Abstract The Amazon biome contains more than half of the remaining tropical forests of the planet and has a strong impact on aspects of meteorology such as the Planetary Boundary Layer (PBL). In this context, the objective of this study was to conduct observational evaluations of the daily cycle of the height of the PLB during its stable (night) and convective (day) phases from data that were measured and/or estimated using instruments such as a radiosonde, SODAR, ceilometer, wind profiler, Lidar and microwave radiometer installed in the central Amazon during 2014 (considered a typical year) and 2015 during which an intense El Niño Southern Oscillation (ENSO) event predominated during the GOAmazon experiment. The results from the four intense observation periods (IOPs) show that during the day and night periods, independent of dry or rainy seasons, the ceilometer is the instrument that best describes the depth of the PBL when compared with *in situ* radiosonde measurements. Additionally, during the dry season in 2015, the ENSO substantially influenced the growth phase of the PBL, with a 15% increase in the rate compared to the same period in 2014.

1. Introduction

The Amazon basin covers about a third of the South American continent and extends for approximately 6.9×10^6 km², of which about 80% are covered by tropical forests (Tanaka et al., 2014; Ghate and Kollias, 2016). The Amazon biome represents more than half of the world's remaining tropical forests, and consequently has a strong impact on the climate of South America, thus is one of the major tropical convective regions in the global climate system (Tang et al., 2016). It provides moisture to the global hydrological cycle and energy to drive the global atmospheric circulation, with with a large influence on meteorological components such as the Planetary Boundary Layer (PBL). Understanding convective systems over the Amazon region through observations is important for understanding and simulating these systems.

In this region there is a substantial quantity of convective activity that occurs during the entire year, but there are significant seasonal differences due to annual variation of atmospheric circulation and thermodynamic structure (Marengo and Espinoza, 2016), and these wet (or rainy) and dry season are well-defined. In this context, during the years 2014 and 2015, in the central Amazon region, the *Green Ocean Amazon* (GOAmazon) project was conducted with the objective of observing the influence of the complex interaction between the pollution plume generated in the city of Manaus-Amazonas, and clouds and vegetation (Martin et al., 2016). This project approached research questions from a multidisciplinary perspective, and one of the studied topics was the physics involved in convective processes in the Amazon with emphasis on differences between wet and dry seasons.

The PBL is a turbulent layer of the atmosphere near the surface that results from the interaction between the surface and the atmosphere. The knowledge of the properties of the PBL has important scientific and practical applications because through this understanding of the PBL operational models of weather and climate forecasting can be refined, pollutant dispersion

processes can be adequately described, the eolic potential of a region can be objectively determined, patterns of ventilation in urban areas can be estimated, and improvements in agricultural techniques can be made (Englberger and Dörnbrack, 2017). Furthermore, a more realistic representation of processes that occur in the PBL can benefit numeric models of weather forecasting with better parameterization of convection, clouds, and rain (Holtslag et al., 2013). The PBL characteristics, related to surface processes, provide important information regarding the priming of the atmosphere for convective initiation (Tawfik and Dirmeyer, 2014).

Holtslag et al. (2013) state that the PBL, since it is the lowest level of the atmosphere, is in continuous interaction with the Earth's surface, with significant turbulent transfer of heat, mass, and *momentum*. According to these authors the PBL presents, during its daily cycle, large variations in temperature, wind, and other variables in response to atmospheric turbulence and convective processes that occur in a tridimensional and chaotic form in timescales that range from seconds to hours, and the length across which these events occur are between a few millimeters up to the entire depth of the PBL (1-2 km) or more in the case of convective clouds.

Neves and Fisch (2015) emphasize that an important characteristic of the PBL is the determination of its height because it is then possible to estimate the volume into which the source of pollution will be dispersed, and this is an important parameter for modeling of atmospheric dispersion. During its daily cycle the PBL undergoes atmospheric processes generated by thermal and mechanical convection during the day and displays stable conditions at night. The height of the PBL during the atmospheric instability phase (principally during the day) is denominated the Convective Boundary Layer (CBL), and that during the stable period (principally at night) is named the Nocturnal Boundary Layer (NBL).

In this context, observational evaluation of the daily cycle of the PBL, with emphasis on the CBL and NBL, represents an important field of study since within the PBL there occur processes that have large impact on society and the terrestrial environment. Therefore, the objective of this study was to contribute to a more thorough understanding of the daily cycle of the height of the PBL through integration and comparison of data that were measured and/or estimated using instruments such as a radiosonde, SODAR, ceilometer, wind profiler, Lidar and microwave radiometer installed by the GOAmazon experiment. Furthermore, this study attempted to verify if the observational methods were representative of the daily variation in the cycle of the CBL and NBL in the central Amazon during 2014 (stated as a normal year) and 2015, and to elucidate the influence of an intense El Niño Southern Oscillation (ENSO) event that occurred in 2015/2016.

2. Material and Methods

In order to conduct this observational study, data from the GOAmazon project 2014/5 were used. The article by Martin et al. (2016) describes the details of the experiment wherein these data were collected, its principal objectives, and some results. These data were collected using the structure that was installed at a research station called T3 (03° 12' 36" S; 60° 36' 00" W), located north of the municipality of Manacapuru in the State of Amazonas, about 9.5 km from the urban area, and about 11.5 km from the left bank of the Solimões River, at the confluence of the mouth of the Manacapuru River (Figure 1) in the central region of the Amazon basin. The T3 station is collocated in an area of pasture, surrounded by native forest with about 35 m of canopy height (Martin et al. 2016).

