Abstract

29 To elucidate the factors governing urban ozone (O₃) pollution during the campaign of G20 summit
30 in 2016 Hangzhou, China, the Weather Research Forecast with Chemistry (WRF-Chem) model was
31 used to simulate the spatial and temporal O₃ evolution in the Yangtze River Delta (YRD) region
32 from 24 August to 06 September 2016. Various atmospheric processes were analyzed to determine
33 the influential factors of ozone formation through integrated process rate method. The results
34 indicated that both the vertical diffusion and the enhanced process of local chemical generation
35 accounted for the increase of surface O₃ concentration in Hangzhou. Local chemical generation was
36 found to positively correlated with O₃ concentrations, with correlation coefficient of 0.77. In
37 accordance with the tropical weather cycle, subsidence air and stagnant weather were induced.
38 Dynamic circulations of O₃ through advection were associated with the urban heat island effect. All
39 these factors intensified ozone pollution in Hangzhou, particularly on 25 August 2016 (O₃-8h: 98
40 ppb). These findings provide insight into urban O₃ formation and dispersion during tropical cyclone
41 events, and support the Model Intercomparison Study Asia Phase III (MICS-Asia Phase III).

54 **1. Introduction**

55 Tropospheric ozone (O_3) is generated by a series of photochemical reactions involving volatile
56 organic compounds (VOCs), nitrogen oxide (NO_x), and carbon monoxide (CO) (Wang et al., 2006).
57 As a primary component of photochemical smog, ground-level O_3 pollution exhibits detrimental
58 effects on human health (Ha et al., 2014; Kheirbek et al., 2013) and the ecosystem (Landry et al.,
59 2013; Teixeira et al., 2011). The contribution of outdoor air pollution sources to premature mortality
60 may increase globally in the coming decades (Lelieveld et al., 2015). O_3 levels in cities in the
61 United States and Europe are increasing more than those in the rural areas of these regions, where
62 peak values decreased during 1990–2010 (Paoletti et al., 2014). Nagashima et al., (2017) reported
63 that long-term (1980–2005) trends of increase in surface O_3 over Japan may be primarily attributed
64 to the continental transport that have contributed to photochemical O_3 production. Urban O_3
65 pollution events can also be observed in developing countries, such as Thailand (Zhang and Kim
66 Oanh, 2002) and India (Calfapietra et al., 2016).

67 Air quality has been deteriorating in China as urbanization and motorization have progressed.
68 Many field and modeling studies have investigated the photochemical characteristics of near-
69 surface O_3 (Tang et al., 2009, 2012; Wang et al., 2013, 2014), the photochemistry of O_3 and its
70 precursors (Xie et al., 2014), interactions of O_3 with $PM_{2.5}$ (Shi et al., 2015), and urban O_3 formation
71 (Tie et al., 2013). In addition to anthropogenic emissions of O_3 precursors, uncontrollable physical
72 and chemical processes involved in meteorological phenomena critically modulate changes in O_3
73 concentration (Xue et al., 2014). In the Yangtze River Delta (YRD) region of China, high O_3
74 concentrations are associated with pollutant transport and diffusion from surrounding areas (Gao et
75 al., 2016; Jiang et al., 2012). Synoptic patterns related to tropical cyclones may be conducive to
76 high O_3 concentrations (Huang et al., 2005). Jiang et al. (2015) reported that enhanced
77 stratosphere–troposphere exchange (STE) driven by a tropical cyclone abruptly increased O_3
78 concentrations (21–42 ppb) in the southeast of China during June 12–14, 2014. STE has been
79 highlighted as a significant contributor to near-surface O_3 concentrations (Lin et al., 2012, 2015).

80 Because relevant data are limited, the complex dynamics in atmospheric processes related to O₃
81 formation are difficult to evaluate, and the main processes that account for high O₃ concentrations
82 are challenging to identify. O₃ pollution characteristics and underlying causes have not been
83 sufficiently investigated in China, especially in relation to extreme meteorological conditions. The
84 lack of relevant data may influence urban pollution prevention efforts.

85 In this study, a regional air quality model, within the framework of the Model Inter-
86 Comparison Study for ASIA phase III (MICS-ASIA III) (Li et al., 2019), was used to elucidate the
87 chemical and physical factors that contributed to O₃ abundance during the G20 (Group of Twenty)
88 summit. The summit was held in Hangzhou, China, and the focus of the summit was the sustainable
89 and healthy development of the world economy. Emergency emission control measures (e.g.,
90 industrial stoppages, limitations of vehicle movement) were implemented over an area with a
91 diameter of approximately 600 km to improve the air quality from 24 August to 06 September 2016.
92 Because of severe concerns regarding O₃ concentrations and the summer cyclonic weather pattern,
93 the aforementioned pollution control event attracted wide policy-related interest. The rest of this
94 paper is organized as follows. Section 2 outlines the methodology and configuration of the model
95 system. Section 3 describes the synoptic weather conditions as well as individual O₃
96 formation-related atmospheric processes. Section 4 discusses causes of O₃ pollution. Finally,
97 section 5 presents a summary of the findings.

