## Abstract

Serious urban ozone (O<sub>3</sub>) pollution was observed during the campaign of 2016 G20 summit in Hangzhou, China, while other pollutants had been significantly reduced by the short-term emission control measures. To understand the underlying mechanism, the Weather Research Forecast with Chemistry (WRF-Chem) model is used to investigate the spatial and temporal O<sub>3</sub> variations in Hangzhou from August 24 to September 6, 2016. The model is first successfully evaluated and validated for local and regional meteorological and chemical parameters by using the ground and upper-air level observed data. High ozone concentrations, temporarily during most day time of the emission control period and spatially from the surface to the top of the planetary boundary layer, are captured in Hangzhou and even the whole YRD region. Various atmospheric processes are further analyzed to determine the influential factors of local ozone formation through the integrated process rate method. Interesting horizontal and vertical advection circulations of O<sub>3</sub> are observed during several short periods, and the effects of these processes are nearly cancelled out. As a result, the ozone pollution is mainly attributed to the local photochemical reactions which are not obviously influenced by the emission reduction measures. The ratio of reduction of Volatile Organic Compounds (VOCs) to that of NO<sub>x</sub> is a critical parameter that needs to be carefully considered for future alleviation of ozone formation. In addition, the vertical diffusion from the upper-air background O<sub>3</sub> also plays an important role in shaping the surface ozone concentration. These results provide insight into urban O<sub>3</sub> formation in Hangzhou and support the Model Intercomparison Study Asia Phase III (MICS-Asia Phase III).

**Keywords:** Ozone pollution, WRF-Chem, Spatial-temporal variation, Process analysis, Air quality.

## 59 **1. Introduction**

60 Tropospheric ozone (O<sub>3</sub>) is generated by a series of photochemical reactions involving volatile  
61 organic compounds (VOCs), nitrogen oxide (NO<sub>x</sub>), and carbon monoxide (CO) (Wang et al., 2006).  
62 As a primary component of photochemical smog, ground-level O<sub>3</sub> pollution imposes detrimental  
63 effects on human health (Ha et al., 2014; Kheirbek et al., 2013) and the ecosystem (Landry et al.,  
64 2013; Teixeira et al., 2011). However, O<sub>3</sub> pollution is a challenging problem worldwide. O<sub>3</sub> levels in  
65 cities in the United States and Europe are increasing more than those in the rural areas of these  
66 regions, where peak values gradually decreased during 1990–2010 (Paoletti et al., 2014).  
67 Nagashima et al., (2017) reported that long-term (1980–2005) trends of increase in surface O<sub>3</sub> over  
68 Japan may be primarily attributed to the continental transport that have contributed to  
69 photochemical O<sub>3</sub> production. Urban O<sub>3</sub> pollution events have also be observed in developing  
70 countries, such as Thailand (Zhang and Kim Oanh, 2002) and India (Calfapietra et al., 2016).

71 Many field monitoring and modeling studies have investigated the photochemical  
72 characteristics of near-surface O<sub>3</sub> pollution (Tang et al., 2009, 2012; Wang et al., 2013, 2014), the  
73 photochemistry of O<sub>3</sub> and its precursors (Xie et al., 2014), the interactions between O<sub>3</sub> and PM<sub>2.5</sub>  
74 (Shi et al., 2015), and the urban O<sub>3</sub> formation (Tie et al., 2013). It is clear that in addition to  
75 anthropogenic emissions of O<sub>3</sub> precursors, uncontrollable physical and chemical processes involved  
76 in meteorological phenomena significantly modulate changes in O<sub>3</sub> concentration (Xue et al., 2014).  
77 In the Yangtze River Delta (YRD) region of China, high O<sub>3</sub> concentrations have been observed  
78 (Gao et al., 2016; Jiang et al., 2012). Synoptic patterns related to tropical cyclones may be one  
79 reason for such high O<sub>3</sub> concentrations (Huang et al., 2005). Jiang et al. (2015) reported that  
80 enhanced stratosphere–troposphere exchange (STE) driven by a tropical cyclone abruptly increased  
81 O<sub>3</sub> concentrations (21–42 ppb) in the southeast of China during June 12–14, 2014, which has been  
82 highlighted as another contributor to near-surface O<sub>3</sub> concentrations under certain conditions (Lin et  
83 al., 2012, 2015). However, the complex dynamics in atmospheric processes related to O<sub>3</sub> formation

84 are so difficult to identify that the O<sub>3</sub> pollution characteristics and underlying causes have not yet  
85 been well understood.

86 Hangzhou, the capital of Zhejiang Province, is located in the center of the Yangtze River Delta  
87 which is one of the most developed areas in China. Resultant from local emissions (Wu et al. 2014,  
88 Hu et al. 2015) and transboundary transport of aerosol and trace gases transport (Liu et al. 2015; Ni  
89 et al. 2018; Zhang et al. 2018), air pollution in Hangzhou has become serious in the recent years. In  
90 2016, Hangzhou city would host the 2016 G20 (Group of Twenty Finance Ministers and Central  
91 Bank Governors) summit during September 4-6. To improve air quality for this event, 14-day  
92 temporarily strict air pollution alleviation measures had been taken to reduce air pollutant emissions  
93 in Hangzhou and surrounding areas from August 24 to September 6, 2016. The emission control  
94 scheme includes a coal-fired power plant capacity 50% reduction since August 24, followed by an  
95 “odd-even” on-road vehicle restriction since August 28, and further emergent VOC reduction from  
96 industrial sectors since September 1 to 6 (Ji et al. 2018; Li et al. 2019; Wu et al. 2019). These short-  
97 term measures provide a valuable opportunity to investigate the response of air quality to the  
98 emission reduction, understand the formation mechanisms of air pollution, and explore effective  
99 policies for long-term air pollution control in the local or regional scale.

100 The effects of emission control on air pollutants during this G20 Summit have been  
101 investigated by several studies using field observations and numerical models. It is demonstrated  
102 that almost all major air pollutants including SO<sub>2</sub>, NO<sub>x</sub> (Li et al. 2019; Wu et al. 2019), fine  
103 particles (Ji et al. 2018; Li et al. 2019; Yu et al. 2018; Wu et al. 2019), and VOCs (Zheng et al. 2019)  
104 have been significantly reduced during the 14-day control period, except O<sub>3</sub>. Su et al. (2017)  
105 monitored the vertical profiles of ozone concentration in the lower troposphere of Hangzhou during  
106 the control period by using an ozone lidar. It was found that the ozone concentrations peaked near  
107 the top of the planetary boundary layer, and the temporary measures took no immediate effect on  
108 ozone pollution. Wu et al. (2019) investigated the variation of air pollution in Hangzhou and its  
109 surrounding areas during the G20 summit by using monitoring data from five sites, and reported

110 that the air quality had been greatly improved by the implementation of the emission control.  
111 However, the average O<sub>3</sub> concentration was increased by 19% compared to the same periods of the  
112 five preceding years. This unique response of ozone pollution to control measures is not well  
113 understood, and of great research interest for better control of ozone pollution in the future.

