC. By taking into account that the change in the attenuation (ΔATN) is caused by an increase of BC mass load on the filter stripe in a corresponding time interval (Δt), and then BC mass concentration can be derived as follows (Saturno et al., 2017):

$$BC = \frac{\sigma_{ATN}}{\alpha_{ATN}} = \frac{A \cdot \Delta ATN}{\alpha_{ATN} \cdot Q \cdot \Delta t}. \quad (2)$$

A is the filter stripe area, α_{ATN} is the BC mass attenuation cross section at a wavelength of 880 nm and Q is the volumetric flow rate. σ_{ATN} was corrected for artefacts based on the filter-based measurement technique (e.g., Weingartner et al., 2003; Virkkula et al., 2007; Collaud Coen et al., 2010; Ran et al., 2016).

The measurement range is 0–1 mg BC m⁻³ with a resolution of 1 ng BC m⁻³, specified by the manufacturer. According to tests of the micro aethalometer in the field and in the laboratory after flight campaign, the accuracy was determined to ± 0.2 µg BC m⁻³ at a response time of 1 Hz.

The effects of meteorological conditions (sensitivity to temperature and humidity) on the instrument's readings and artefacts were characterised on different types of airborne platforms (e.g., Ferrero et al., 2014; Ran et al., 2016; Chyliński et al., 2018). However, a direct comparison of the AE51 on UAS relating to ground observations was missing so far. Pikridas et al. (2019) showed that the AE51 is a feasible tool for BC measurements on UAS in an area of high background aerosol particle concentration. Flight campaigns were conducted in Athens and Cyprus. The results are based on comparison of three different miniaturised absorption instruments (e.g. AE51) on UAS with ground based monitoring of MAAP (Multi Angle Absorption Photometer) and one micro aethalometer of type AE33. According to results of the Athens campaign, the correlation of AE51 was $R^2=0.76$ by sampling close to ground in relationship between MAAP and AE33. BC was underestimated by the AE51 of 6 to 7%, thus within the given accuracy of 10%. However, the comparison during the Cyprus campaign showed a high overestimation of 22–55% BC by the AE51, possibly caused by low background aerosol particle concentration at the research site. The low performance of the instrument for small background concentration in generally clean air masses is one major issue of the AE51 (e.g., Ferrero et al., 2014; Lee, 2019). The impact should be of minor relevance for the current study that addresses an area with high PM concentrations, that partially exceed WHO guidelines (Adon et al., 2019). However, during laboratory tests it became apparent that readings of the micro aethalometer are also sensitive to changes in temperature and humidity. This will be further addressed.

2.3.1 Influence of Temperature Changes and Data Post-Processing

As example, the impact of temperature changes on the attenuation is shown for a flight that was performed with ALADINA on 14 July 2016 (flight ID 41 of 53 total measurement flights). Figure 2 presents the internal temperature from the micro aethalometer (PCBtemp) during the measurement period from 05:16 until 06:30 UTC that varied between 27 and 36 °C. This flight was chosen as the worst case scenario during the study. In order to determine the temporal evolution of temperature, the bit noise has to be filtered out by any smoothing algorithm. Taken from laboratory tests in a temperature chamber, the influence factor of temperature changes on BC measurements was determined to be in the order of $0.25 \mu\text{g BC (dT/dt)}^{-1}$. Applied for the current case, largest temperature gradients were observed between 05:16 and 05:30 UTC during the first steps of the ascent, leading to a bias (shown in BC Error, lower panel of Fig. 2) of $3 \mu\text{g BC m}^{-3}$. BC data were corrected with the internal temperature changes measured directly at the BC sensor for the whole study. Here, it should be clarified that these first steps of ascent, and similar to all other flights, do not directly affect the here presented analysis. These first steps correspond to take-off that is handled in remote control by the responsible pilot. However, exclusively automatic flight tracks were used in order to obtain comparable vertical profiles and neglecting horizontal patterns. One possible cause of these large temperature gradients might be internal heating of the aircraft. During landing and preparation of the next research flight, the aircraft was exposed directly to sunlight. Another effect that could lead to this high BC error might be the load of the optical part. The error was reproducible in the laboratory, but the exact source of the error could not be determined. More tests in field studies would be mandatory.

During post-processing, the readings of the BC attenuation were phase shift free low pass filtered at different time scales in 10, 30 and 60 seconds. Therefore, a high pass Butterworth filter of third order was used, running forward and backward in

order to eliminate phase shifts. Averaging was not applied for the attenuation signal in avoidance of poor frequency responses. Figure 3 shows the high variability of the attenuation signal for 1 s temporal resolution during a measurement flight between 15:58 and 16:42 UTC on 10 July 2016. The results with the highest possible temporal resolution but still acceptable noise (standard deviation smaller than $0.3 \mu\text{g m}^{-3}$ or 22% of the signal) were obtained by a low pass filter with a span of 10 s. The mean attenuation was $1.59 \pm 0.30 \mu\text{g m}^{-3}$, varying between 0.5 and $2.5 \mu\text{g m}^{-3}$. As the frequency response will be lost by a span of 30 s or more, the method of 10 s low pass filter was used for BC measurements of ALADINA profiles, except for the model comparison in Sect.3.3. The simulations were run prior to statistic overview in Sect. 3.1 with a span of 1 s.

2.4 Model Description of COSMO-ART for DACCIWA

In this section, a short description of the model COSMO-ART (Consortium for Small-scale Modelling–Aerosols and Reactive Trace gases) is shown and with respect to the simulation set up for the DACCIWA measurement campaign. COSMO-ART is a comprehensive online coupled model system (Vogel et al., 2009) based on the operational weather forecast model COSMO (Baldauf et al., 2011). COSMO-ART includes a comprehensive chemistry module to describe the gaseous composition of the atmosphere and secondary aerosol formation. Chemical reactions are calculated with RADMKa (Regional Acid Deposition Model Version Karlsruhe; Vogel et al., 2009), which is based on RADM2 (Regional Acid Deposition Model, Stockwell et al., 1990). Physical processes, including transport, turbulent diffusion, and dry and wet deposition are treated together with photochemistry and aerosol dynamics using the modal approach. The size distribution of aerosol within COSMO-ART is approximated by eleven log-normal distributions (modes), considering the Aitken and nucleation mode (with and without BC core), fresh BC, and the coarse mode (sea salt and mineral dust). COSMO-ART explicitly treats the ageing of BC particles transferring them from external to internal mixtures as described in Riemer et al. (2004). For DACCIWA, the COSMO-ART model system was applied quasi-operational during the DACCIWA measurement campaign, to support the decision-making of research aircraft flight tracks within the aircraft special observing period (27 June–17 July 2016) and to derive model climatologies of the spatial distribution of the southern West African air pollution. More details of the model set up for DACCIWA can be taken from Deetz et al. (2018). The continuous forecasts were initiated on 8 May and were active until 31 July 2016, covering the simulation domain 25°W – 40°E and 20°S – 35°N with a grid mesh size of 28 km and 3 h model output. ICON forecasts were used as meteorological boundary conditions and MOZART (Model for OZone and Related chemical Tracers) as aerosol/chemistry boundaries. The simulations consider the emission of mineral dust, sea salt, biogenic volatile organic compounds, dimethyl sulphide and emissions from biomass burning and anthropogenic origin. Thus, BC is related to anthropogenic emissions and emissions from biomass burning. But feedbacks of the prognostic aerosol on the aerosol direct and indirect effect are not considered in these simulations.