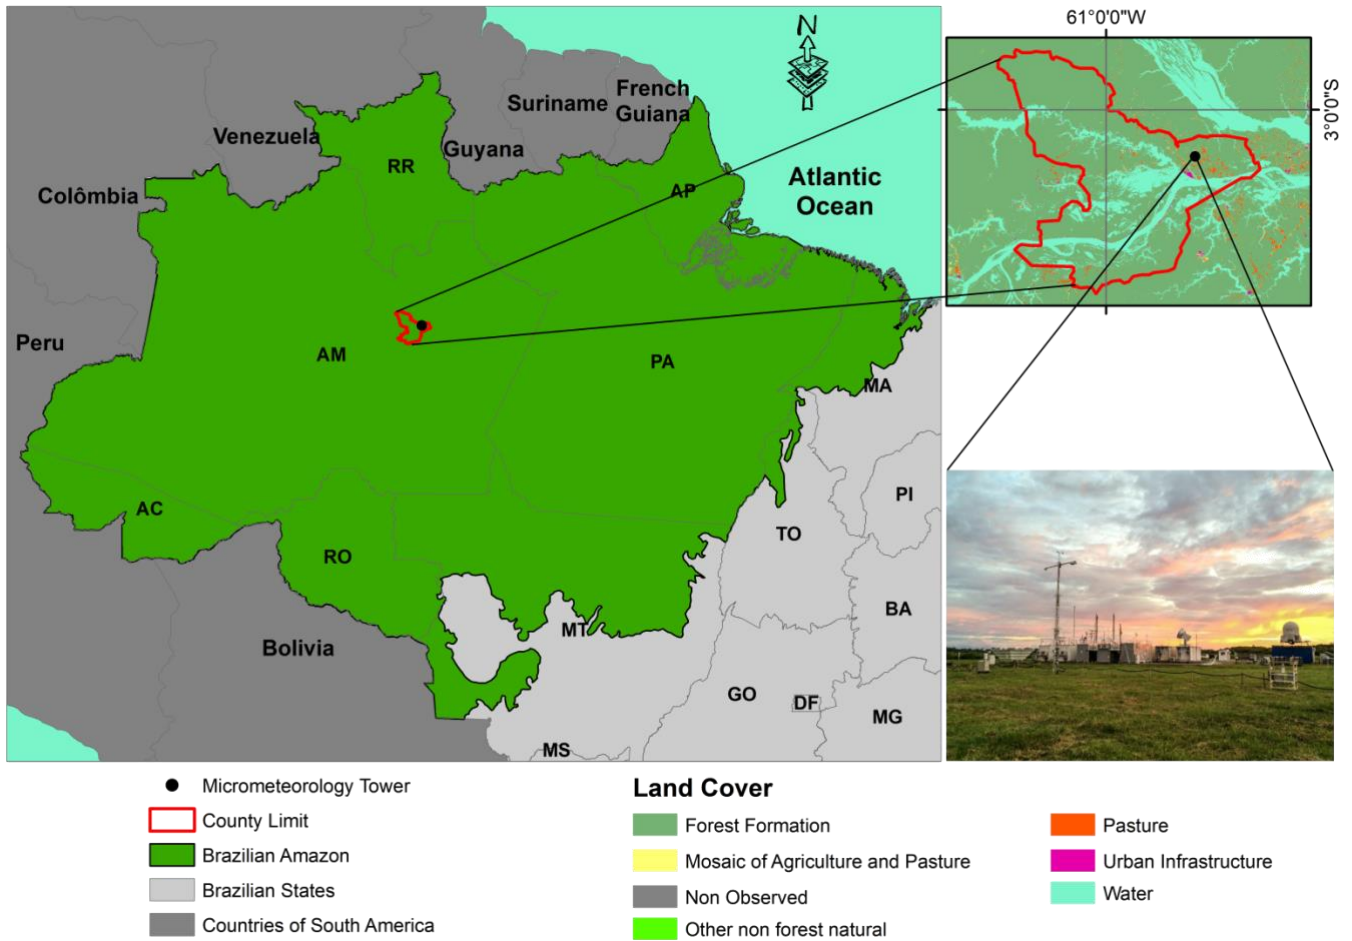

Figure 1: Location of the atmospheric measurement experiments in Manacapuru, Amazonas, Brazil.

At the experimental site of the T3 station, instruments were installed to obtain measurements of the hydrological cycle, PBL energy flux, and other micrometeorological variables, and the data from these measurements are available on the site of ARM - Climate Research Facility (<https://www.arm.gov>). For the current study, four intense observation periods (IOP) were defined in order to capture the peak of the rainy (February and March) and dry (September and October) seasons of 2014 and 2015. The dates for each IOP were IOP1 and IOP3, February 15 to March 31, 2014 and 2015, and IOP2 and IOP4, from September 1 to October 15, 2014 and 2015. For the daily cycle analysis of the PBL it was considered the sunrise at 06 LT and the sunset at 18 LT, not varying throughout the year.

In order to measure the height of the PBL, instruments that probe the lower troposphere including a Wind Profiler (WP), Ceilometer, SODAR, Microwave Radiometer Profiler (MWP) and Lidar were used, and these data were compared to data taken in situ obtained using radiosondes (RS), and this method is described below.

2.1 Radiosonde (*in situ*) – RS

In this experiment, RS measurements were obtained using a system that included a DIGICORA (MW12) (Vaisala Inc., Finland) with radiosonde model RS92SVG. The RS was coupled to a meteorological balloon that had an average ascension rate of 5 m s⁻¹, and the readings were taken at 02, 08, 14 and 20 Local Time (LT), and during the IOPs 1 and 2 and extra RS was done at 11 LT to better characterize the convective phase. From the RS measurements, the following data were measured as functions of time during a free-balloon ascent: pressure (hPa), air temperature (dry bulb) (°C), relative humidity (%), wind velocity (m s⁻¹) and wind direction (deg). With these measurements, others derived quantities were computed and used in this study: altitude (m), geographic position (latitude and longitude), dew point temperature (°C), u-component of wind velocity (m s⁻¹) and v-component of wind velocity (m s⁻¹).