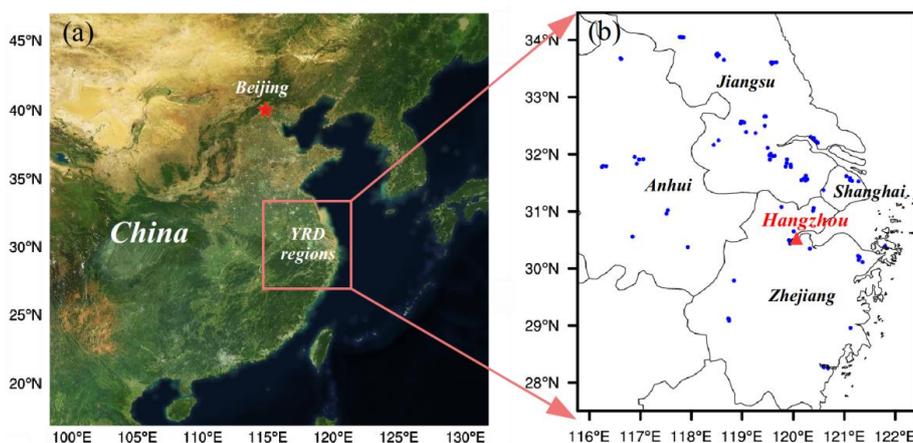

98 **2. Methodology**

99 **2.1. Regional chemistry modeling system**

100 To investigate the interactions among emissions, meteorological phenomena, and chemical
101 phenomena, the Weather Research Forecast with Chemistry model (WRF-Chem) was used to
102 simulate temporal and spatial changes in O₃ concentration. WRF-Chem is a regional online-coupled
103 air quality model that simultaneously simulates air quality components and meteorological
104 components by using identical transport schemes, grid structures, and physical schemes (Grell et al.,
105 2005). Two model domains were designed in this study (Fig. 1a): an outer domain (horizontal

106 resolution: 30 km) covering East China (20.0 °N–44.5 °N, 99.0 °E–126.5 °E) and an inner domain
107 (horizontal resolution: 6 km) covering the YRD region (27.6 °N–32.7 °N, 116.9 °E–122.4 °E). The
108 “Lambert conformal conic” projection was applied with domain center at 34 °N, 111 °E. There is a
109 total of 31 vertical layers with model top at 50 hPa. The simulation period was from 17 August to
110 06 September 2016, and simulations of the first week were used to spin up the model. Hourly model
111 outputs for 24 August to 06 September were used in the analysis. Additional details regarding the
112 configuration of the WRF-Chem model are described in our previous study (Ni et al., 2018).

113 **Fig. 1.** Double-nested simulation domains. (a) Domain 1: 30 km in East China with 102 (W–E) × 111 (S–N) ×
114 31 (vertical layers) grids. The copyright of map is own to © Google; (b) Domain 2: 6 km in the Yangtze River Delta
115 (YRD) region with 100 (W–E) × 115 (S–N) × 31 (vertical layers) grids. Blue dots denote the air quality
116 monitoring sites.

117 The meteorological boundary and initial conditions were determined from the global objective
118 final analysis (FNL) data of the National Centers for Environmental Prediction (Kalnay et al., 1996).
119 The FNL data were also assimilated to domain 1 (East China), and the grid-nudging method
120 (Stauffer et al., 1991) was used to reduce the meteorological integral errors. The chemical initial and
121 boundary conditions were dynamically downscaled from the model for ozone and related chemical
122 tracers, version 4 (MOZART4) (Emmons et al., 2010) simulation results; the relevant data are
123 available at <https://www.acom.ucar.edu/wrf-chem/mozart.shtml>.