2.5 Measurement Site

The measurement flights were performed at the local airfield ($8^\circ 1' \text{N}$, $2^\circ 27' \text{E}$, 185 m above sea level, a.s.l.) south-west of Savè, Benin, in the period between 2 and 16 July 2016. The commune covers an area of $2 \times 10^4 \text{ km}^2$ with approximately 100,000 inhabitants. The Savè supersite of Karlsruhe Institute of Technology (KIT) and Université de Toulouse (Université de Toulouse

III- Paul Sabatier, UPS) was installed at a distance of 4 km SW of the airfield close to Gobè (Fig. 4). An overview of the Savè supersite and mounted instrumentation are given in Kalthoff et al. (2018). Both measurement sites are connected with the main road RNIE2. The airfield consists of dry and sandy soils and is surrounded by agricultural land. During the experiment, 53 flights were performed on different daytimes with a total flight duration of 32 h and a total flight distance of approximately 2260 km. Within the study, 155 vertical profiles were realised up to a maximum height of 1600 m a.g.l. allowing the analysis of ABL conditions in connection with the vertical distribution of BC. Although Savè supersite was at a distance of 4 km, horizontal flights were in most cases directed parallel to the current wind direction measured at the supersite.

2.5.1 Ceilometer and Wind Profiler

In order to retrieve information on cloud cover, cloud base height, wind speed and wind direction during the UAS operation, ceilometer and wind profiler data were used from the Savè supersite.

The CHM15k ceilometer was employed to obtain the temporal evolution of cloud characteristics during the DACCIWA campaign (Handwerker et al., 2016). From the measurements of the attenuated backscatter coefficient profiles the cloud base height is determined based on a threshold method (manufacturer Lufft, personal communication, 2016). The manufacturer algorithm allows for the detection of up to three cloud base heights at a temporal resolution of 1 min and 15 m vertical resolution. In this study, only the first detected cloud base height is shown, since the focus is on low-level clouds.

High-resolution information of flow conditions (wind speed and wind direction) is obtained from a sodar (for the lower part of the ABL, Wieser et al., 2016) and an ultra-high-frequency (UHF) wind profiler (above 200 m a.g.l.) measurements.

The sodar is an active remote sensing instrument, which was continuously running during the campaign. The retrieved information is based on the reflection of acoustic pulses at temperature inhomogeneities in the air with subsequent Doppler analysis. The instrument provides profiles of horizontal wind speed and direction and the backscatter at 30 min temporal resolution and 10 m vertical resolution between 30 and 600 m a.g.l. in altitude.

The UHF wind profiler installed at Savè supersite by UPS is a 1274 MHz Doppler radar and it works with five beams to document the vertical structure of atmospheric dynamics up to the middle troposphere. It allows the retrieval of the three wind components. The wind profiler operated continuously from 19 June to 30 July 2016 with two acquisition modes (75 and 150 m vertical resolution, respectively) in a time resolution of 2 min. This radar is used in Dione et al. (2019) for the characterisation of the low-level atmosphere dynamics during the whole DACCIWA campaign. More details on data availability and technical characteristics of this radar can be found in Derrien et al. (2016). In this study, the data was averaged over 15 min using the low mode (0-3 km) for the analysis of wind speed and wind direction during the studied days.

2.5.2 Gas Concentrations of NO_x and CO

Measurements of trace gases were taken on two separate towers. Nitrogen monoxide (NO) and nitrogen dioxide (NO_2) were measured on an 8 m high tower and carbon monoxide (CO) was measured separately at 3.5 m. Both towers were located at the Savè supersite, 80 m away from each other, and were generally upwind from the main neighbouring town of Savè and the power generator used for the whole instrumentation.

CO atmospheric mixing ratios were measured with a modified Model 48C-TL CO Analyzer (Thermo-environmental Instruments Inc.) with a detection limit of 12 ppb_v. A dynamic dilution method by flow regulators is used for the CO calibration. The dilution is made with a commercial reference CO-N₂ mix at 450 ppm_v (air liquid bottle) into zero air made by Sofnocat 423. Every 3 or 4 years, the flow regulators device is sent to the French Laboratoire national d'Essais for check and calibration.

- 5 NO and NO₂ were measured with a Model 42C-TL NO-NO₂-NO_x (Thermo-environmental Instruments Inc.) with 0.05 ppb_v detection limit. The Model 42C-TL NO-NO₂-NO_x was calibrated before and after the campaign by using a reference NO₂ air mixture, i.e. NO in N₂ diluted with zero air. Reference NO, and NO₂ were ISO 6141:2015 certified at 8.73 and 8.58 ppm for NO, before and after the campaign, respectively, and 9.28 ppm for NO₂, both with 5 % precision (Pacifico et al., 2019).

10 All data of the trace gases were sampled every 10 s, filtered and averaged to produce 1 and 30 min values. The data is accessible from Derrien et al. (2016).

3 Results and Discussion

First, an overview is presented with respect to the small-scale vertical variability of BC that was measured with ALADINA during the two week period (2-16 July 2016) of DACCWA. Further, a particular case (14-15 July 2016) is analysed in detail that shows enhanced layers of BC which are not issued from primary emissions. This is subsequently supported by comparison
15 with ground data of gas concentrations and model results of COSMO-ART. During the case study, weather conditions were typical for the WAM, mainly influenced by the occurrence of a low-level jet and low-level clouds which are shown by ground base monitoring of wind profiler and ceilometer. Thus, those shown observations might be reproducible for other investigation periods of the WAM season.

3.1 Summary of the Vertical Variability of BC during the Experiment

- 20 Figure 5a shows BC mass concentration, potential temperature and water vapour mixing ratio calculated in 20 m intervals in the lowermost 1100 m a.g.l. along 155 vertical profiles. Figure 5b represents the standard deviation of the mean profiles for corresponding parameters shown in Fig. 5a. The vertical distribution of the minimum BC mass concentration was almost not detectable in the lowermost 600 m a.g.l., but increased up to $1.64 \pm 0.2 \mu\text{g m}^{-3}$ at higher altitudes. The total maximum of $14.01 \mu\text{g m}^{-3}$ was measured at the height of 200 m a.g.l., but was only observed during one day on 15 July 2016. The mean
25 BC mass concentration (\overline{BC}) varied between $1.79 \mu\text{g m}^{-3}$ and $2.42 \mu\text{g m}^{-3}$, and the standard deviation for all altitude intervals was $\pm 0.31 \mu\text{g m}^{-3}$. The vertical distribution of \overline{BC} showed three dominant distinguished layers at the heights of 200, 600 and 920 m a.g.l. (Fig. 5b). The mean potential temperature ($\overline{\theta}$) was between 300.6 and 304.1 K in the vertical distribution and represented an overall stable stratification of the ABL, as the majority of the measurement flights was performed in the morning hours. The mean water vapour mixing ratio (\overline{q}) varied between 14.24 and $16.24 \pm 0.52 \text{ g kg}^{-1}$ and decreased with altitude in
30 the lowermost 1100 m a.g.l.