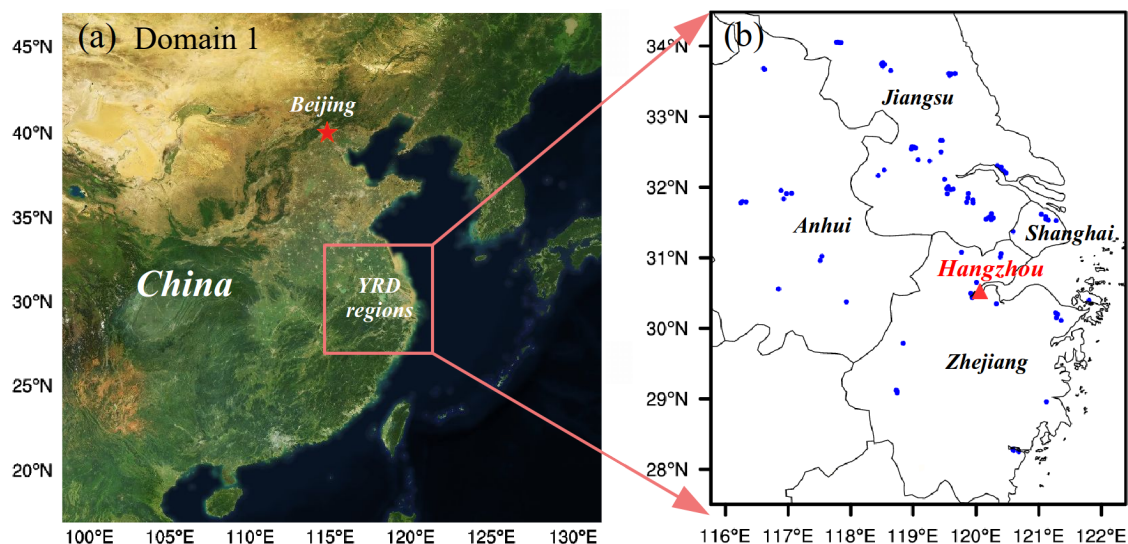

114 To this end, a regional air quality model, within the framework of the Model Inter-Comparison  
115 Study for ASIA phase III (Li et al., 2019), is used to investigate the spatial-temporal characteristics  
116 of ozone pollution in Hangzhou during the G20 Summit in the present work. Process analysis is  
117 conducted to understand the chemical and physical factors that contribute to O<sub>3</sub> abundance. It is  
118 found that the serious ozone pollution happened, mainly resultant from the local photochemical  
119 reactions which are not under good control by the emission reduction measures. The rest of this  
120 paper is organized as follows. Section 2 outlines the methodology and configuration of the model  
121 system. Section 3 presents the model evaluation, the spatial-temporal characteristics of ozone  
122 pollution, and the analysis of related atmospheric processes. Section 4 discusses the underlying  
123 causes of O<sub>3</sub> pollution. Finally, a summary is made.

## 124 **2. Methodology**

### 125 **2.1. Regional chemistry modeling system**

126 To investigate the interactions among emissions, meteorological phenomena, and chemical  
127 phenomena, the Weather Research Forecast with Chemistry model (WRF-Chem) is used in the  
128 present study. The WRF-Chem is a regional online-coupled air quality model that can  
129 simultaneously simulate air quality components and meteorological components by using identical  
130 transport schemes, grid structures, and physical schemes (Grell et al., 2005). Two model domains  
131 are designed: an outer domain (horizontal resolution: 30 km) covering East China (20.0°N–44.5°N,  
132 99.0°E–126.5°E) and an inner domain (horizontal resolution: 6 km) covering the YRD region  
133 (27.6°N–32.7°N, 116.9°E–122.4°E), as shown in Fig.1. The “Lambert conformal conic” projection  
134 is applied with the domain center at 34°N, 111°E. A total of 31 vertical layers are used with the  
135 model top at 50 hPa. The simulation period is from 17 August to 6 September 2016, and the first-

136 week simulation is used to spin up the model. Hourly model outputs for 24 August to 06 September  
137 are used in the analysis. The gas mechanism CBMZ (Chemical Bond Mechanism Version Z)  
138 (Zaveri and Peters, 1999) is used for model simulations. For additional details regarding the model  
139 parameterization schemes, please refer to a previous study (Ni et al., 2018).

140

141 **Fig. 1.** Double-nested simulation domains. (a) Domain 1: 30 km in East China with 102 (W–E) × 111 (S–N) × 31  
142 (vertical layers) grids; (b) Domain 2: 6 km in the Yangtze River Delta (YRD) region with 100 (W–E) × 115 (S–N)  
143 × 31 (vertical layers) grids. Blue dots denote the air quality monitoring sites. The copyright of the background  
144 map belongs to Google Map © Google.

145 The meteorological boundary and initial conditions are determined from the global objective  
146 final analysis (FNL) data of the National Centers for Environmental Prediction (Kalnay et al., 1996).  
147 The FNL data are mapped to domain 1 (East China), and the grid-nudging method (Stauffer et al.,  
148 1991) is used to reduce the meteorological integral errors. The chemical initial and boundary  
149 conditions are dynamically downscaled from the simulation results of model for ozone and related  
150 chemical tracers, version 4 (MOZART4) (Emmons et al., 2010).

## 151 2.2. Emissions

152 The 2016 Multiresolution Emission Inventory for China (MEIC, 0.25° × 0.25°;  
153 <http://www.meicmodel.org/>) is used for the outer domain (Fig. 1a) with a spatial resolution of 30  
154 km (Li et al., 2017), including species of SO<sub>2</sub>, NO<sub>x</sub>, CO, NH<sub>3</sub>, PM<sub>2.5</sub>, and VOCs from the power,

155 industrial, residential, transportation, and agricultural sectors. Inventories of finer anthropogenic  
156 emissions for the YRD region over the year of 2014 compiled by Shanghai Academy of  
157 Environmental Sciences are used for the inner domain (Fig. 1b). These inventories have been well  
158 documented in previous studies (Huang et al., 2011; Li et al., 2011; Liu et al., 2018). The fine  
159 emission inventories include major sectors such as large point sources, industrial sources, mobile  
160 sources, and residential sources. The anthropogenic emissions over the YRD region are mainly  
161 located over the industrial and urban areas along the Yangtze River as well as over Hangzhou Bay.  
162 In this study, the emission inventories for the two domains are projected into horizontal and vertical  
163 grids as hourly emissions, with temporal and vertical profiles obtained from Wang et al. (2011).  
164 VOCs emissions are categorized into modeled species, according to von Schneidemesser et al.  
165 (2016). In addition, biogenic emissions are generated offline using the Model of Emission of Gases  
166 and Aerosols from Nature (MEGAN) (Guenther et al., 2006). Dust emissions are calculated online  
167 from surface features and meteorological fields by using the Air Force Weather Agency and  
168 Atmospheric and Environmental Research scheme (Jones et al., 2011). Other emissions, such as  
169 those from biomass burning, aviation, and sailing ships, accounting for very small fraction during  
170 this period, are therefore not considered here. However, it is worth noting that these base  
171 inventories have been modified in the simulation to reflect the realistic emissions according to the  
172 control measures taken in the period presented in the introduction.

### 173 **2.3. Atmospheric processes analysis**

174 To understand the underlying mechanism of O<sub>3</sub> formation, individual physical and chemical  
175 processes of O<sub>3</sub> formation are investigated by using the integrated process rate (IPR) analysis in the  
176 WRF-Chem model (Jffries and Tonnesen, 1994). The IPR analysis differentiates changes in  
177 pollutant concentrations from individual atmospheric process which quantitatively elucidates the  
178 contributions of each process, mainly including advection, diffusion, emission, deposition, clouds  
179 process, aerosol and gaseous chemistry. The IPR analysis has been widely applied and demonstrated  
180 to be an effective tool for investigating the relative importance of individual processes and

181 interpreting O<sub>3</sub> concentrations (Goncalves et al., 2009; Tang et al., 2017; Shu et al., 2016). In the  
 182 present work, we consider gas chemistry, vertical diffusion, horizontal and vertical advections as the  
 183 main atmospheric processes for O<sub>3</sub> formation. Other processes, such as cloud process and horizontal  
 184 diffusion, play minor roles and are thus not considered.

#### 185 2.4. Evaluation metrics

186 To increase the confidence in interpretations of model results, model outputs should first be  
 187 evaluated based on observations. Accordingly, the model results derived from domain 2 are  
 188 compared with hourly surface observational data obtained from 96 air quality monitoring sites in  
 189 the YRD region (blue dots, Fig. 1b) in this study. These observational data are downloaded from  
 190 <http://www.pm25.in>, and O<sub>3</sub> as well as its precursor NO<sub>2</sub> are evaluated, in terms of statistical  
 191 measures, namely the mean fractional bias (MFB), the mean fractional error (MFE), and the  
 192 correlation coefficient ( $R$ ), following the recommendation of the US Environmental Protection  
 193 Agency (US EPA, 2007). Additionally, the meteorological parameters are evaluated based on the  
 194 observational data, including temperature at 2 m (T2), relative humidity at 2 m (RH2), 10 m wind  
 195 speed (WS10) and direction (WD10), from the Meteorological Assimilation Data Ingest System