96 From these data, the potential temperature (θ) and specific humidity (q) were extrapolated and their vertical profiles were
97 used for the determination of the height of the PBL. At the CBL phase, the heights were identified by the vertical level where
98 there was a systematic increase in potential temperature and a sudden reduction in specific humidity, and this method is
99 called the profile method, as described in detail by Santos and Fisch, (2007), Seidel et al., (2010) and Wang et al. (2016).
100 However, at the NBL phase, the heights were determined by the height where the vertical θ gradient was null or less than a
101 defined number (0.01 K m^{-1}) starting from the surface. This statement relates the maximum distance from the surface where
102 the radioactive night cooling operates, as described in detail by Santos and Fisch (2007), Neves and Fisch (2011).

103 **2.2 Wind Profiler (WP)**

104 In order to construct a wind profile (WP) at the study site, a Radio Acoustic Sound System (RASS) model RWP915 from
105 Vaisala Inc. (Finland) was used for direct and continuous measurements of the PBL. The WP are Doppler instruments used
106 to detect the vertical wind profile, and they function at a frequency of 50 MHz to 16 GHz. The WP/RASS installed at the
107 study site operates at 915 MHz to measure the wind profile. The RASS transmitter aids in the measurement of the profiles of
108 the vertical temperature. The RWP/RASS operates through transmission of electromagnetic waves in the atmosphere and
109 measures the intensity and frequency of the backscatter of the waves, assuming that atmospheric dispersion elements are
110 moving with the average wind profile.

111 Since this is an instrument that operates at a high frequency and using smaller intervals of space between layers, it is
112 frequently used for tropospheric observations, especially for the PBL. The method used in this study is described by Wang et
113 al. (2016), wherein the height of the PBL was estimated using the vertical profile of electromagnetic refraction of WP, where
114 the maximum of this index occurs in the upper part of the PBL.

115 **2.3 SODAR**

116 In the study area a Mini SODAR (Sound Detection and Ranging) (model Sodar MFAS and RASS A032002, SCINTEC,
117 Rottenburg, Germany) was installed. This monostatic equipment consists of an emission/receiving antenna with an area of
118 1.96 m^2 , and functions at a power of 10 W and a frequency of approximately 2 kHz. Using the SODAR profiles of wind
119 velocity and direction were obtained at intervals of 30 min at a maximum height of 400 m.

120 Through remote sensor measurement by the SODAR the height of the PBL was calculated for its night phase (NBL) through
121 the determination of the maximum wind height (jet). This method was suggested by Neves and Fisch (2011) and showed
122 good results for the Amazon due to its operational limit (400 m) and taking into account that the NBL in the region has an
123 average depth of 100 to 300 m.

124 **2.4 Lidar**

125 Lidar was also used to estimate the height of the PBL using a LIDAR model Stream Linex[®] from Halo Photonics
126 (Worcestershire, UK), a single autonomous instrument from the most recent line of products from this company for
127 atmospheric remote sensing. These systems are adequate for meteorological studies of the PBL and also for measurements of
128 cloud cover, vertical wind profiles, and air quality monitoring (Gouveia et al., 2017).

129 These instruments employ a laser transmitter operating at a wavelength of $1.5 \text{ }\mu\text{m}$, low pulse energy ($\sim 100 \text{ }\mu\text{J}$), and high
130 pulse repetition frequency (15 kHz). These instruments have full upper hemispherical scanning capability and provide range-
131 resolved measurements of attenuated particle backscatter coefficient and radial velocity. The fundamentals of its operation
132 are similar to those of radar in which pulses of energy are transmitted to the atmosphere, the energy that is bounced back to
133 the receiver is collected and measured as a resolved signal in time (Newsom, 2012).

134 Lidar uses a technique of heterodyne detection (method of extraction of coded information as a phase modulation and/or the
135 frequency of a wavelength) in which the return signal is mixed with a reference laser beam (a local oscillator) of a known

frequency. A computer within the instrument then processes the signal determining the Doppler frequency change using the spectrum from the signal. The energy content of the Doppler spectrums can also be used to determine attenuated backscattering.

Lidar operates in the near infrared wavelength and is sensitive to retro-diffusion of aerosols at the micrometer scale, therefore it is capable of measuring wind speeds under clear sky conditions with a very high precision (normally 10 cm s⁻¹). Lidar also possesses a superior capacity for hemispheric sweeping, thus permitting tridimensional mapping of turbulent fluxes within the PBL. Using the variance of the vertical wind speed (σ_{w2}) provided by the Lidar, the method of Huang et al. (2017) was employed, where the authors define the depth of the PBL as a layer in which σ_{w2} exceeds a specific limit (0.1 m² s⁻²).

2.5 Ceilometer

The PBL was also monitored using a Ceilometer model CL31 from Vaisala Inc. (Finland). The Vaisala ceilometers are a type LIDAR remote sensing instruments that operating through a maximum vertical range of 7.700 m and register the intensity of optical backscattering at the near-infrared wavelength between 900 and 1100 nm through the emission of a vertical pulse that is autonomously executed. These measurements are used to produce derived products that are recorded: the height of the cloud base, the retrieval of the particle backscatter coefficient and PBL height (Wiegner et. al., 2014; Shukla et al., 2014; Morris, 2016; Geiß et al. 2017; Carneiro et al., 2020). Although the ceilometer measures the reflection of the aerosols layer (so the mixing layer height), it was assumed as the diurnal PBL height) as the entrainment zone is very shallow. So, during all manuscript, this information (backscatter aerosols) was assumed as PBL height. The ceilometer is a high temporal resolution instrument with a measurement interval of 2 s, and a sampling rate of 16 s and is a powerful tool for measuring the height of the PBL during its daily cycle (day and night phases) to a high level of detail. The ceilometer signal is resulting over backscattering light by particles at atmosphere, then intensity of backscattering depends on the concentration of particles in the air (Morris, 2016). Ceilometers use a pulsed diode laser lidar (light detection and ranging) technology to determine the attenuated backscatter, and the particle backscatter coefficient are obtained from these data, and subsequently the heights of the cloud base and the PBL are calculated (Wiegner et. al., 2014; Kotthaus et al., 2016; Morris, 2016; Geiß et al. 2017).