All mean values showed a sharp gradient at the height of 600 m a.g.l. One explanation for this could be less data availability above this height. The research flights are restricted below cloud base, as ALADINA is not rain proof. The first part of the

measurement period (2-8 July 2016) was during the post-onset phase of the WAM season (Knippertz et al., 2017). This period was influenced by low-level clouds with a median height of cloud top at 587 m a.g.l., taken from 06:00 UTC radiosondes at Savè (Kalthoff et al., 2018). This part corresponds to almost half (25 of 53) of the research flights. Although, nocturnal low-level clouds dissolved during the day, a large portion of vertical profiles still remained below 600 m a.g.l. Drier periods occurred during the vortex phase of the WAM that was predominant from 9 until 17 July 2016 (Knippertz et al., 2017).

Taken from the statistic overview of \overline{BC} , BC seems to occur in the whole ABL. No clear evidence is visible of local pollution near surface. One explanation could be the performance of ALADINA during daytime so that in some cases the ABL was already well mixed and BC was lifted from ground through the ABL. However, this can not be supported by $\bar{\theta}$ that shows an overall stable ABL. This relationship presumes that observed BC originated prior to the observation periods, probably during night or even earlier. Another possibility could be horizontal advection that caused distinguish layers of BC in the ABL. Here, the understanding of BC in the ABL can not be fully described by previous observations like Wilcox et al. (2016) and Liu et al. (2018). Directly emitted BC would have probably warmed the ABL by absorption that further caused stable conditions and a lower ABL height but with increased humidity. This is in contrast to here observed reduced humidity due to the decline of \bar{q} in the ABL. Therefore, it is essential to take into account other aspects that might affect the BC distribution within the ABL.

3.2 BC Observations during Case Study on 14–15 July 2016

The following section addresses the vertical distribution of BC measured with ALADINA on two days in this period (14 and 15 July 2016). The first day was influenced by a nocturnal low-level jet and free of low-level clouds. The second day was affected by a nocturnal low-level jet and by the presence of low-level clouds, see Babić et al. (2019a).

An overview of the performed measurements is presented in Tab. 1. The flight time of ALADINA is given in UTC (local time = UTC +01:00). In addition, gas concentrations of NO_x and CO (Derrien et al., 2016) are presented for the flight periods in 1 min average. The total maximum NO_x concentration of 1.9 ppb_v was observed in the morning between 06:41 and 08:40 UTC on 15 July 2016 simultaneously with the maximum CO concentration of 259 ppb_v.

Backscatter data indicate that there was a well mixed layer in the afternoon on 14 July 2016, and low-level clouds appeared temporarily above 800 m a.g.l. (Fig. 6a). On the following day, low-level clouds formed below 250 m a.g.l. at about 07:00 UTC (Fig. 6b). The enhanced aerosol load disappeared, which can be seen by the enhanced backscatter at an altitude up to 300 m a.g.l. from midnight to 07:00 UTC in Fig. 6b. Afterwards, the clouds lifted up to 750 m a.g.l. at 11:00 UTC and dissolved completely at 14:00 UTC in the lowermost 2 km a.g.l. In addition, a second layer of clouds built up at the height between 1050 and 2000 m a.g.l.

Wind conditions are shown in Fig. 7. The wind speed was moderate between 3 and 6 m s⁻¹ in the lowermost 2 km a.g.l. in the night from 13 July until the early morning at 06:00 UTC on 14 July (Fig. 7a). The observed low-level jet intensified in the course of the night and reached the maximum speed in the early morning hours. The strip of high wind speed has dissolved at midday, simultaneously with the occurrence of clouds. However, in the afternoon, there is a low-level wind maximum of 6–8 m s⁻¹ at the height between 200 and 600 m a.g.l. that persisted for more than 12 h at the same altitude (Fig. 7b). At 07:00 UTC on 15 July, when low-level clouds were present, the wind speed reached a maximum of 9 m s⁻¹ between the height of

800 and 1000 m a.g.l. After the dissolving cloudiness at 12:00 UTC, a wind speed of 3 m s^{-1} was observed. Measured wind speed and wind direction are a combination of the persistent monsoon flow and the maritime inflow that arrives typically in the early evening hours (Dione et al., 2019; Adler et al., 2019).

Figure 8a displays three vertical profiles between the height of 100 and 800 m a.g.l. obtained with ALADINA at 06:15, 06:55 and 07:27 UTC on 14 July 2016. The ABL was stably stratified with the base of the inversion layer at 400 m a.g.l. At the heights of 450 to 500 m a.g.l. a dry air mass was observed, as can be seen from the profile of the water vapour mixing ratio. Above the inversion layer and in accordance with the different type of air mass, an increase of BC was observed in the residual layer. The total maximum BC of $2.75 \mu\text{g m}^{-3}$ was measured at the height of 600 m a.g.l. in the first profile at 06:15 UTC. The enhanced BC concentration at this altitude was still visible 1 h later. The wind direction varied between SE and SW and the vertical distribution of the wind speed showed a significant increase close to the inversion layer. At 07:27 UTC the wind speed increased up to 12 m s^{-1} between the height of 400 and 500 m a.g.l.

The structure of the ABL was well mixed at noon and before the evening transition (Fig. 8b) leading to homogeneous conditions of q and BC in the vertical distribution. The wind direction changed from SW to SE in the lowermost 200 m a.g.l. and the wind speed was constant with 5 m s^{-1} in the lowermost 800 m a.g.l.

On the following day (15 July 2016) the ABL was influenced by the formation of low-level clouds around 07:00 UTC. The same parameters as shown in the previous part are presented in Fig. 9. In this case, three vertical profiles are displayed at 05:33, 06:10 and 06:46 UTC before low-level clouds occurred. The UAS was operated between 100 and 900 m a.g.l. and the ABL was stable with a capping inversion layer at 300–400 m a.g.l. The fourth vertical profiles was performed at 08:29 UTC below the cloud base maximum height of 320 m a.g.l. The last profile was carried out at 16:52 UTC after the dissolution of low-level clouds below 650 m a.g.l. The ABL was well mixed and q decreased in comparison with the profiles in the morning hours. BC decreased to $1.5 \mu\text{g m}^{-3}$ at the height of 300 m a.g.l. One explanation could be wash out by low-level clouds. Another possibility of BC reduction might be caused by the change in wind direction to SSW. Probably, a different type of air mass with cleaner air was observed in the investigation area. The wind speed increased close to ground level up to 5 m s^{-1} but decreased to 3.2 m s^{-1} at 600 m a.g.l.

3.3 Comparison of ALADINA Observations with COSMO-ART Model Results

In this section, ALADINA BC profiles are compared with the model results of COSMO-ART obtained during the case study. For the comparison it has to be considered that COSMO-ART has a grid mesh size of 28 km and the lowest 1000 m are resolved by only eleven layers. This makes a direct comparison with airborne point observations difficult. Nevertheless, the simulations with COSMO-ART provide added value to this study: BC can be separated into fresh BC, aged BC in the Aitken and aged BC in the accumulation mode, allowing to discussing potential sources of BC. Further, simulations allow to embedding the local observations into larger spatial scales. Riemer et al. (2004) indicated BC ageing time scales of 8 h close to source regions and 2 h above source regions for daytime conditions during summer, predominantly related to ageing via the condensation of sulphuric acid on BC particles.

Figure 10 shows the spatio-temporally collocated total BC profiles of ALADINA with 1 Hz temporal resolution and COSMO-ART for six different time intervals. In addition, the COSMO-ART results for fresh BC, aged BC (Aitken mode) and aged BC (accumulation mode) are indicated.