196 **Table 1.** Discrete statistical indicators used in the model evaluation

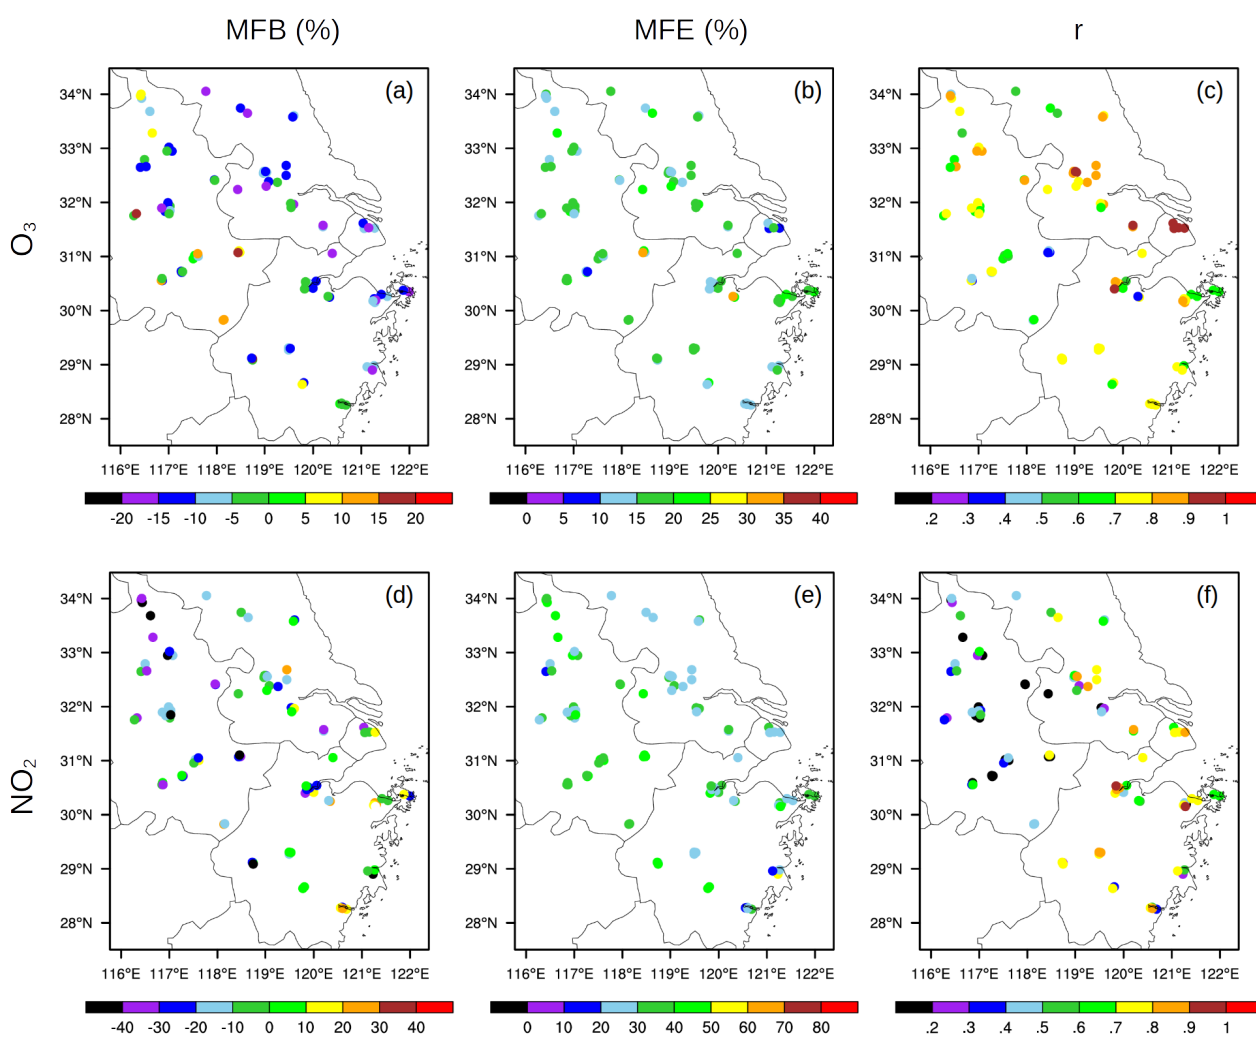

Metrics	Definition	Range
Mean Fractional Bias (MFB)	$MFB = \frac{2}{N} \sum_{i=1}^N \frac{S_i - O_i}{S_i + O_i} \times 100\%$	-200% to 200%
Mean Fractional Error (MFE)	$MFE = \frac{2}{N} \sum_{i=1}^N \frac{ S_i - O_i }{S_i + O_i} \times 100\%$	0 to 200%
Correlation Coefficient ( $r$ )	$r = \frac{\sum_{i=1}^N (S_i - \bar{S})(O_i - \bar{O})}{\sqrt{\sum_{i=1}^N (S_i - \bar{S})^2 \sum_{i=1}^N (O_i - \bar{O})^2}}$	0 to 1
Mean Bias (MB)	$MB = \frac{1}{N} \sum_{i=1}^N (S_i - O_i)$	$-\infty$ to $+\infty$
Gross Error (GE)	$GE = \frac{1}{N} \sum_{i=1}^N  S_i - O_i $	0 to $+\infty$
Root Mean Square Error (RMSE)	$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N (S_i - O_i)^2}$	0 to $+\infty$

$N$  is the number of samples.  $S_i$  and  $O_i$  are values of simulations and observations at time or location  $i$ , respectively.

197 (<https://madis.noaa.gov>). Following the study of Zhang et al. (2014), commonly used mean bias  
 198 (MB), gross error (GE), and root mean square error (RMSE) are calculated as the statistical  
 199 indicators. All used statistical indicators are summarized in Table 1.

200 Besides the above evaluation of single-point based time series results, the vertical spatial  
 201 distribution of modeled  $O_3$  in Hangzhou is also evaluated by comparisons with observed differential  
 202 absorption LiDAR (DIAL) data (Su et al. 2017). In the DIAL technique, the mean gas concentration  
 203 over a certain range interval is determined by analyzing the LiDAR backscatter signals for laser  
 204 wavelengths tuned “on” ( $\lambda_{on}$ ) and “off” ( $\lambda_{off}$ ) in a molecular absorption peak of the gas under