The standard procedure for the PBL heights determination from Vaisala ceilometers is the software package BL-VIEW developed by the manufacturer (see more details in Morris, 2016; Geiß et al. 2017).

2.6 Microwave Radiometer Profiler (MWR)

Data were also used from a Microwave Radiometer Profiler model MP3000A from Radiometrics Corp., Boulder, CO, USA. This instrument provides vertical profiles of temperature, humidity, and liquid water content at a sampling rate of 60 s and average values at intervals of approximately 5 minutes. The profiles are deduced from measurements of radiance values of absolute microwaves (expressed as “brightness temperature”) obtained at 12 different frequencies at intervals of 22-30 and 51-59 GHz. This type of data is useful as input into numerical models of weather forecasting which need high resolution profiles in continuous time.

To obtain the potential temperature throughout the daily cycle, it was necessary to interpolate the pressure profiles of the RS using to the method of polynomial interpolation. Together with the MWR air temperature profiles, the daily cycle of the potential temperature profile was calculated. And so, the height of the PBL was estimated by the profile method.

177 Table 1 presents a synthesis of the instruments used in this study, the observation periods, and temporal and spatial
 178 resolutions.

	RS		WP		SODAR		<i>Ceilorometer</i>		MWR		<i>Lidar</i>	
Observation period	Jan/2014	to	Jan/2014	to	Feb/2014	to	Jan/2014	to	Oct/2014	to	Jan/2014	to
	Dec/2015		Dec/2015		Dec/2015		Dec/2015		Dec/2015		Ago/2015	
Variables observed	Pressure; Temperature ; Humidity; Wind speed and direction		Wind (u, v, w); Wind direction		Horizontal wind velocity (u,v); Wind direction; Vertical wind velocity (w);		Height of base of clouds; PBL height; Vertical visibility;		Temperature; Relative humidity;		Variation of vertical velocity (σ_w^2);	
Vertical resolution (m)	~10		60		10		10		~100		30	
Temporal resolution	4 to 5 times/day		1 hour		30 min		16 s		60 s		10 min	

179
 180 The remote sensors instruments capture multi-layers from the heights of the PBL in the transition interval day-night
 181 (between 17 and 18 LT) shown in Figure S1 (presented in the Supplement). However, as the one of the goals of this paper is
 182 to have a complete picture of the PBL cycle, the NBL heights in this interval were neglected in Figures 4 and 6, in order to
 183 show only the decay of the CBL convection.

184 Determination of monthly rainfall for both study years was done using data taken with a disdrometer model Parsivel2 (OTT
 185 Hydromet GmbH, Germany), with a temporal resolution of 10 minutes. To measurements of turbulence flows were used to
 186 the eddy covariance (EC) system composed of a three-dimensional (3-D) sonic anemometer (model WindMaster Pro, Gill
 187 Instruments Limited, Hampshire, UK) coupled with an open-path infrared gas analyzer (IRGA) (LI-7500, LICOR Inc.,
 188 Lincoln, Nebraska, USA) at 10 m above ground. The EC provides an estimate of the net exchange of energy and mass
 189 between the terrestrial surface and the atmosphere. The estimated flux is given by a scalar magnitude that is defined as the
 190 average of the product of the fluctuations of the vertical velocity and the concentration that is being transported. In practice,
 191 this technique consists of taking observations of variables of the product at a high frequency (10 Hz), and from this large
 192 number of samples of each variable the statistical covariation is calculated between them. In this manner the system provides
 193 in situ measurements of turbulent fluxes of momentum, sensible and latent heat, and carbon dioxide to the surface.

194 The measurements of radiation and soil heat flux were done every 30 minutes using the Surface Energy Balance System
 195 (SEBS), which consists of measurements of solar and terrestrial radiation collected using radiometers, and the radiation
 196 balance by a net radiometer model CNR4/CNF4, (Kipp & Zonen, Delft, The Netherlands) installed at 2 meters above the
 197 ground. There was coupling of sensors measuring soil heat flux by flux plates (HFT-3, Hukseflux Thermal Sensors, Delft,
 198 The Netherlands) buried at 0.02 m depth in this system.

199 In the results obtained, the average and standard deviations values were computed for different time intervals along the PBL
 200 daily cycle (Tables 2 and 3). The computed Pearson's correlation coefficient (r) showed values higher than 0.6 for all remote
 201 sensors related to the RS, especially for the ceilometer which showed correlations around 0.8. Also, a significant statistical
 202 test (t-Student with 95%) was applied for the 45 days of each IOP, with 2 degrees of freedom, and the results showed that
 203 there is statistical significance between the remote sensors and RS (Tables S1 to S4 in the Supplement).

205 Analysis of the meteorological variables revealed that accumulated precipitation was different between years (Figure 2). The
 206 year 2014 was similar to the normal climatology (for the city of Manaus - data extracted from INMET, 2018) for the region
 207 (2,300 mm), with a total of 2,451 mm. This high rate of rainfall can be understood as a response of the dynamic fluctuation
 208 of the nearly permanent center of convection, associated with a high rate of local evapotranspiration, which contributed to
 209 recycling of water vapor and rainfall (Nobre et al., 2009; Rocha et al., 2017). In contrast, the year 2015 registered a
 210 significant reduction (approximately 30%) of the total rainfall in relation to the previous year, with a total accumulation of
 211 1,764 mm, well below the normal climatological average. This reduction is associated with the occurrence of the El Niño
 212 Southern Oscillation (ENSO) event of that year (ECMWF, 2017; Macedo and Fisch, 2018; Newman et al., 2018).
 213

214
 215 **Figure 2: Distribution of accumulated monthly precipitation (mm) for the years 2014, 2015, and the normal**
 216 **climatological pattern.**

217
 218 During 2014, monthly accumulated precipitation was always above 50 mm month⁻¹, and during representative months of
 219 IOP1 (February and March, 2014) the total accumulated precipitation was 720 mm. However, during IOP2 (September and
 220 October, 2014) the total accumulated precipitation was 185 mm, yielding a reduction of nearly 75% of accumulated
 221 precipitation during IOP1. According to Ferreira et al. (2005), this difference between the rainy and dry seasons occurs
 222 because rainfall distribution in the Amazon is very irregular, with high spatial and temporal variability. Marengo et al.
 223 (2017) provide a more detailed explanation of this characteristic to central Amazonia and include the large-scale forcing role
 224 in the description of rainfall during the rainy and dry seasons.