For 14 July 2016 (see Fig. 10a–d) a full diurnal cycle of BC profiles from 06:00 to 18:00 UTC is presented. In the morning hours the observations show increased concentrations above 500 m a.g.l. with the peak of around $3.0 \mu\text{g m}^{-3}$ at 600 m a.g.l. (Fig. 10a). This peak is represented in the model. The best agreement is found for aged BC in the accumulation mode. However, COSMO-ART shows near-surface concentrations of up to $3 \mu\text{g m}^{-3}$ that are higher than the observations. Until noon, the vertical profile of BC shows a vertically constant BC concentration, likely due to vertical mixing in the ABL (Fig. 10b and c). COSMO-ART results of aged BC in the accumulation mode match very well these observations. The observed BC concentration peak at the altitude of 900 m a.g.l. is not seen by COSMO-ART, and may be an artefact induced by the formation of cloud patches as seen by the ceilometer (Fig. 6a). Between 12:00 and 18:00 UTC, no significant change in the measured vertical BC profile is visible. In the simulations, the contribution of BC in the accumulation mode decreases and the concentration of BC in the Aitken mode increases, leading to a better agreement of the observations with the total BC concentration (Fig. 10d). At 06:00 UTC on 15 July 2016 (see Fig. 10e) observation and model indicate an enhanced BC concentration below 400 m a.g.l. The vertical profile, capturing the lowest 900 m a.g.l., shows a representative agreement of observation and model of total BC. Around the height of 200 m a.g.l., ALADINA indicates high BC concentrations of more than $16 \mu\text{g m}^{-3}$ that are not represented in COSMO-ART. The discrepancy could be based on the 1 s sampling of ALADINA that is strongly noisy. The first assumption was turbulent mixing near the cloud edge that might have led to high variability of the sampling flow, thus on BC data. Another possibility could be droplets that disturbed the signal. However, it cannot be ruled out that this is an artefact induced by high humidity prior to the onset of cloud formation, which occurred around that time. Finally, at 18:00 UTC, the observed BC profile corresponds to the aged BC in the accumulation mode.

Figure 11 shows a South-North cross section of the total BC concentration and wind speed up to an altitude of 1500 m a.g.l. for 14 July 2016. The location of the airborne observations at Savè is indicated by the dashed line. The wind speed transect clearly shows the nocturnal low-level jet with its maximum around the height of 500 m a.g.l.. From 13 July 2016 at 21:00 UTC until 14 July 2016 at 09:00 UTC, the jet propagates northwards. The vertical transect of the BC concentration indicates that the low-level jet is linked to lower BC concentrations, which was observed with ALADINA at 06:15 and 07:30 UTC on 14 July 2016 (Fig. 8), as well. The coastline is approximately at 6.2°N , so the low BC concentrations especially occur over the Gulf of Guinea. In front of the jet, an air mass with high BC burden (up to $20 \mu\text{g m}^{-3}$ near the surface) is visible. At 00:00 UTC, the BC concentration maximum is directly over Savè, however, this is not related to local emissions.

Three aspects seem to justify this hypothesis: (1) Concentrations of NO_x and CO do not indicate anthropogenic local emissions for the observed time period. (2) Fig. 10 shows negligible fractions of fresh BC which indicates less influence of local emissions. (3) By considering also the time steps before 13 July 2016 at 21:00 UTC, it becomes clear that the polluted air mass is transported from the South in front of the northward propagating maritime inflow. Since the low-level jet has its maximum around 500 m in altitude, the clean air mass of the jet puts a wedge into the polluted air mass in front (e.g. visible on 14 July 2016 at 06:00 UTC). This leads to a near surface pollution branch below the jet axis and an elevated pollution

branch above the jet axis. This is also visible in the modelled profiles of Fig. 10a, and in the observed profiles, a clearly enhanced BC concentration in the upper branch, a minimum at around 400-500 m a.g.l. and a slightly enhanced near-surface BC concentration is visible. At 12:00 UTC, the vertical mixing in the ABL leads to a rather homogeneous distribution of BC in the vertical profile. Even if the peak observed at 12:00 UTC around 900 m a.g.l. over Savè (see Fig. 10c) may be partly induced by cloud artifacts, its altitude fits to the location of the modelled elevated pollution branch in Fig. 11. From 14 July 2016 at 12:00 UTC on, a reestablishment of a pollution layer can be observed between 7 °N and 8 °N.

4 Conclusions

This article aims at understanding the relationship between the vertical distribution of BC and ABL processes in southern West-Africa. The investigation area is supposed to be one of the major sources for BC emissions worldwide (Lioussé et al., 2014). But where do those BC emissions originate, especially in the ABL? Beyond surface measurements, the role of BC is difficult to assess within the ABL due to lacking column measurements. ALADINA was applied for meteorological profiling and BC measurements during the extensive field experiment of DACCWA at Savè, Benin, in 2–16 July 2016.

BC was measured with a micro aethalometer, model AE51, that has been proved as feasible tool on UAS, but it suffers from artefacts that were one subject of this paper. Prior to analyses, BC data were corrected with bias caused by the dependence of the instrumentation on internal temperature during ascents and descents. Further, a low pass filter was applied for the readings with a resolution of 10 s.

For a statistical overview, BC was averaged for altitude intervals of 20 m steps along 155 vertical profiles of the whole measurement period. In contrast to initially expectations, no clear influence of primary BC emission was observed in the vertical distribution. It was shown that BC occurred in the whole ABL and did not decrease depending on the altitude. Thus, maxima and minima of BC concentration could be caused by other aspects than solely from ABL conditions. One explanation could relate to horizontal advection processes that might have brought about different types of air masses with distinguished layers of BC. Another explanation could be based on regional-scale. The measurement period was influenced by the WAM season, leading to high occurrence of nocturnal low-level jet and low-level clouds that could have strongly affected the vertical distribution of BC due to dynamics in the ABL. (e.g., Dione et al., 2019; Kalthoff et al., 2018; Adler et al., 2019; Babić et al., 2019b).

One case study (14–15 July 2016) was presented in detail in order to clarify possible other impacts on the BC distribution. Therefore, ground observations of wind profiler, ceilometer and gas concentrations were used from Savè supersite, 4 km away from the research flights. NO_x and CO did not show any clear evidence of local emissions at ground. However, a maximum of $\text{BC}=2.81 \pm 0.30 \mu\text{g m}^{-3}$ was observed in the residual layer between the heights of 400 and 600 m a.g.l. in relation to a nocturnal low-level jet with wind speeds larger than 12 m s^{-1} . The lifted BC layer was vertically mixed during clear sky conditions during the day and the mass concentration increased continuously in the lowermost 1100 m a.g.l. On the next day, low-level clouds formed in the early morning that might have led to wash out in the lowermost 400 m a.g.l. BC decreased from 3.87 ± 0.79 to $2.51 \pm 0.13 \mu\text{g m}^{-3}$ in the same altitude. The UAS observations were supported and spatially extended by a comparison with

the model output of COSMO-ART during the event. In all cases, the contribution of fresh BC to the total BC was negligible in COSMO-ART, indicating that local sources were not the major contributor of BC over Savè. The analysis of longitudinal vertical transects of the modelled wind speed and the BC mass concentrations revealed that transport processes with maritime inflow from the south could be the most relevant contributors of the observed BC.