124 **2.2. Emissions**

125 The 2016 Multiresolution Emission Inventory for China (MEIC, $0.25^\circ \times 0.25^\circ$;
126 <http://www.meicmodel.org/>) was used for the outer domain (Fig. 1a) with spatial resolution of 30
127 km (Li et al., 2017), including species of SO_2 , NO_x , CO, NH_3 , $\text{PM}_{2.5}$, and VOCs from the power,
128 industrial, residential, transportation, and agricultural sectors. Inventories of finer anthropogenic
129 emissions for the YRD region (Fig. 1b) over the year of 2014 were compiled based on the bottom-
130 up method by Shanghai Academy of Environmental Sciences. These inventories have been
131 documented in detail in previous studies (Huang et al., 2011; Li et al., 2011; Liu et al., 2018). Thus,
132 only brief discussions of these inventories are presented herein. The fine emission inventories
133 include major sectors such as large point sources, industrial sources, mobile sources, and residential
134 sources. The anthropogenic emissions over the YRD region are mainly located over the industrial
135 and urban areas along the Yangtze River as well as over Hangzhou Bay. In this study, the emission
136 inventories for the two domains were projected into horizontal and vertical grids as hourly
137 emissions, with temporal and vertical profiles obtained from Wang et al. (2011). VOCs emissions
138 were categorized into modeled species, according to von Schneidmesser et al. (2016). In addition,
139 biogenic emissions were generated offline using the Model of Emission of Gases and Aerosols from
140 Nature (MEGAN) (Guenther et al., 2006). Dust emissions were calculated online from surface
141 features and meteorological fields by using the Air Force Weather Agency and Atmospheric and
142 Environmental Research scheme (Jones et al., 2011). Other emissions (i.e., those from biomass
143 burning, aviation, and sailing ships), accounting for very small fractions during this period, were
144 therefore not considered in this study.

145 **2.3. Atmospheric processes analysis**

146 To understand the mechanism underlying O_3 formation, individual physical and chemical
147 processes of O_3 formation were investigated using integrated process rate (IPR) analysis in the
148 WRF-Chem model. IPR analysis has been widely applied; this method has been proven to be an
149 effective tool for demonstrating the relative importance of individual processes and for interpreting

150 O₃ concentrations (Goncalves et al., 2009; Tang et al., 2017; Shu et al., 2016). The present study
151 investigated atmospheric processes involved in O₃ formation, including gas chemistry, vertical
152 diffusion, and horizontal and vertical advection. Other processes (i.e., cloud processes and
153 horizontal diffusion) that either play minor roles or result in the formation of a sink (i.e., dry and
154 wet deposition) were not considered in this study.

155 **2.4. Evaluation method**

156 To increase the confidence in interpretations of model results, model outputs should first be
157 evaluated based on observations. Accordingly, in this study, the model results derived from domain
158 2 were compared with hourly surface observational data obtained from 96 air quality monitoring
159 sites in the YRD region (blue dots, Fig. 1b). These data were downloaded from <http://www.pm25.in>.
160 The air pollutants assessed were O₃ and NO₂. Model performance was evaluated using statistical
161 measures, namely mean fractional bias (MFB), mean fractional error (MFE), and correlation
162 coefficient (*R*), following the recommendation of the US Environmental Protection Agency (US
163 EPA; 2007). The formula used in this evaluation is presented in Table S1. Additionally, the
164 meteorological parameters were evaluated based on observational data—including temperature at 2
165 m (T2), relative humidity at 2 m (RH2), and 10 m wind speed (WS10) and direction (WD10)—from
166 the Meteorological Assimilation Data Ingest System (<https://madis.noaa.gov>). Following the study
167 of Zhang et al. (2014), commonly used mean bias (MB), gross error (GE), and root mean square
168 error (RMSE) were calculated as the statistical indicators; corresponding equations are denoted in
169 Table S1.