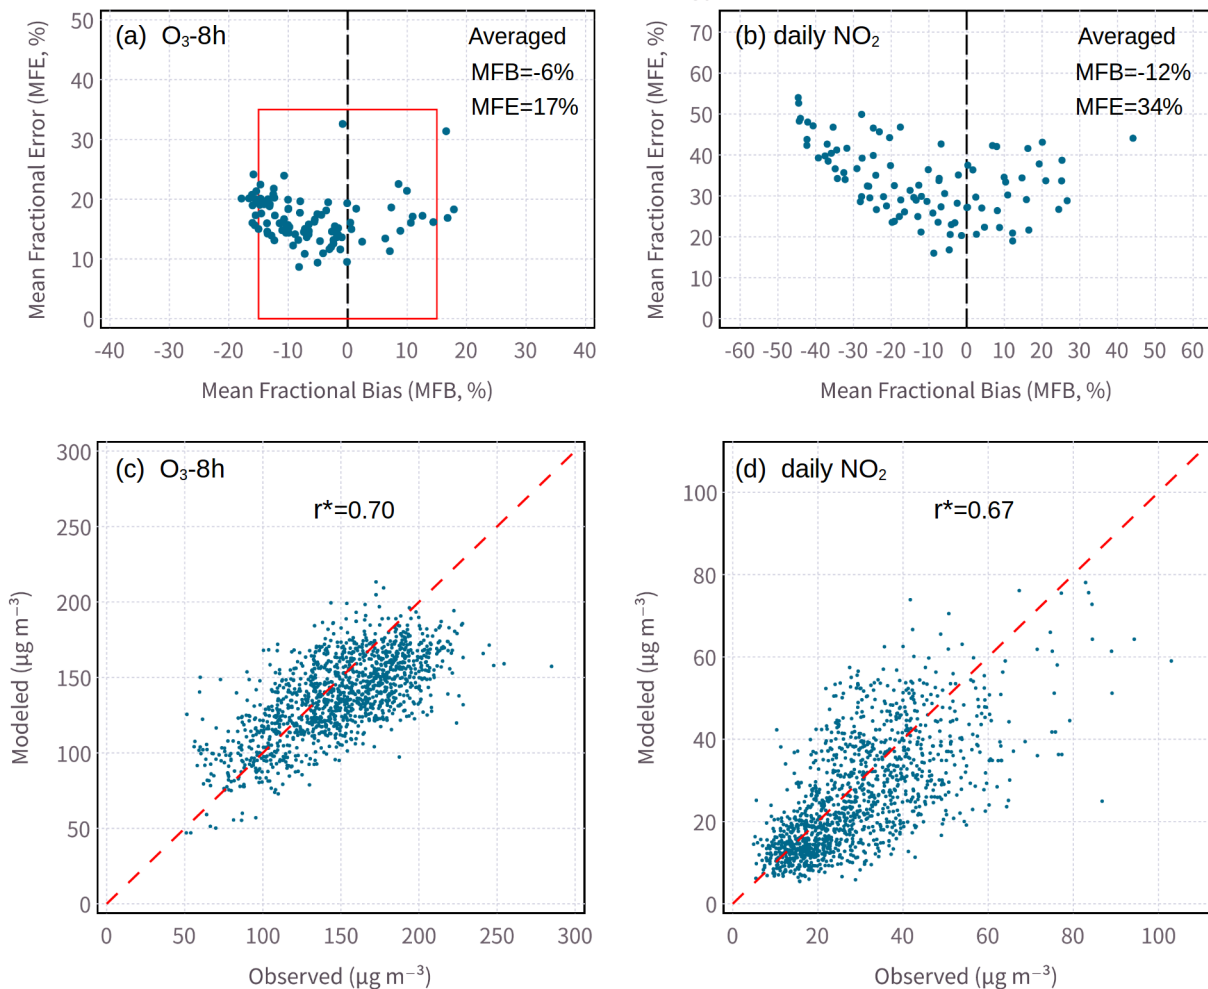

205  
 206 **Fig. 2.** Comparison of modeled air pollutant concentrations against measurements in 96 monitoring sites over  
 207 YRD region during August 24–September 6, 2016: Mean fractional bias (MFB), mean fractional error (MFE) and  
 208 Pearson’s correlation coefficient ( $r$ ) of  $O_3$  (a–c) and  $NO_2$  (d–f), respectively.

209 investigation (Browell et al., 1998). In the DIAL data of O<sub>3</sub>, the vertical height available is from 0.3  
210 km to 3 km due to the limitations of the signal-to-noise ratio and detection range.

### 211 3. Results

#### 212 3.1. Model performance

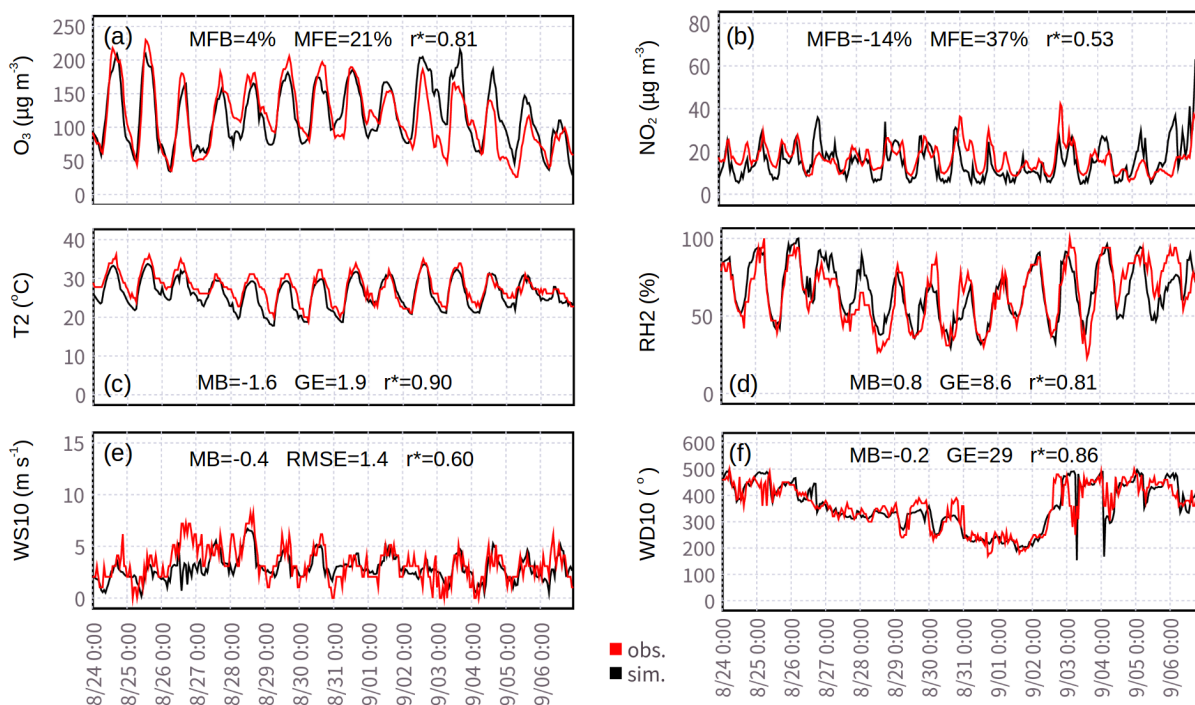

213 We first evaluate the overall performance of WRF-Chem for the YRD region by incorporating  
214 data from the 96 air quality monitoring sites. Specifically, the maximum daily 8 h (MDA8) ozone  
215 and daily mean NO<sub>2</sub> concentrations at the surface are used. The spatial distributions of MFB and  
216 MFE for O<sub>3</sub> and NO<sub>2</sub> are illustrated in Fig. 2. In general, the model-simulated air pollutant  
217 concentrations agree well with the observations, with MFB and MFE for most of the sites meeting

218

219 **Fig. 3.** Comparisons of modeled and observed concentrations of the air pollutants from 96 air quality monitoring  
220 sites across the YRD from 24 August to 06 September 2016 (1,344 pairs). Scatter plots for MFB and MFE of (a)  
221 O<sub>3</sub> and (b) NO<sub>2</sub>. Performance goals (red box) for O<sub>3</sub> are the benchmarks. Scatter plots for daily observed and  
222 modeled (c) O<sub>3</sub> and (d) NO<sub>2</sub>.

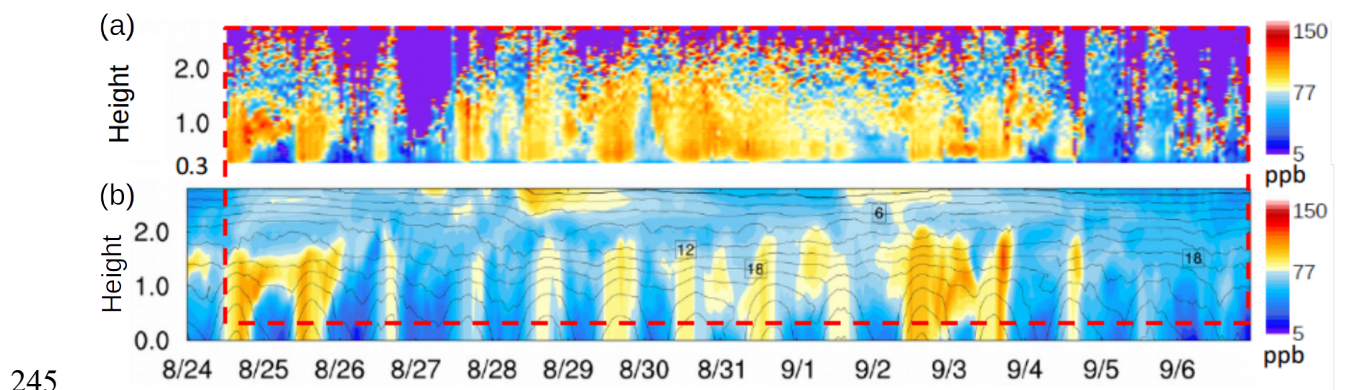

223 the benchmarks (MFB<15%; MFE<35%) (US EPA, 2007). A scatter plot of MFB/MFE is shown in  
 224 Fig.3, further demonstrating the capability of the present model in reproducing the observations,  
 225 which is also supported by the high correlation between model and observation (Fig. 3c, d).

226  
 227 **Fig. 4.** Modeled air pollutants and meteorological parameters compared with measurements at the Hangzhou  
 228 monitoring site from 24 August to 06 September 2016. Surface concentrations of (a) O<sub>3</sub> and (b) NO<sub>2</sub>, (c)  
 229 temperature at 2 m (T2), (d) relative humidity at 2 m (RH2), (e) wind speed at 10 m (WS10) and (f) wind  
 230 direction at 10 m (WD10).