- 5 This hypothesis can be supported by tracer experiments of Deroubaix et al. (2019), who showed that Savè is partly influenced by city plumes near the coast, namely Lomé, Accra and Cotonou due to maritime inflow from south. The modelled period was 1–7 July but the conditions of the vortex phase on 14 July 2016, unusual during the monsoon season, included transport of aged biomass burning aerosol and decreased humidity, as described in Knippertz et al. (2017) and Flamant et al. (2018) so that long range transport from city plumes might be the source of observed BC in Savè.
- 10 The strength of the here shown study is the high capability to further understand transport processes of BC on small-scale by using UAS that are linked to regional-scale during the WAM season. However, the relationship between BC and the ABL needs more profound investigations. In addition, the impact of possible aged and transported BC within the ABL should be taken into account in future investigations that could equally contribute to a reduction of air quality and even further interact with low-level clouds.
- 15 *Data availability.* The data used in this study (Derrien et al., 2016; Handwerker et al., 2016; Wieser et al., 2016; Bärffuss et al., 2017) are available on the SEDOO database (<http://baobab.sedoo.fr/DACCIWA/>).

Author contributions. KoD and BeV provided the COSMO-ART model contributions. KaB delivered the ceilometer profiles. ChD studied the wind profiler data. FeP and CoJ were responsible for the gas concentration observations. KoB, FaP, and AsL handled the preparation and operation of the UAS, as well as the post-processing of the UAS data. FrE contributed to the statistical analysis of the UAS measurements.

20 BiA, NoK and FaL coordinated the project, and provided access to ground observation data. BaA wrote the publication under critical review and input from all co-authors.

Competing interests. The authors declare that they have no conflict of interest.

- Acknowledgements.* The DACCIWA project has received funding from the European Union Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 603502. BA was financially supported by the German Research Foundation (DFG) under the project number LA 2907/5-2. The authors from TU Braunschweig wish to thank UPS and KIT for being part of the DACCIWA project. We gratefully acknowledge Lutz Bretschneider, Endres Kathe and Birgit Zachrau for their support in preparation of the UAS ALADINA and during the experiment on site. Figure 1. The pictures show the measurement units of the UAS ALADINA during DACCIWA, in Savè. (a) The nose of ALADINA is equipped with meteorological sensors for calculating the three dimensional wind vector with one multihole probe (number 1), temperature (number 2–4) and humidity (number 4 and 5). The air probe is sampled with one aerosol inlet (number 6) mounted at the tip of the aircraft’s nose. (b) The micro aethalometer AE51 is installed in the front compartment of the aircraft for adjusting the centre of gravity. The air stream is dried with silica gel before measuring (see the blue box close to the AE51). Photo: Institute of Flight Guidance, TU Braunschweig.

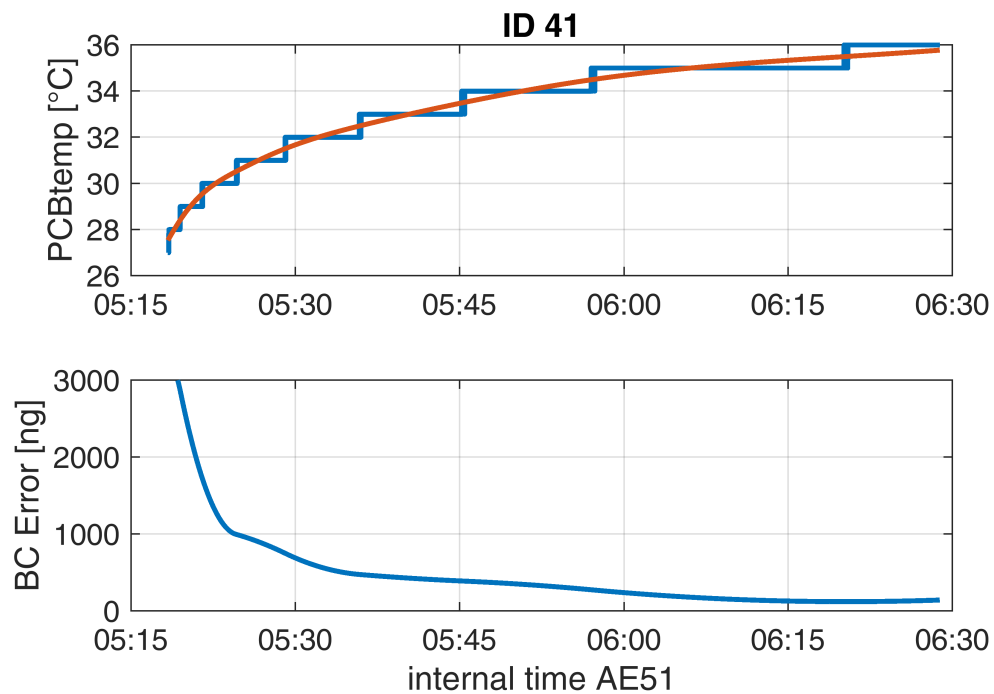

Figure 2. The figure shows the internal temperature (PCBtemp) of the aethalometer AE51 during the measurement flight from 05:16 until 06:30 UTC on 14 July 2016 (top). The bit noise was smoothed for the time interval (red line). The figure at the bottom represents the calculated error of the black carbon mass concentration.

Figure 3. BC mass concentration measured during one flight between 15:58 and 16:42 UTC on 10 July 2016. The raw signal of BC (grey line) was phase shift free low pass filtered after post-processing with 10 s (red line), 30 s (green line) and 60 s (blue line).

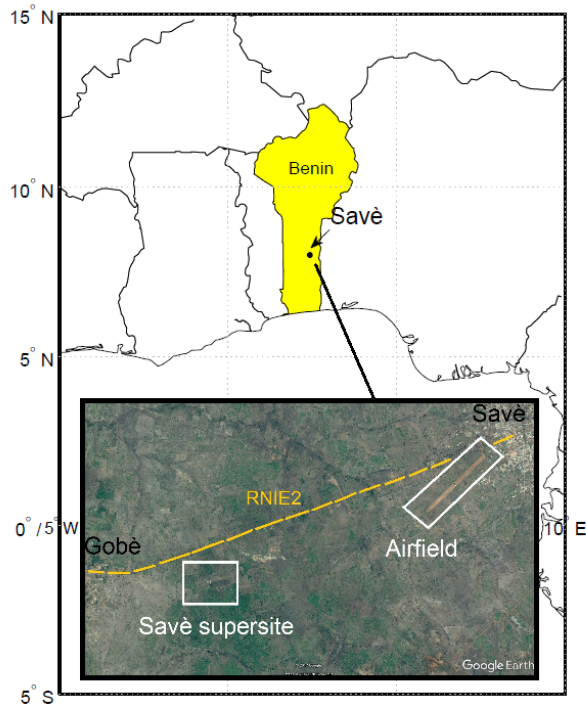

Figure 4. The map shows the position of the measurement site Savè in Benin (marked in yellow), West Africa. The UAS ALADINA was operated at the local airfield of Savè during the field experiment DACCIWA from 2 until 16 July 2016. The Savè supersite of Karlsruhe Institute of Technology (KIT) and Université de Toulouse III- Paul Sabatier (UPS) was located in the south-west with a distance of 4 km to the airfield. The sites are connected via the main road RNIE2 (dashed yellow line). The picture was created with **Google Earth** on 28 April 2017.