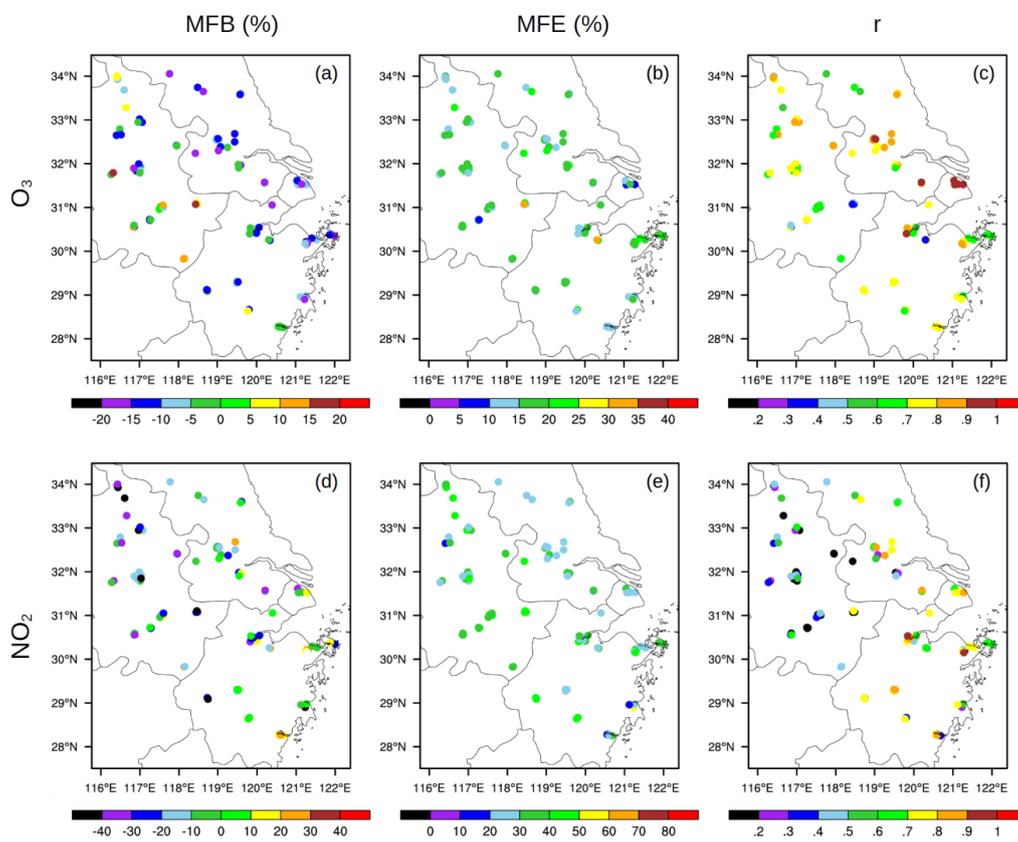

170 The vertical distribution of modeled O₃ in Hangzhou was evaluated based on comparisons with
171 observed differential absorption LiDAR (DIAL) data (Su et al. 2017). In the DIAL technique, the
172 mean gas concentration over a certain range interval is determined by analyzing the LiDAR
173 backscatter signals for laser wavelengths tuned “on” (λ_{on}) and “off” (λ_{off}) in a molecular absorption
174 peak of the gas under investigation (Browell et al., 1998). The DIAL technique can be used to
175 measure O₃ concentrations above or near a specific location (Browell, 1989). In our DIAL datasets,

176 the vertical height available was from 0.3 km to 3 km due to the limitations of the signal-to-noise
177 ratio and detection range.

178 3. Results

179 3.1. Model performance evaluation

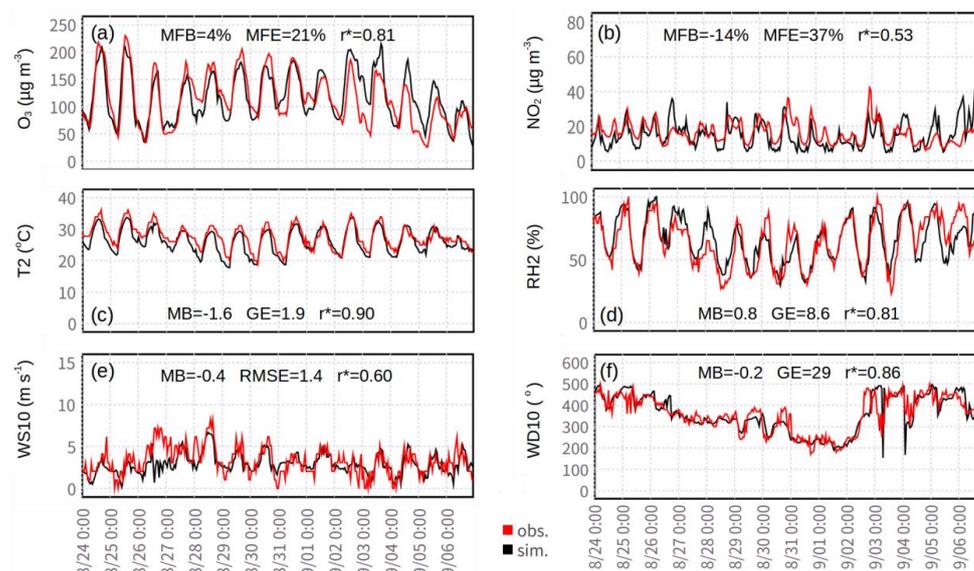

180

181 **Fig. 2.** Comparison of modeled air pollutants concentrations against measurements in 96 monitoring sites over
182 YRD region during August 24–September 6, 2016: Mean fractional bias (MFB), mean fractional error (MFE) and
183 Pearson's correlation coefficient (r) of O_3 (a–c) and NO_2 (d–f), respectively.