231 After the above overall evaluation of the present model in the whole YRD region, the site of  
 232 Hangzhou will be focused on for further analysis. The time series of hourly simulated and observed  
 233 air pollutants (O<sub>3</sub>, Fig. 4a; NO<sub>2</sub>, Fig. 4b) and meteorological factors (T2, Fig. 4c; RH2, Fig. 4d;  
 234 WS10, Fig. 4e; and WD10, Fig. 4f) at Hangzhou are presented in Fig. 4. It is found that all modeled  
 235 data are statistically significantly correlated with the observed data at the 95% level. The MFB and  
 236 MFE for both O<sub>3</sub> and NO<sub>2</sub> are well below the benchmarks (MFB/MFE: 15%/35%; US EPA, 2007)  
 237 and the observed diurnal variations are well reproduced. For meteorological parameters,  $\leq \pm 0.5^\circ\text{C}$ ,  
 238  $\text{GE} \leq 2.0^\circ\text{C}$ , 10 m wind speed ( $\text{MB} \leq 0.5 \text{ m/s}$ ,  $\text{RMSE} \leq 2.0 \text{ m/s}$ ) and 10 m wind direction ( $\text{MB} \leq$   
 239  $\pm 10^\circ$ ,  $\text{GE} \leq 30^\circ$ ). McNally (2009) suggested a relaxed benchmark for 2 m temperature ( $\text{MB} \leq$   
 240  $\pm 1.0^\circ\text{C}$ ). In this study, the 10 m wind speed and wind direction (Fig. 3e, f) results are well within

241 the benchmarks. The GE of 2 m air temperature ( $1.9^{\circ}\text{C}$ ; Fig. 3c) also satisfies the criteria, but the  
 242 MB is slightly higher ( $-1.6^{\circ}\text{C}$ ) which has also been noted in a previous study (Zhang et al., 2014).  
 243 These comparisons further demonstrate that the present model is able to correctly predict the time  
 244 series of both meteorological parameters and air pollutants of  $\text{O}_3$  and  $\text{NO}_2$  in Hangzhou.

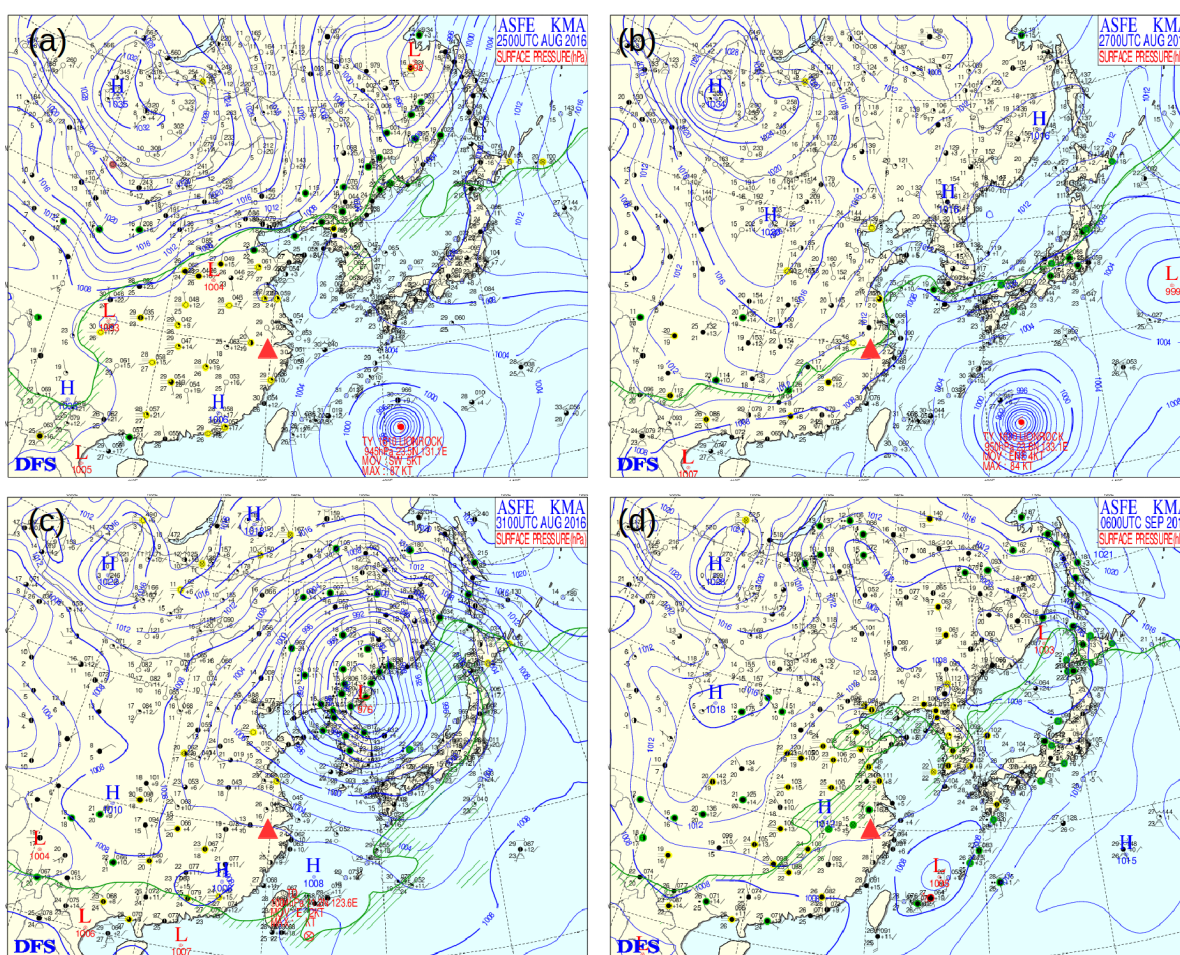

246 **Fig. 5.** Vertical comparison of hourly (a) observed (from differential absorption LiDAR) and (b) simulated  $\text{O}_3$   
 247 concentrations (ppb) in Hangzhou from 24 August to 06 September 2016. Purple regions in the top panel denote  
 248 invalid data with a low signal-to-noise ratio. To facilitate direct comparison, the red dashed line is added to  
 249 indicate the ozone level recorded for the same time periods (starting from 12:00, 24 August) and vertical heights  
 250 (0.3–3 km) in the observations and simulation results.

251 To further evaluate the capability of the model to predict the vertical structure of ozone  
 252 concentration, the vertical distribution of the modeled  $\text{O}_3$  in Hangzhou from 24 August to 06  
 253 September 2016 is qualitatively compared with the DIAL data, as shown in Fig. 5. It is interesting  
 254 to find that the present model can successfully predict the spatial-temporal distribution of ozone in  
 255 Hangzhou. All observed major features of ozone are well captured by the model. This gives us high  
 256 confidence and lays a solid foundation for further exploring the pollution characteristics and  
 257 influencing factors of ozone in Hangzhou during the G20 summit.

### 258 3.2. Spatial-temporal variations of $\text{O}_3$ pollution

259 To discuss spatial-temporal characteristics of  $\text{O}_3$  pollution in Hangzhou, the whole emission  
 260 control period can be divided into three stages according to the reduction intensity of the measures.  
 261 August 24-27, 2016 is the first stage (S1) during which industrial and construction emission  
 262 controls were implemented. During the second stage (S2, August 28-31), traffic restrictions were

263 further added. September 1-6 2016 is the third stage (S3) with the emergent VOCs control further  
 264 implemented. Figs. 4(a) and 4(b) in the above section also present the temporal evolution of O<sub>3</sub> and  
 265 its precursor NO<sub>2</sub> in Hangzhou city during the emission control period of G20 summit. It is evident  
 266 that the NO<sub>2</sub> has been significantly reduced by the emission control measures and the concentration  
 267 is well below the national level-II standard of 200 μg/m<sup>3</sup>. However, the concentration of O<sub>3</sub> keeps  
 268 high levels for the whole 14 days, with 7 days of MDA8 are above and 4 days are close to the  
 269 national level-II standard (GB-3095–2012) of 160μg/m<sup>3</sup>. This serious O<sub>3</sub> pollution indicates that the  
 270 emission control measures seem to make no obvious effect on ozone, which is consistent with  
 271 previous observations (Su et al. 2017; Wu et al. 2019). The diurnal variation of O<sub>3</sub> is similar for the

272  
 273 **Fig. 6.** Synoptic circulation in East Asia during the 2016 G20 summit. Weather charts for four representative  
 274 periods at 08:00 LST on (a) 25 August, (b) 27 August, (c) 31 August, and (d) 06 September 2016. LST: Local  
 275 Sidereal Time; H: High-pressure system; L: Low-pressure system. The red triangle denotes the location of  
 276 Hangzhou city.