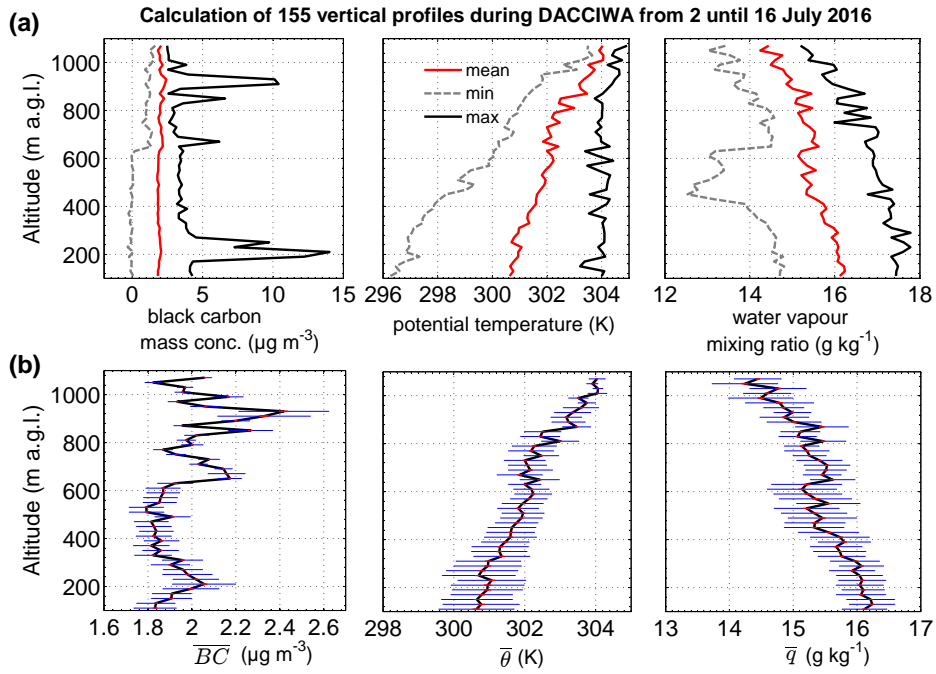

Figure 5. Summary of 155 vertical profiles from 100 to 1100 m a.g.l. measured with ALADINA during the field experiment of DACCIWA on 2–16 July 2016. From left to right: Vertical profiles of black carbon mass concentration (BC) measured with the aethalometer and 10 s low pass filtering, potential temperature θ and water vapour mixing ratio q . The red line represents the mean value, the grey dashed lines stands for the total minimum and the black solid line is the total maximum of all vertical profiles, averaged in 20 m altitude intervals. At the bottom: The mean values of BC (\overline{BC}), θ ($\overline{\theta}$) and q (\overline{q}) in the 20 m steps, and the corresponding standard deviation for each height interval.

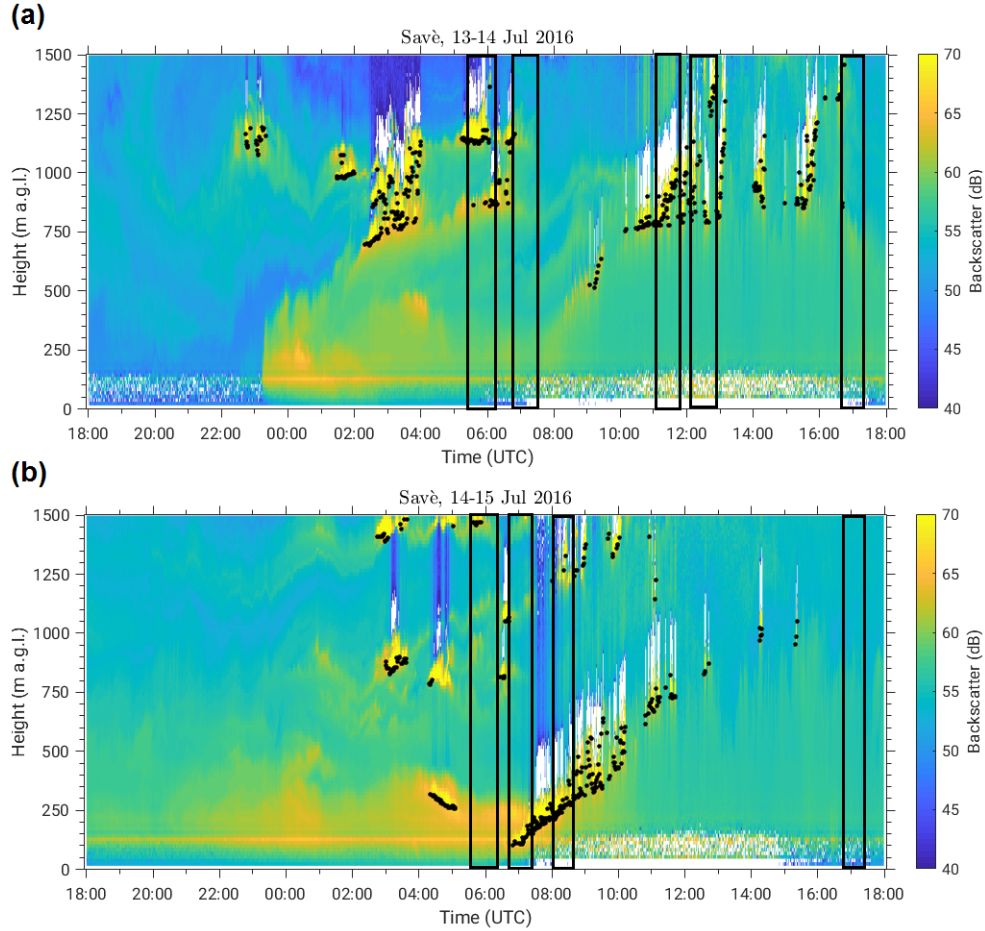

Figure 6. Backscatter signal of KIT ceilometer (Handwerker et al., 2016) installed at Savè supersite between (a) 18:00 UTC on 13 July 2016 and 18:00 UTC on 14 July 2016 and (b) in the period of 18:00 UTC on July 14 2016–18:00 UTC on July 15 2016. On July 14, different layers of atmospheric particles were observed during the day. At midday, clouds were detected at 800 m a.g.l. and dissolved at 18:00 UTC. On July 15, low-level clouds occurred at 07:00 UTC in the lowermost 200 m a.g.l., lifted up to the height of 750 m a.g.l. at 11:00 UTC and dissolved in the afternoon at 14:00 UTC in the lowermost 1.5 km. The black boxes indicate the flight periods of the UAS ALADINA.