225 While 2015 had a large reduction in rainfall, during the months of the period of intense observation of the rainy season
 226 (IOP3) the accumulated precipitation was 398 mm, representing a reduction of approximately 50% of the total accumulated
 227 precipitation during the rainy season of 2014 (IOP1). During IOP4, the total accumulated precipitation was well below the
 228 normal climatological value, as well as in comparison to the same period in 2014 (IOP2), with a total registered precipitation
 229 of 68 mm, a reduction of approximately 65% compared to IOP2. This occurred due to the EN event being more intense
 230 during these months (ECMWF, 2017; Newman et al., 2018). The ENSO event (2015/2016) was considered one of the most
 231 intense of recent years, with an intensity similar to that which occurred during 1982/83 and 1997/98 (ECMWF, 2017).

3.1. Typical year (2014)

Daily cycles of 30-minute averages of the components of the balance of energy are presented in Figure 3 for the period IOP1 (Figure 3A) and IOP2 (Figure 3B) for 2014. The shaded area for Figure 3 which represented the standard deviations values, were computed for each 30 min time interval. It is also shown in the following Figures 4 to 6.

In these figures, the radiation balance (Rn) had positive values between 06 and 18 LT, with 455 W m⁻² for IOP1 at 12 LT, and IOP2 had greater intensity of Rn with 534.5 W m⁻² at 11 LT.

The latent heat flux (LE) showed that the majority of the available net radiation (daytime conditions) was used for this flux. Both periods had similar maximum values, with 355.9 (IOP1) and 350 W m⁻² (IOP2) at 12 LT. However, there was a reduction of net radiation converted into LE between the periods, with 75% in IOP1 and 66% in IOP2. Since IOP2 refers to the dry season in the region, this presented lower water availability in the system (surface-atmosphere), which resulted in the lowest LE/Rn partition in comparison IOP1.

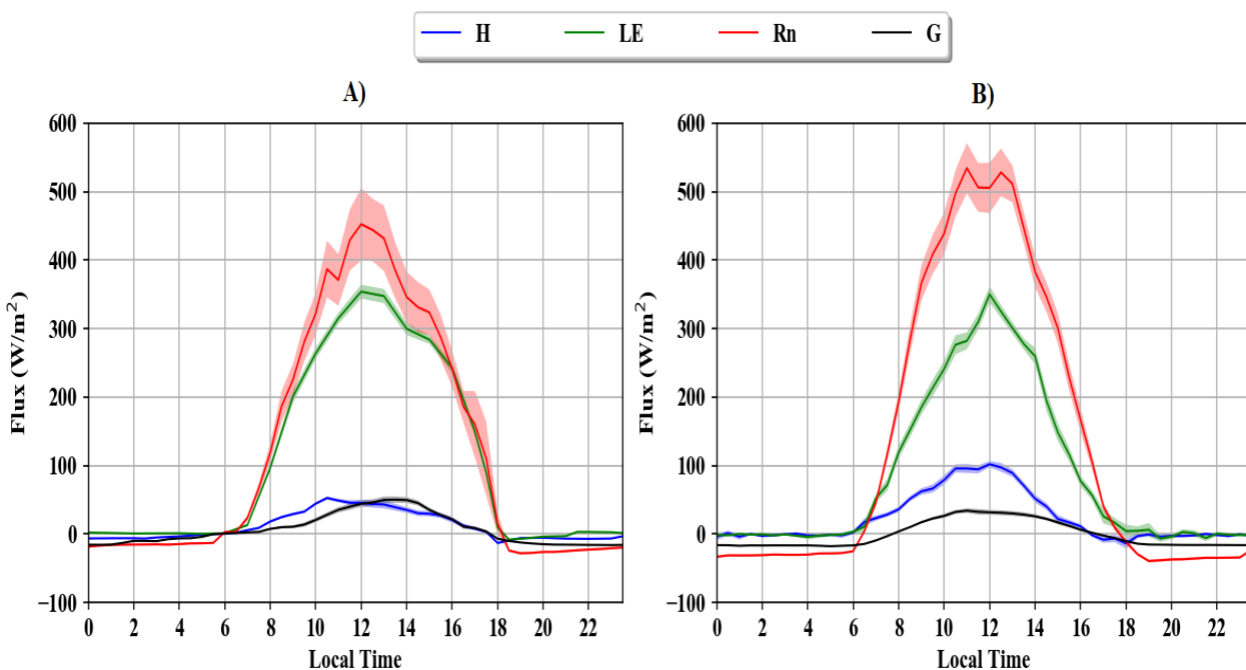

Figure 3: Average daily cycle of the radiation balance (Rn) (W m⁻²), sensible heat flux (H) (W m⁻²), latent heat flux (LE) (W m⁻²) and soil heat flux (G) (W m⁻²) during the IOPs 1 (A) and 2 (B). The shaded represents the standard deviation.

In the Amazon, especially during the rainy season, only a small fraction of Rn (about 10%) is transformed into sensible heat flux (H), and this maximum of 52 W m⁻² occurred at 10:30 LT during IOP1, while for IOP2, due to lower precipitation values and soil moisture deficit, there was an increase of 21% of the fraction of Rn transformed into H, with a maximum of 112.8 W m⁻² at 12 LT.