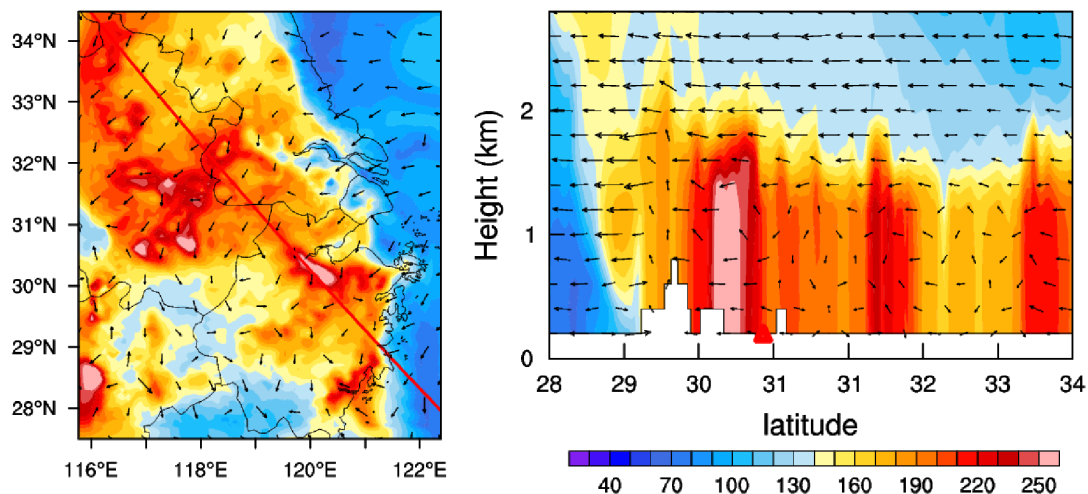

277 three stages with a peak value at the time around 16:00 and a valley value at the time around 8:00 of  
278 each day. However, the variation magnitude in Stage 2 is obviously lower than those of other stages,  
279 which will be further discussed later.

280 Fig. 5 also clearly shows this diurnal variation of O<sub>3</sub> in the ground level. However, nocturnal  
281 O<sub>3</sub>-rich mass is observed during certain periods in the upper air (approximately 1 km), such as  
282 August 25, August 31, and September 3, which makes an n-shaped distribution pattern of the O<sub>3</sub> in  
283 the upper air. This kind of spatial distribution of ozone will promote vertical exchange of O<sub>3</sub> in the  
284 area. In general, high concentrations of O<sub>3</sub> appear vertically until the top of the planetary boundary  
285 layer (PBL, approximately <2 km), suggesting the ozone pollution is not a local but a regional  
286 phenomenon in the whole low-level (from surface to close to the PBL height) region.

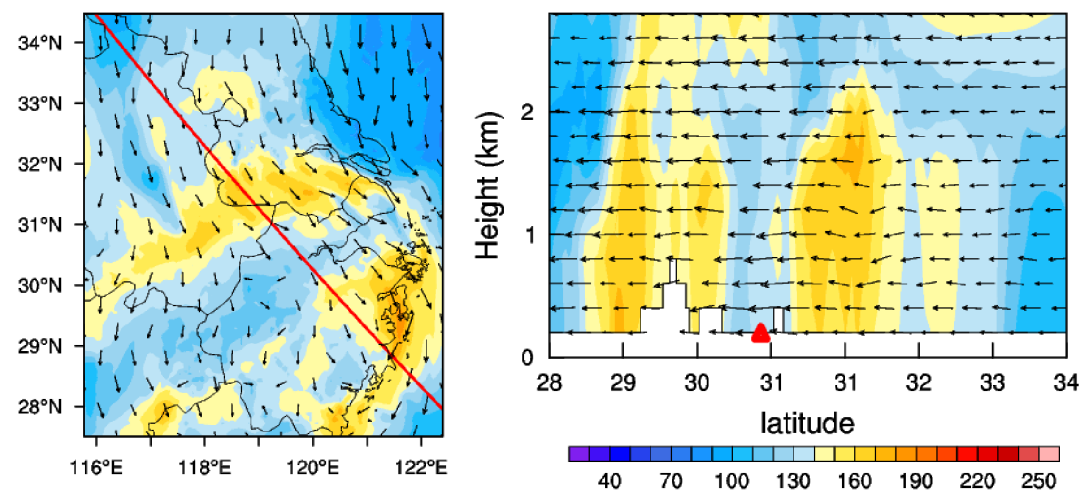

287 Considering the synoptic circulation is closely related to regional O<sub>3</sub> abundance, four  
288 representative surface weather charts obtained from the Korea Meteorological Administration are  
289 presented in Fig. 6. In the early stage, strong and uniform high-pressure fields covered vast regions  
290 of southeastern China, and a tropical cyclone moved northeastward over the East China Sea (Fig.  
291 6a). In the middle stage (Fig. 6b), the tropical cyclone approached the YRD region, bringing strong  
292 north wind fields to this area. As a result, the long narrow rain band arrived in Hangzhou (red  
293 triangle) on 27 August 2016. In the later stage (Fig. 6c), the cyclone continuously moved and  
294 eventually hit the land, and the tropical high in the YRD region recovered gradually. Finally, the  
295 cyclone faded, and a rainstorm appeared over most of the YRD region (Fig. 6d).

296 The typical hourly vertical and horizontal O<sub>3</sub> distributions in the YRD region are further  
297 presented in Fig.7. The wind fields are also included for better understanding. For stagnation days  
298 with weak wind fields and strong radiation before or after the tropical cyclone, meteorological  
299 conditions are unfavorable for pollutant dispersion. As a result, O<sub>3</sub> pollution is more regional and  
300 intense, with an hourly peak O<sub>3</sub> concentration of 250 µg/m<sup>3</sup> appeared within the planetary boundary  
301 layer in the whole YRD region, as shown in Figs. 7a and 7c. In these conditions, photochemical