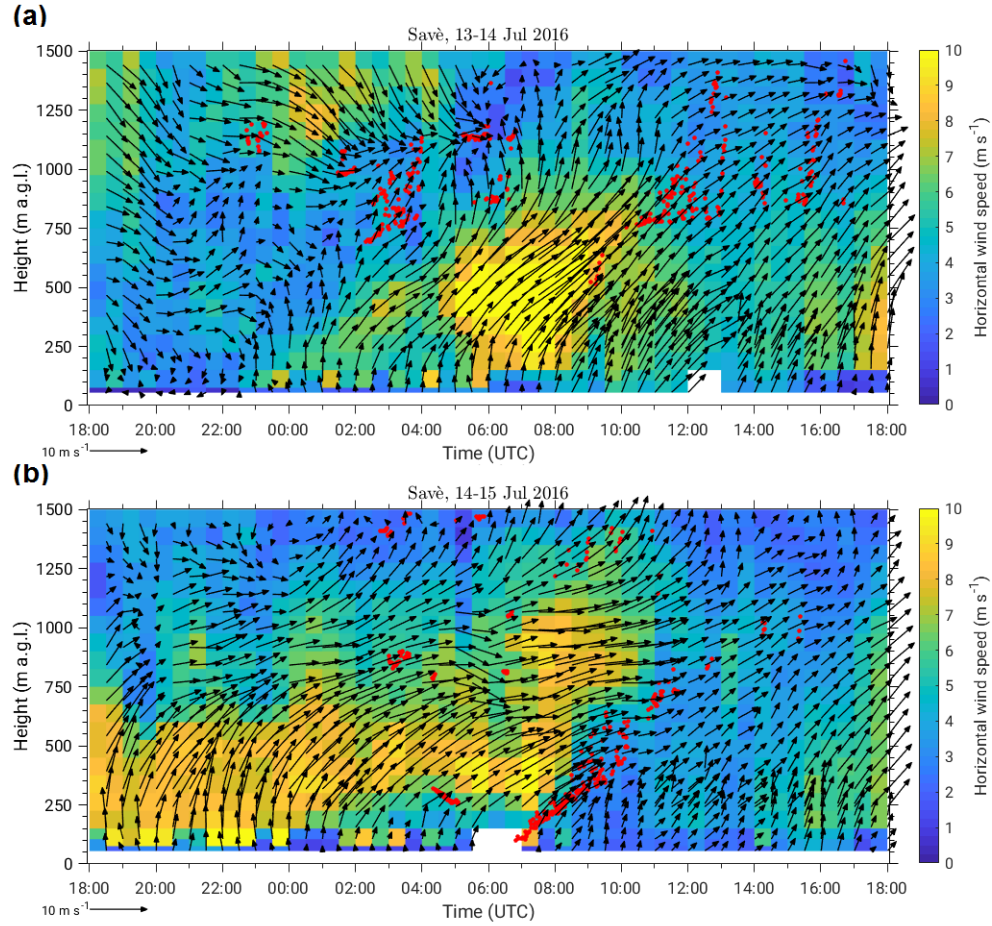

Figure 7. Time series of the wind speed and the wind direction at Savè supersite during DACCIWA (Derrien et al., 2016). The wind speed is indicated in the colour bar and the direction in arrows (a leftwards horizontal arrow stands for wind direction from E; from bottom to top for S wind). The wind speed in the lowermost 1.5 km was measured with the wind profiler of UPS between (a) 18:00 UTC on 13 July 2016 until 18:00 UTC on 14 July 2016 and (b) from 18:00 UTC on 14 July 2016–18:00 UTC on 15 July 2016. The red dots display the cloud base height measured with the ceilometer.

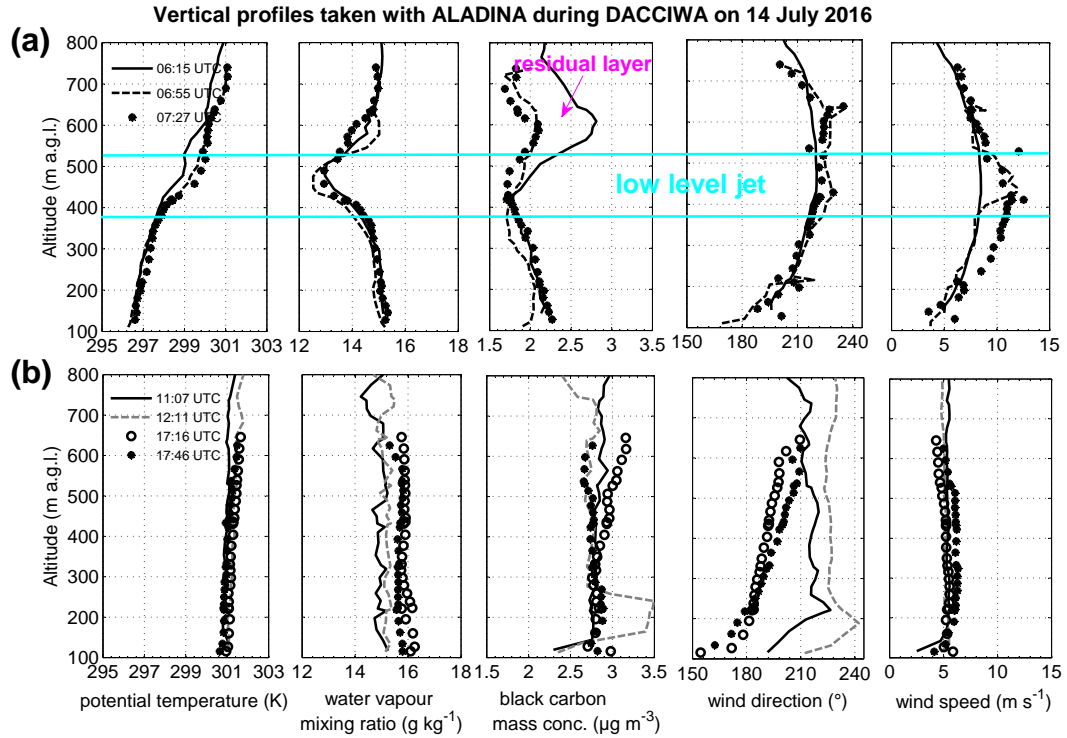

Figure 8. Vertical profiles taken with ALADINA between the height of 100 and 800 m a.g.l. on 14 July 2016. From left to right: potential temperature, water vapour mixing ratio, black carbon mass concentration, wind direction and wind speed (a) in the morning from 06:16 until 07:27 UTC and (b) during the cloud formation below the height of 800 m a.g.l. at 11:07 and 12:11 UTC and during the evening transition at 17:16 and 17:46 UTC. The horizontal turquoise line indicates the altitude range of the nocturnal low-level jet (see Fig. 7a).

Figure 9. Five selected vertical profiles measured with ALADINA between the height of 100 and 900 m a.g.l. from 05:33 until 16:52 UTC on 15 July 2016. From left to right: potential temperature, water vapour mixing ratio, black carbon mass concentration, wind direction and wind speed. The red horizontal line shows the altitude of low-level clouds formed at 07:00 UTC, derived from the backscatter signal of the ceilometer (see Fig. 6b).