184 We first evaluated the overall performance of WRF-Chem for the YRD region by incorporating
185 data from the 96 air quality monitoring sites. Specifically, the maximum daily 8 h (O_3 -8h) ozone
186 and daily mean NO_2 concentrations at the surface were used. In general, the model-simulated air
187 pollutant concentrations agreed with the observations. The spatial distributions of MFB and MFE

188 for O_3 and NO_2 at the 96 observational sites over the YRD region are illustrated in Fig. 2. The
189 results reflected reasonable performance, with MFB and MFE for most of the sites meeting the
190 benchmarks (MFB: 15%; MFE: 35%) proposed by the US Environmental Protection Agency (US
191 EPA; 2007). A scatter plot of MFB/MFE was shown in Fig. S1a,b in the supporting information,
192 further hinting the ability of model in reproducing the observations, which is also reflected by the
193 high correlation between model and observations (Fig. S1c,d in the supporting information). Other
194 model evaluations with satellite retrievals during this period can be seen in our previous study (Ni
195 et al., 2019).

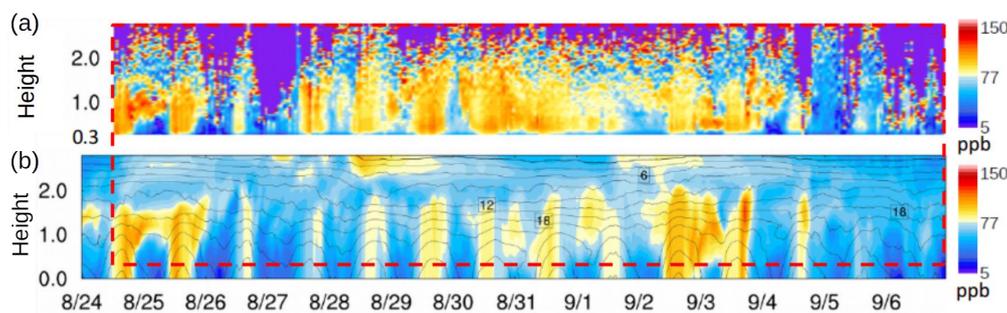

196 **Fig.3.** Modeled air pollutants and meteorological parameters compared with measurements at the Hangzhou
197 monitoring site from 24 August to 06 September 2016. Surface concentrations of (a) O_3 and (b) NO_2 , (c)
198 temperature at 2 m (T_2), (d) relative humidity at 2 m (RH_2), (e) wind speed at 10 m (WS_{10}) and (f) wind
199 direction at 10 m (WD_{10}).

200 Following the overall evaluation of the greater YRD region, the site of Hangzhou was focused
201 on for further analysis, and WRF-Chem simulations of the site's air quality and meteorological
202 conditions were assessed. The time series of hourly simulated and observed air pollutants (O_3 , Fig.
203 3a; NO_2 , Fig. 3b) and meteorological factors (T_2 , Fig. 3c; RH_2 , Fig. 3d; WS_{10} , Fig. 3e; and WD_{10} ,

204 Fig. 3f) are presented in Fig. 3. All modeled data were statistically significantly correlated with the
205 observed data at the 95% level. Overall, WRF-Chem well represented the observed diurnal
206 variations. For example, the MFB and MFE for both O₃ and NO₂ were near the benchmarks in
207 particular of O₃ levels (MFB/MFE: 4%/21%), and were well below the benchmarks (MFB/MFE:
208 15%/35%; US EPA; 2007).

209 For evaluation of meteorological parameters, Emery et al. (2001) proposed benchmarks,
210 including 2 m air temperature ($MB \leq \pm 0.5^\circ\text{C}$, $GE \leq 2.0^\circ\text{C}$), 10 m wind speed ($MB \leq 0.5$ m/s,
211 $RMSE \leq 2.0$ m/s) and 10 m wind direction ($MB \leq \pm 10^\circ$, $GE \leq 30^\circ$). McNally (2009) suggested a
212 relaxed benchmark for 2 m temperature ($MB \leq \pm 1.0^\circ\text{C}$). In this study, 10 m wind speed and wind
213 direction (Fig. 3e,f) results were well within the proposed limits. The GE of 2 m air temperature
214 (1.9°C ; Fig. 3c) also satisfied the criteria; however, the MB was slightly higher (-1.6°C), and a
215 slightly high temperature bias was also noted in a previous study (Zhang et al., 2014). Overall,
216 favorable performance was noted for the simulation of meteorological parameters in comparison
217 with observations.