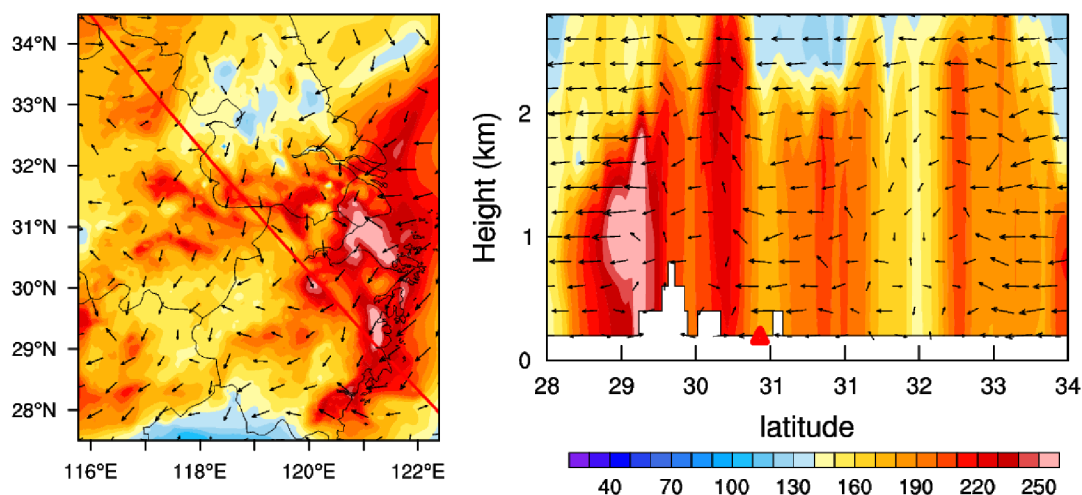

(a) 14:00 Aug. 25, 2016

(b) 14:00 Aug. 27, 2016

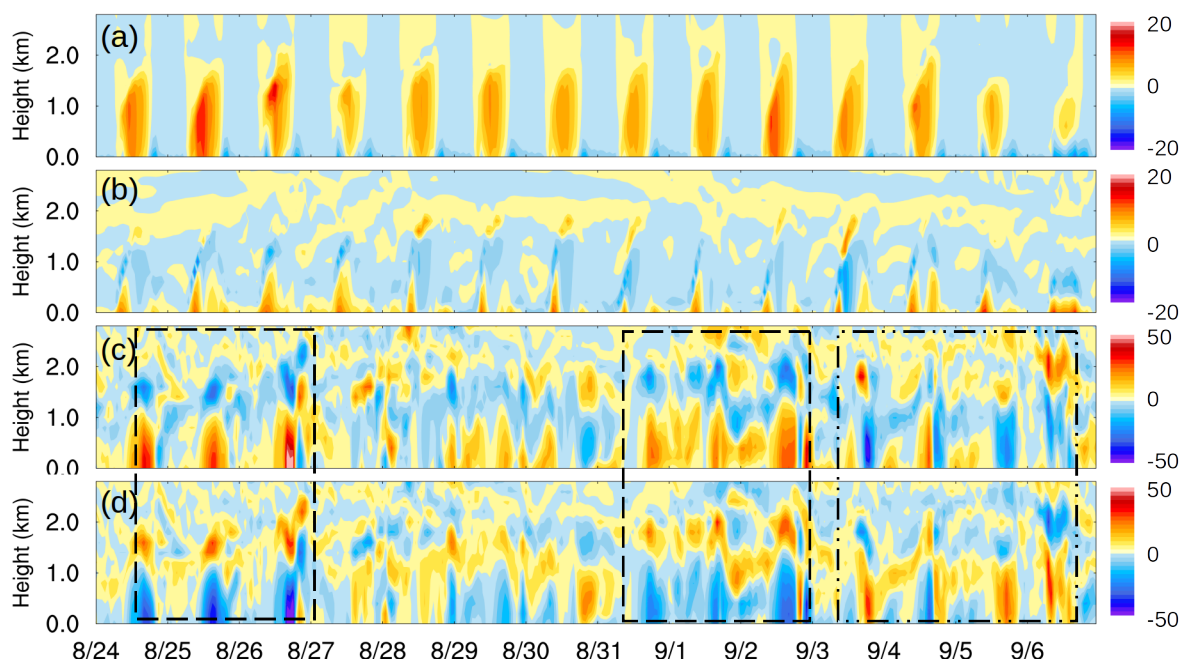

(c) 16:00 Sep. 02, 2016

302  
303 **Fig. 7.** Surface and low-level O<sub>3</sub> distributions ( $\mu\text{g m}^{-3}$ ) and wind fields (vectors,  $\text{m s}^{-1}$ ) for representative episodes.  
304 (a) Stagnant weather before the tropical cyclone, (b) pollutant transport when the tropical cyclone approached, and  
305 (c) stagnant weather after the cyclone. The red line denotes the cross-section line of low-level O<sub>3</sub> distributions.  
306 The red triangle denotes the location of Hangzhou.

307 reactions dominate the ozone formation and accumulation. This phenomenon is consistent with the  
 308 satellite-derived tropospheric O<sub>3</sub> distribution in the area (Su et al. 2017), and is also supported by  
 309 the observed ozone data from the 96 sites in the YRD region as shown in Fig. 3c. During the 14-day  
 310 emission control period of G20 summit, 52% of the observed ozone samples from the 96 sites are  
 311 above the China's national level-II standard (160μg/m<sup>3</sup>), suggesting that regional ozone pollution  
 312 appears in the YRD region during the study period. As the cyclone approached on 27 August, a  
 313 large belt of O<sub>3</sub> mass appeared in the upwind direction and moved toward Hangzhou under a  
 314 prevailing north wind field (Fig. 7b). Regional pollutant transport may play an important role under  
 315 this condition. However, because of the rain and cooling effects from the cyclone, the ozone  
 316 concentration is relatively low in the whole YRD region.

### 317 3.3. Process analysis of O<sub>3</sub> formation

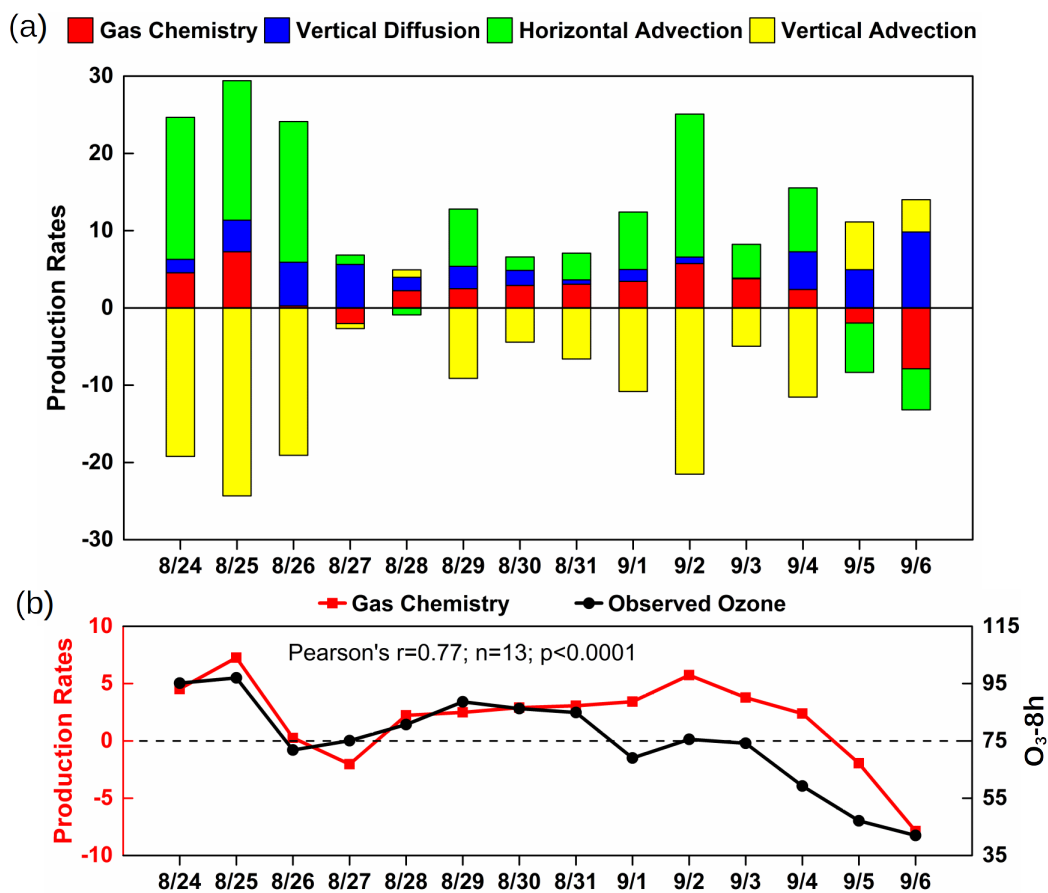

318  
 319 **Fig. 8.** Hourly variations in the change rate of low-level O<sub>3</sub> (ppb h<sup>-1</sup>) resulted from (a) gas chemistry, (b) vertical  
 320 diffusion, (c) horizontal advection, and (d) vertical advection in Hangzhou.

321 To further investigate the underlying mechanism of O<sub>3</sub> pollution, hourly variations in the  
 322 change rate of low-level O<sub>3</sub> resulting from different physical and chemical processes are presented  
 323 in Fig.8. It is evident that gas chemistry is the dominant factor to the strong generation of abundant  
 324 O<sub>3</sub> in the entire planetary boundary layer (<2 km) in the daytime but causes small amount of

325 depletion of O<sub>3</sub> at the near-surface height (<0.3 km) in the nighttime (Fig. 8a). High concentration  
 326 of O<sub>3</sub> diffuses from the upper layer downward to the ground through vertical diffusion during the  
 327 whole study period, which is obvious in the daytime (Fig. 8b). However, this effect is relatively  
 328 weak compared to other processes. Horizontal and vertical advectons seem to play more important  
 329 roles in shaping the near-surface O<sub>3</sub>, as indicated in Figs. 8c and 8d. Several interesting dynamic O<sub>3</sub>  
 330 circulations are observed between the near-surface and upper-air regions and indicated by the  
 331 dashed boxes. During the periods of 24-26 August and 31 August to 2 September 2016, O<sub>3</sub>-rich  
 332 mass in the lower layer (<1 km) travels to Hangzhou through horizontal advection, and is then  
 333 transported upward to the higher layer through vertical advection. At this higher layer, the mass

334  
 335 **Fig. 9.** (a) Daytime mean (08:00–17:00 LST) change rate of simulated surface O<sub>3</sub> (ppb h<sup>-1</sup>; left y axis) resulted  
 336 from gas chemistry, vertical diffusion, horizontal and vertical advectons in Hangzhou. (b) Correlation of daytime  
 337 mean gas chemistry generation (ppb h<sup>-1</sup>; left y axis) and observed surface-level maximum for daily 8h  
 338 concentration of O<sub>3</sub> (ppb; right y axis) in Hangzhou. China's national level-II standard is approximately 75 ppb  
 339 (160 μg m<sup>-3</sup>).