Nevertheless, only a small percentage of Rn is converted into heat flux in the soil (G), with a maximum of 50 W m⁻² for both IOPs. These results showed that independent of the season, this flux is always low, and is limited to about 5% of the total available energy.

Figure 4 shows the hourly average of the heights of the PBL for the IOP1 (Figure 4A), and IOP2 (Figure 4B) and the Table 2 shows standard deviations values in different time intervals along the PBL daily cycle. In which, the sunrise and sunset times were marked by the vertical lines of 06 and 18 LT respectively, since the study area is near to the equator line and there are

not changes at these times. The RS (*in situ* measurements) was considered as truth depth of the Boundary Layer, while the others presented estimated by remote sensing.

Figure 4: Daily cycle of the height of the PBL during IOP1 (A) and IOP2 (B) experimental periods. The vertical lines represent sunrise (06 LT), sunset (18 LT) (full line) and NBL erosion (dashed line). The shaded represents the standard deviation.

During the phase in which the NBL is formed (between 00 and 06 LT), the IOP1 showed small vertical oscillations of its depth due to the occurrence of sporadic rainfall (Figure 4A). The results obtained from the ceilometer between 00 and 03 LT showed that the depth of the PBL varied between 180 and 280 m, and after 04 LT there was an increase in the maximum height to 350 m, which was reduced in the following hours to 275 m by 06 LT (sunrise).

The measurements made with the WP also showed some oscillations in the height of the NBL, with a reduction in height between 00 and 02 LT from 280 m to 250 m, and then an increase to a maximum of 350 m at 04 LT, remaining constant until 06 LT. The SODAR results during this interval showed lower variation of NBL depth during this same interval. The variation observed from the measurements by the different sensors is related to intermittent mechanical turbulence which could be the result of the presence of clouds and rain during some days and not on others, thus provoking an increase in wind variability during the night which has the effect of deepening the NBL. However, in this same interval during IOP2 (Figure 4B) the NBL was very stable with an average height of 250 m for all sensors (ceilometer, WP, SODAR, MWR and Lidar), thus corroborating the explanation of the influence of rainfall on the determination of variability of depth of the NBL.

The results found for the height of the NBL were similar to those reported by Neves and Fisch (2011), in a study using SODAR in southwestern Amazon, where the authors observed NBL heights varying from 150 to 329 m. However, Acevedo et al. (2004), also studying in a pasture site in the Amazon (in Santarém-PA), observed lower NBL heights than those from the current study (between 50 to 150 m), and this difference occurs because of different geographic conditions (influence of river breeze, fog formation, etc). An example of these influences, in the Santarém region the authors related several cases of formation of fog during the night, which was not observed at the pasture site in Rondônia (see Neves and Fisch, 2015) nor at T3 site.

289 **Table 2 Standard deviation calculated for PBL height measurements of instruments at different intervals of the daily**
290 **cycle.**

σ – IOP1 (February 15 to March 31, 2014)				
Hours	00 – 06 LT	06 – 09 LT	09 – 18 LT	18 – 23 LT
Ceilometer	38.2	59.0	61.7	53.7
Lidar	-X-	49,2	92,0	-X-
MWR	-X-	-X-	-X-	-X-

291 * “X” represents where absences measurements occurred

292
293 The phase of the erosion of the NBL according to Stull (1988) begins after sunrise (at 06 LT in Amazon) and ,the complete
294 erosion of the NBL occurs when the whole layer is mixed, the potential vertical gradient is almost null and as a consequence
295 there is a high growth rate (above 100 m h⁻¹), so, during this phase there are still several layers. In the IOP1 (Figure 4A), the
296 erosion phase was occur 3 hours after sunrise, where it was observed that in the first hours on this phase there is no increase
297 in the PBL depth, only after 08 LT occurred an increase in PBL heights (average rate of 22.8 m h⁻¹). This occurs due to a
298 lower H flux (Figure 3A), which causes the erosion of the NBL to progress slowly, and total erosion occurs only at 09 LT
299 when average rate is 102 m h⁻¹.

300 In contrast, in the IOP2 (Figure 4B), as a function of greater stability of the NBL and the positive values of Rn and H
301 occurring earlier, initial erosion of the NBL begins at 06 LT and there is a rapid increase in the depth of the PBL compared
302 to IOP1, and this increase continues in the subsequent hours at a rapid rate of 70.8 m h⁻¹, which causes the NBL to be
303 completely eroded by 08 LT. This result demonstrates that the erosion of the NBL in this region is conditioned by greater
304 availability of energy in the early hours of the morning, and by how much of this energy will be used for heating of the
305 atmosphere (H).

306 The transition from nighttime to daytime is very complex. Although the H has become positive (so heating the atmosphere),
307 this amount of energy did not completely warm the atmosphere and eroded of the NBL (see Figures S3 and S4 in the
308 Supplement).

309 In IOP1, after complete erosion of the NBL the development phase of the convective boundary layer (CBL) begins, and due
310 to the slow erosion of the NBL the growth of the CBL begins at 11 LT with a typical height of 850 m and an average
311 increase of 102 m h⁻¹, until it reaches its greatest depth at 1,180 m at 13 LT. However, soon after the maximum is registered,
312 the CBL presents a small reduction in depth (13.3 m h⁻¹), due to the low value of H, which did not exceed 50 W m⁻². This
313 surface flux, added to the entrainment flux at the top of CBL, was not sufficient to maintain turbulence in this layer, that
314 showed a reduction after this time.