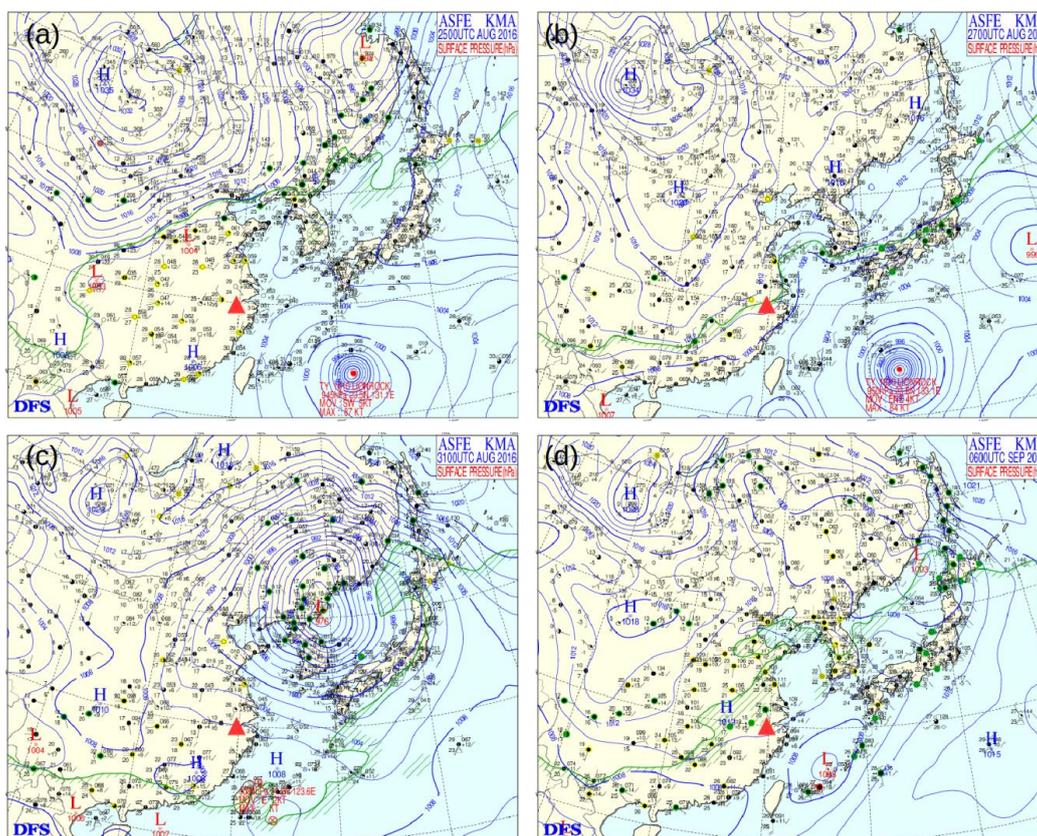

218 **Fig. 4.** Upper-level comparison of hourly (a) observed (from differential absorption LiDAR) and (b) simulated O₃
219 concentrations (ppb) in Hangzhou for 24 August to 06 September 2016. Purple regions in the top panel denote
220 invalid data with a low signal-to-noise ratio. To facilitate direct comparison, the red dashed line indicates the
221 ozone level recorded for the same time periods (starting from 12:00, 24 August) and vertical heights (0.3–3 km)
222 in the observations and simulation results.

223 To further evaluate the ability of the model to reproduce the vertical structure of ozone
224 concentration, the vertical distribution of the modeled O₃ was qualitatively compared with the

225 DIAL datasets (Fig. 4). The comparison revealed that the model results were consistent with the
226 observations. Diurnal O₃ variations were mainly observed within the planetary boundary layer
227 (approximately <2 km). Notably, the model captured a nocturnal O₃-rich mass, which exhibited an
228 n-shaped distribution in the upper air (approximately 1 km) on 25 August 2016.

229 3.2. Synoptic weather system

230 **Fig. 5.** Tropical cyclone evolution in East Asia during the 2016 G20 summit. Weather charts for four
231 representative periods at 08:00 LST on (a) 25 August, (b) 27 August, (c) 31 August, and (d) 06 September 2016.
232 LST: Local Sidereal Time; H: High-pressure system; L: Low-pressure system. The red triangle denotes the
233 location of Hangzhou. The copyright of map is own to © Korea Meteorological Administration.