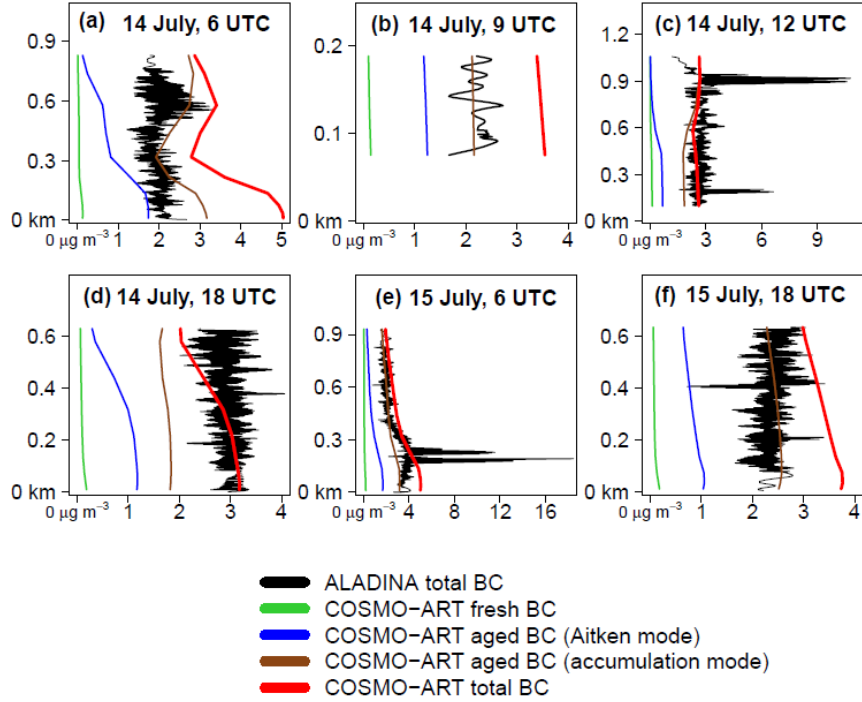

Figure 10. Vertical profiles of BC in $\mu\text{g m}^{-3}$ at Savè for (a–d) 14 July 2016 and (e–f) 15 July 2016. The ALADINA observations of the total BC are denoted in black, the COSMO-ART results for fresh BC, aged BC (Aitken mode), aged BC (accumulation mode) and the total BC are shown in green, blue, brown and red, respectively. The observations were temporally assigned to the three hourly model output with a deviation not larger than 1 h and by subsequently interpolating the model data to the ALADINA altitudes. Within these time steps, ALADINA conducted several ascents and descents. It is assumed that the observations within the time steps are measured instantaneously.

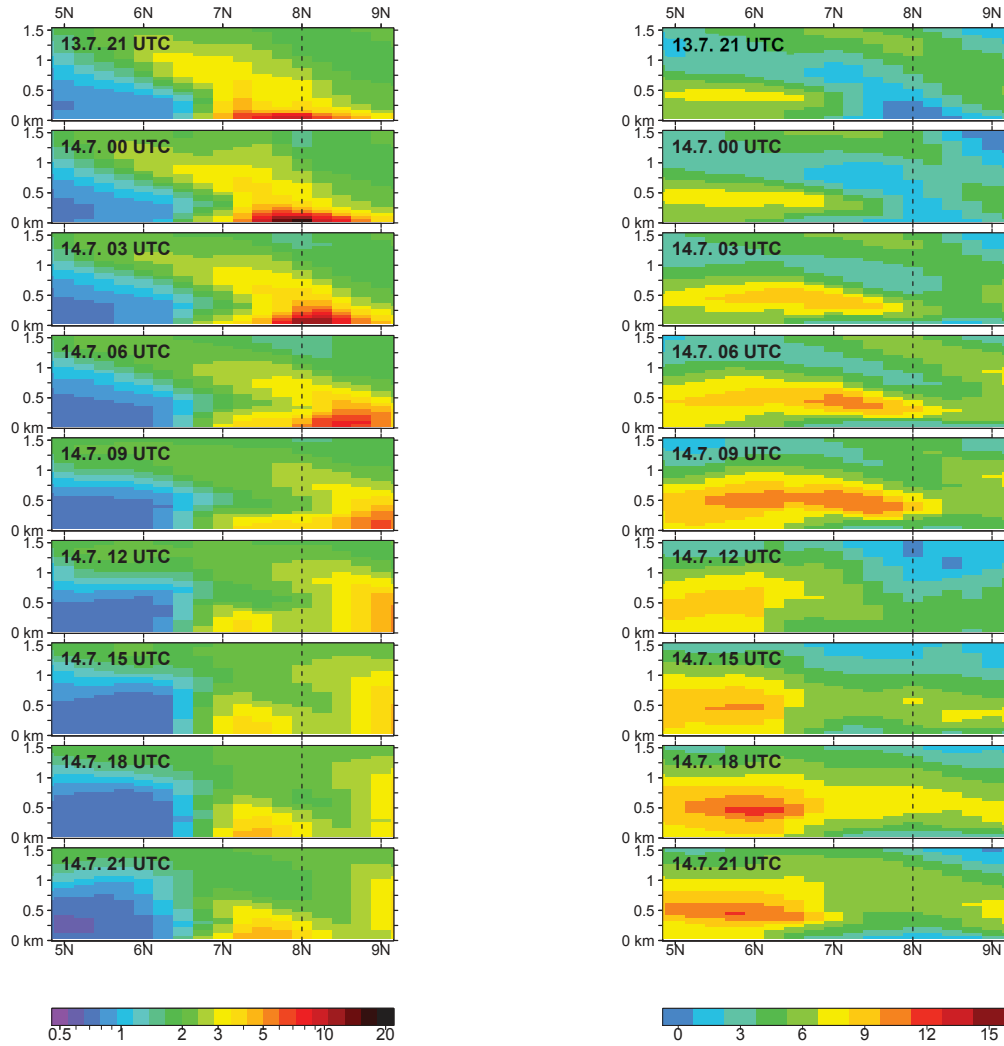

Figure 11. Vertical transect (km a.g.l.) from COSMO-ART of the total BC in $\mu\text{g m}^{-3}$ (left) and wind speed in m s^{-1} (right) along the longitude of Savè between 21:00 UTC on 13 July 2016 until 21:00 UTC on 14 July 2016. The dashed line indicates the location of Savè.

Table 1. Measurements performed with the UAS ALADINA during DACCIWA on 14–15 July 2016. The table presents the flight time in UTC, cloudy conditions indicated by the lowest cloud base and gas concentrations variations of NO_x and CO during corresponding flight time as a possible indicator for local emissions, sampled at Savè supersite by UPS.

Flight number	Day in July 2016	Flight time take off – landing	Cloud base	NO _x	CO
1	14	05:28–06:19 UTC	1200 m	0.7–1.1 ppb _v	158–231 ppb _v
2	14	06:51–07:32 UTC	>2000 m	0.6–0.8 ppb _v	162–195 ppb _v
3	14	11:03–11:43 UTC	1000 m	0.7–1.8 ppb _v	153–203 ppb _v
4	14	12:07–12:56 UTC	800 m	0.6–0.8 ppb _v	146–208 ppb _v
5	14	16:42–17:23 UTC	1000 m	0.9–1.5 ppb _v	179–218 ppb _v
6	14	17:42–18:24 UTC	>2000 m	1.0–1.7 ppb _v	189–232 ppb _v
7	15	05:27–06:13 UTC	1700 m	1.0–1.3 ppb _v	214–249 ppb _v
8	15	06:41–07:24 UTC	300 m	1.4–1.9 ppb _v	224–259 ppb _v
9	15	08:00–08:40 UTC	400 m	1.4–1.9 ppb _v	203–239 ppb _v
10	15	16:48–17:22 UTC	>2000 m	0.8–1.4 ppb _v	156–194 ppb _v
11	15	17:40–18:22 UTC	>2000 m	1.1–1.3 ppb _v	180–215 ppb _v