315 During IOP2, with the NBL being rapidly degraded, the CBL that subsequently formed had a more rapid development, with
316 an average growth rate of 175.2 m h⁻¹. The CBL had a more prolonged phase, with maximum depth registered at 13:30 LT
317 of 1,590 m. After this maximum of the CBL there was a slight reduction in its growth rate (-39,2 m h⁻¹) until 17:30 LT,

when H returned to a null value. This depth is similar to that reported by Fisch et al. (2004), in a study of the CBL in a pasture in Rondônia in the southwestern Amazon, where the authors observed a maximum depth in the dry season of 1,650 m. Neves and Fisch (2015) also observed in Rondônia that in the initial formation of the CBL during the dry season there was very rapid growth between 08 and 11 LT, with maximum heights at 14 LT of about 1,500 m.

3.2. El Niño year (2015)

The energy fluxes for IOP 3 (Figure 5A) and IOP 4 (Figure 5B) show that during the 2015 rainy season, Rn IOP3 behaved in an analogous manner as in the rainy season of 2014 (IOP1), with a maximum of 488 W m⁻² at 12 LT. However, during the dry season of 2015 (IOP4) there was an increase in intensity compared to IOP2, with maximum Rn equal to 555.2 W m⁻² at 12 LT. This greater flux of net radiation to the surface will be converted into heat flux, meaning that there is greater energy available during the dry season of 2015 compared to that of 2014 due to less cloud cover, a common characteristic in years with ENSO events (Macedo and Fisch, 2018).

The LE registered a maximum of 310 W m⁻² during IOP3 at 12 LT. This result represented 65% of the partitioning of Rn. These results are within the range of results for LE in this region, for which 70% of Rn is generally converted into LE (Von Randow et al., 2004; Andrade et al., 2009). Due to the low the low water availability during IOP4 there was a reduction in the partitioning of Rn into the LE flux, only about 35% in comparison with IOP3, resulting in a reduction of more than 50%. The maximum LE registered was at 12 LT and was 179 W m⁻², while during IOP3 just 17% of Rn was converted into H, with a maximum H observed at 13 LT of 86 W m⁻². During IOP4, H had larger averages and 60% of Rn was converted into H, with a maximum of 280 W m⁻² at 12 LT. Furthermore, in 2015 during IOPs 3 and 4, only a small percentage of Rn was converted into G, with a maximum of 40.0 W m⁻² in IOP3 and 50.0 W m⁻² in IOP4, both at 12 LT.

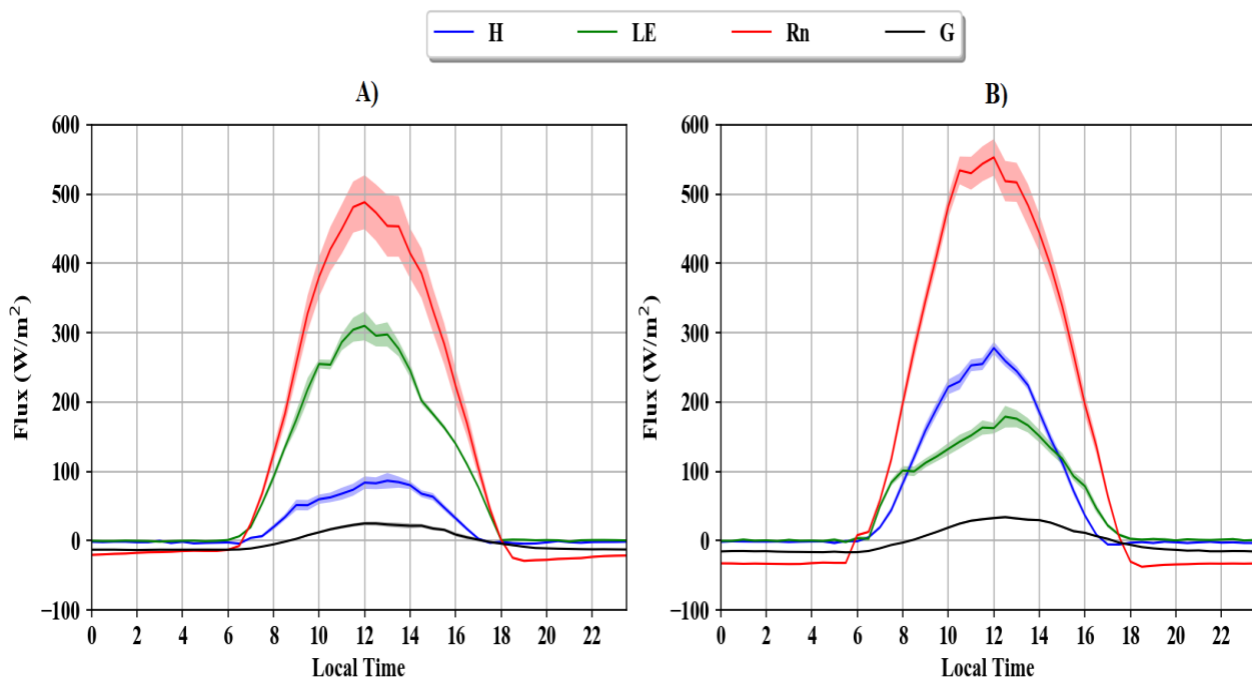

Figure 5: Average of the daily cycle of net radiation (Rn) (W m⁻²), sensible heat flux (H) (W m⁻²), latent heat flux (LE) (W m⁻²) and soil heat flux (G) (W m⁻²) in the study region during the IOPs 3 (A) and 4 (B). The shaded represents the standard deviation.