340 subsequently travels away from Hangzhou to other places through horizontal advection in a circular  
341 manner. This phenomenon might be associated with the urban heat island circulation (Lai and  
342 Cheng, 2009). However, during the period of September 3-6 2016, similar circulation phenomenon  
343 is observed, but the flow direction is reverse. The O<sub>3</sub>-rich mass travels downward to the ground  
344 through vertical advection and is then transported to surrounding regions through horizontal  
345 advection. This downward circulation is also related to the meteorological conditions after the  
346 cyclone. In addition, the horizontal and vertical advectons of O<sub>3</sub> take on a chaotic status during  
347 August 27-30, 2016, suggesting that complicated variable meteorological conditions happened in  
348 the time. This is also the reason for the lower magnitude of diurnal variation in Stage 2.

349 Fig. 9 shows the daytime mean change rate of simulated O<sub>3</sub> at the ground level resulted from  
350 various atmospheric processes and the correlation of gas chemistry generation and observed  
351 maximum for daily 8h concentration of O<sub>3</sub>. As a whole, the main sources of local surface ozone in  
352 Hangzhou are from gas chemistry, vertical diffusion, and horizontal advection, with mean  
353 production rates of 1.9, 3.3, and 6.7 ppb h<sup>-1</sup>, respectively, from August 24 to September 6, 2016,  
354 and the major sink is vertical advection. However, during some days such as September 5-6, the gas  
355 chemistry consumes O<sub>3</sub> while the vertical advection increases it. In general, strong net horizontal  
356 and vertical advectons of O<sub>3</sub> are observed for most days of the period, except August 27-28 during

357  
358 **Fig. 10.** Simulated hourly downward short wave flux at ground surface in Hangzhou (W m<sup>-2</sup>) during August 24 to  
359 September 6, 2016.

360 which the strongest northwest cold winds (Fig. 4e) occurred and made the net advections of O<sub>3</sub>  
361 negligible. Similar to Fig. 8, dynamic O<sub>3</sub> circulations are observed for the periods of August 24-26,  
362 August 31 to September 2, and September 5-6. Particularly, the circular direction is reverse during  
363 September 5-6 and the net gas chemistry is to consume ozone due to weak solar radiation in the  
364 days as shown in Fig. 10.

365 In addition, the variation trend of the daytime mean production rate of gas chemistry is  
366 consistent with the observed MDA8 concentration and the local chemical generation has large  
367 positive correlation (Pearson's  $r = 0.77$ ) with the observed MDA8 concentrations (Fig. 8b). This  
368 indicates a trade-off effect among vertical diffusion, horizontal advection, and vertical advection.  
369 High O<sub>3</sub> concentrations (i.e., 25 August 2016 MDA8: 98 ppb) are always accompanied by strong  
370 radiation and prolific generation of gas chemical reactions. It is also interesting to find that vertical  
371 diffusion may partially compensate for gas chemistry when the chemical reaction rate is relatively  
372 low or negative. For example, during August 26-27 and September 5-6, the vertical diffusion rates  
373 are higher than the chemical production rates. The low O<sub>3</sub> episode on these periods may result from  
374 local chemical consumption.

#### 375 **4. Discussion**

376 The above results demonstrate that high ozone concentrations are observed, temporarily during  
377 most day time of the emission control period of G20 summit, and spatially in Hangzhou and even  
378 the whole YRD region, from the surface to the top of the planetary boundary layer. Strong  
379 horizontal and vertical advections appear, but they form circulations due to special meteorological  
380 conditions so that the effects of them almost cancel each other out. As a result, the serious ozone  
381 pollution in Hangzhou is mainly resultant from the local photochemical reactions. When the  
382 photochemical reactions are weak, the vertical diffusion from the upper-air notable background O<sub>3</sub>  
383 further compensates for the local surface ozone concentration. Therefore, it is of great importance to  
384 understand why the strict emission control measures make no obvious effect on the local  
385 photochemical reactions of ozone generation.

386 Chemical generation of O<sub>3</sub> is the net effect of photochemical generation and titration  
387 consumption. VOC oxidation (Jenkin et al., 1997; Sillman, 1999) in photochemical reactions  
388 provides critical oxidants (i.e., RO<sub>2</sub>) that efficiently convert NO to NO<sub>2</sub>, resulting in further  
389 accumulation of O<sub>3</sub> (Wang et al., 2017). The chemical generation of O<sub>3</sub> is controlled by NO<sub>x</sub> and  
390 VOCs depending on which substance is lack in the reactions. As a consequence, there are two  
391 sensitivity regimes of O<sub>3</sub> production, namely, the NO<sub>x</sub>-limited and VOC-limited regimes. Previous  
392 studies have shown that the sensitivity pattern of surface O<sub>3</sub> formation in Hangzhou is dominant by  
393 the VOCs-limited regime (Yan *et al.* 2016; Li *et al.*, 2017; Su *et al.*, 2017). In this regime, if the  
394 regional reduction of VOCs is much higher than that of NO<sub>x</sub>, the O<sub>3</sub> concentration can be reduced,  
395 otherwise if the regional reduction of VOCs is much less than that of NO<sub>x</sub>, the inhibitory effect of  
396 NO<sub>x</sub> on O<sub>3</sub> generation will be weakened, and the O<sub>3</sub> concentration will increase remarkably (Wang  
397 et al. 2015). According to the studies of Su et al. (2017), Zheng et al. (2019), and Wu et al. (2019),  
398 it can be deduced that NO<sub>x</sub> has been significantly reduced by about 60%, at least two times of the  
399 reduction of VOCs in Hangzhou. The influence of stringent emission control measures on VOCs is  
400 not as immediate and effect as that on NO<sub>x</sub>, which is associated with the fact that there was a large  
401 amount of biogenic VOC emission in Hangzhou and surrounding regions (Liu et al. 2018; Wu et al.  
402 2020). In fact, the average temperature during the study period is as high as around 31°C (Fig. 4c),  
403 which facilitates the biogenic VOC emissions and photochemical reactions. As a result, the  
404 photochemical generation of O<sub>3</sub> was not under control and high concentration of ozone appeared.  
405 However, it is worth noting that after the emergent VOCs control measures had been implemented  
406 in the area during the third stage, the net generation rate of O<sub>3</sub> gradually reduces since September 2,  
407 2016, leading to a period of relatively low ozone concentration together with other meteorological  
408 effects. These discussions implicate that to alleviate ozone pollution, the ratio of reduction of VOCs  
409 to that of NO<sub>x</sub> is the key parameter based on the O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity analysis. As the biogenic  
410 VOCs are important sources of the total VOCs in the YRD region, it is necessary to balance the  
411 reduction of NO<sub>x</sub> to make the ratio within effective regime in the future.

## 412 **5. Conclusions**

413 To understand the unique response of ozone to short-term emission control measures during  
414 the G20 summit in Hangzhou, the spatial-temporal characteristics and process analysis of O<sub>3</sub>  
415 pollution are investigated by using the WRF-Chem model. Statistical evaluations of meteorological  
416 and chemical parameters suggest that the model system is able to reasonably predict the observed  
417 data for both the ground and upper-air levels in MICS-Asia III. High ozone concentrations are  
418 observed, temporarily during most day time of the emission control period of G20 summit, and  
419 spatially in Hangzhou and even the whole YRD region, from the surface to the top of the planetary  
420 boundary layer. Horizontal and vertical advection circulations are captured in Hangzhou, with  
421 horizontal advection the source and vertical advection the sink of the surface O<sub>3</sub> in Hangzhou.  
422 Consequently, the serious ozone pollution is mainly resultant from the local photochemical  
423 reactions which are not under good control by the emission reduction measures. As the surface O<sub>3</sub>  
424 formation in Hangzhou is dominant by the VOCs-limited regime, the significant reduction of NO<sub>x</sub>  
425 compared to that of VOCs is unfavorable to chemical generation of O<sub>3</sub>. The ratio of reduction of  
426 VOCs to that of NO<sub>x</sub> based on the O<sub>3</sub>-NO<sub>x</sub>-VOCs sensitivity analysis is a critical parameter for  
427 reduction of ozone formation from photochemical reactions. In addition, it is found that the vertical  
428 diffusion from the upper-air notable background O<sub>3</sub> also plays an important role in shaping the  
429 surface ozone concentration when the photochemical reactions are weak.