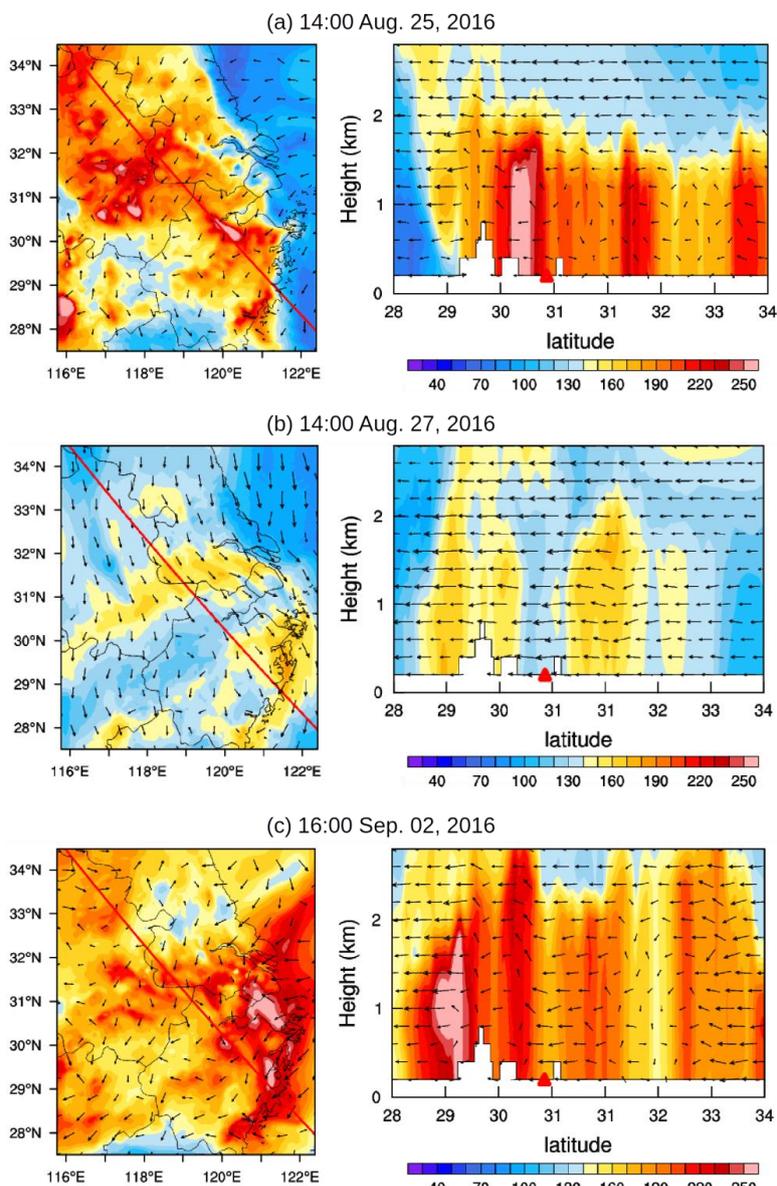

234 Considering the synoptic circulation is closely related to O₃ abundance, four representative
235 surface weather charts obtained from the Korea Meteorological Administration were used to track
236 the tropical cyclone (Fig. 5). In the early stage of the tropical cyclone during 24 and 25 August 2016

237 (Fig. 5a), strong and uniform high-pressure fields covered vast regions of southeastern China. A
238 tropical cyclone moved northeastward over the East China Sea. In the middle stage (Fig. 5b), the
239 tropical cyclone approached the YRD region, bringing strong north wind fields to this area. The
240 long narrow rain band arrived in Hangzhou (red triangle) on 27 August 2016. In the later stage (Fig.
241 5c), the cyclone continuously moved toward Japan and eventually hit the land. The tropical high in
242 the YRD region recovered gradually. Finally, the cyclone faded, and a rainstorm appeared over most
243 of the YRD region. This rainstorm continued from approximately 02 through 07 September 2016
244 (Fig. 5d, for clarity, only the data for 06 September are presented).