The daily cycle of CBL during IOP3 (Figure 6A), as well as in IOP1, showed vertical oscillations of the NBL's heights (between 00 and 06 LT), of 200 m (00:30 LT) to 375 m (03 LT). The WP and the SODAR yielded lower depths than did the ceilometer and the MWR. However, during IOP4 (Figure 6B) the NBL was more stable, with an average height of 250 m,

346 similar to what was observed during IOP2. The result from 0 to 06 LT confirms that in the Amazon region the NBL is more
 347 stable during the dry season compared to the rainy season, when it has larger variation in its depth. The Table 3 show
 348 standard deviations values in the different time intervals.
 349

350 **Figure 6: Daily cycle of the height of the PBL during IOP3 (A) and IOP4 (B) experimental periods. The vertical lines**
 351 **represent sunrise (06 LT), sunset (18 LT) (full line) and NBL erosion (dashed line). The shaded represents the**
 352 **standard deviation.**
 353

354 The IOP3 demonstrated a similar erosion pattern for the NBL to that observed during IOP1, with the NBL still established
 355 between 06 and 08 LT. From this time onward there was an increase in depth of the CBL with an average growth rate of 19.6
 356 m h⁻¹. In this manner, just as in IOP1, the erosion of the NBL during IOP3 occurred slowly, with total degradation at 09 LT.
 357 This result is similar to that which was observed during the same phase in IOP1, where the NBL was less stable, and together
 358 with lower availability of energy at the surface, caused a slower erosion of the NBL. However, the erosion phase during
 359 IOP4, in response to an increase in R_n and H , occurred earlier (06 LT). Additionally, during the dry season of 2015, the rate
 360 of ascension was higher during the subsequent hours and reached 76.1 m h⁻¹, such that the NBL was completely eroded at 08
 361 LT.
 362

363 The development during IOP3 occurs in an analogous manner to that observed during IOP1, with weak vertical development
 364 of the maximum depth. At 10 LT the CBL begins to develop and has a height of 830 m and a growth rate of 100.3 m h⁻¹,
 365 reaching a maximum depth of 1,069 m (13:30 LT), demonstrating a shallower CBL during the wet season. However, in
 366 contrast to IOP1, IOP3 had a CBL established during the entire evening period, probably as a function of lower frequency of
 367 rainfall, and IOP4, during the 2015 dry season, had greater development of convection after erosion at 08 LT, with a high
 368 growth rate of 193 m h⁻¹, and at 11 LT the CBL was completely established. With the CBL established as a result of greater
 369 heating of the atmosphere by H , there was greater depth of the CBL, reaching a maximum of 1,925 m at 14 LT, and this was
 370 influenced by the strong EN event, which intensified the dry season in the region, and has caused the highest values of H .
 371 This caused greater thermal convection in the development of the CBL, which increased its depth by 21% in relation to that
 372 observed in IOP2. This maximum depth of the CBL during IOP4 is not commonly found in studies conducted in the Amazon
 373 region before, however Lyra et al. (2003), using radiosonde data, reported a maximum height of 2,200 m during the dry
 374 season of 1994 in Rondônia.
 375

Table 3 Standard deviation calculated for PBL height measurements of instruments at different intervals of the daily cycle.

σ – IOP3 (February 15 to March 31, 2015)				
Hours	00 – 06 LT	06 – 09 LT	09 – 18 LT	18 – 23 LT
Ceilometer	29.4	57.1	67.7	64.5
Lidar	-X-	52.1	90.3	-X-
MWR	32.3	59.8	84.7	39.8
RWP	20.4	49.2	79.4	28.6
Sodar	15.5	-X-	-X-	29.0
σ – IOP4 (September 1 to October 15, 2015)				
Hours	00 – 06 LT	06 – 09 LT	09 – 18 LT	18 – 23 LT
Ceilometer	27.4	54.7	83.6	45.0
Lidar	-X-	-X-	-X-	-X-
MWR	30.5	55.0	109.7	30.6
RWP	31.1	57.9	119.6	47.8
Sodar	30.6	-X-	-X-	29.7

* “X” represents where absences measurements occurred

4. Conclusions

During the four IOPS the results show that during daytime and nighttime intervals, independent of weather conditions, the ceilometer is a promising sensor with good accuracy for direct and continuous measurement of the height of the PBL (which on average ranged from 250 meters - NBL to 1,900 meters - CBL) when compared to *in situ* from RS. The RS, in spite of it being a proven high-precision method, in this experiment it was launched only on synoptic times plus an extra at 15 UTC. Hence, it did not capture a high temporal resolution (like the remote sensors) daily cycle evolution of the height of the PBL, due to the long time interval between launches (each 6 h). While the MWR, WP and the Lidar were satisfactory for estimates of the convective phase (CBL) of the PBL, during the nocturnal phase (NBL) these sensors overestimated heights. Additionally, the SODAR under- and overestimated the NBL during these periods.

The intense EN event of 2015/2016 influenced the development phase of the CBL during the dry season of IOP4, and it had a growth rate of about 15% higher than the results from IOP2, and a sensible heat flux (responsible for heating the air) that was higher than the standard values for the central Amazon. As a consequence, more intense convective movements were occurred and had contributed to a stronger vertical development of the layer.

The NBL erosion showed differences between seasons, presenting an erosion time of 2 hours in the dry IOPs (2 and 4), and 3 hours in the wet IOPs (1 and 3). A more detailed analysis of CLN erosion is being elaborated in Carneiro and Fisch (2020).

Supplement. The supplement related to this article is available on- line at: [acp-2019-578-supplement-version2.pdf](https://www.arm.gov/research/campaigns/amf2014goamazon)

Data availability. The data sets used in this publication are available at the ARM Climate Research Facility database for the GoAmazon2014/5 experiment (<https://www.arm.gov/research/campaigns/amf2014goamazon>, last access: 1 June 2019).

Author contributions. RGC and GF designed the numerical experiments and the first author performed the simulations as a part of his PhD. RGC performed data analysis, assisted by GF. RGC and GF prepared the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. Institutional support was provided by the National Institute of Space Research (INPE), the National Institute of Amazonian Research (INPA), and Amazonas State University (UEA). Rayonil G. Carneiro acknowledges a Brazilian National Council for Scientific and Technological Development (CNPq) graduate fellowship (140726/2017-9). Rayonil G Carneiro and Gilberto Fisch thanks the GOAMAZON Project group for provide the data available for this study.