245 3.3. O₃ pollution episode

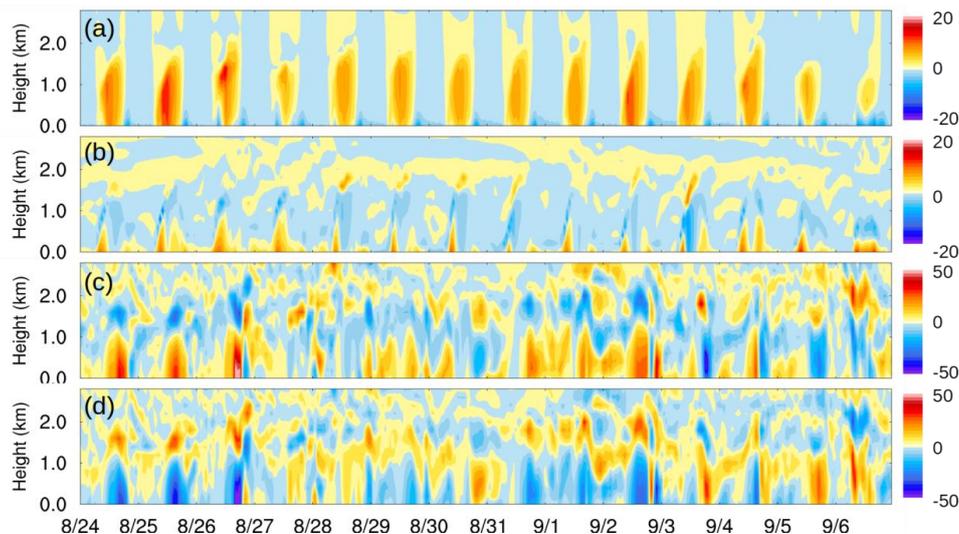

246 In Fig. 6, hourly vertical and horizontal O₃ distributions and wind fields in the YRD region are
247 presented for three representative episodes according to the movement of the tropical cyclone. For
248 stagnation days with weak wind fields (i.e., 25 August and 02 September) before or after the
249 tropical cyclone, meteorological conditions were unfavorable for pollutant dispersion. O₃ pollution
250 was more regional and intense, with an hourly peak O₃ concentration of 250 µg m⁻³ below the high
251 layer (2 km) around Hangzhou (Fig. 6a,c). As the cyclone approached (on 27 August), a large belt
252 of O₃-rich mass (>160 µg m⁻³) appeared in the upwind direction and moved toward Hangzhou
253 under a prevailing north wind field (Fig. 6b). Transboundary pollutant transport played a critical
254 role in these processes, and this finding was consistent with the atmospheric trajectories from North
255 China (Fig. S2). This southward transport of pollutants may supply raw materials for photochemical
256 O₃ generation.

257
258 **Fig. 6.** Surface and upper-level O₃ distributions ($\mu\text{g m}^{-3}$) and wind fields (m s^{-1}) for representative
259 episodes. (a) Stagnant weather before the tropical cyclone, (b) pollutant transport when the tropical cyclone
260 approached, and (c) stagnant weather after the cyclone. The red line denotes the cross section line of upper-level
261 O₃ distributions. The red triangle denotes the location of Hangzhou.

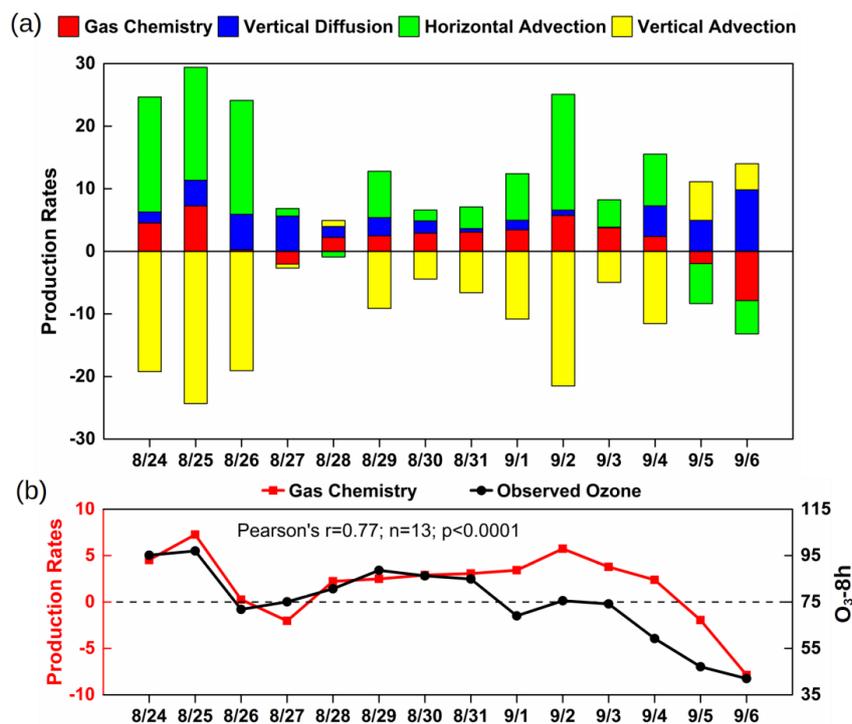

262 **3.5. Process analysis of O₃ formation**

263 **Fig. 7.** Hourly variations in the change rate of upper-level O₃ (ppb h⁻¹) resulting from (a) gas chemistry, (b)
264 vertical diffusion, (c) horizontal advection, and (d) vertical advection in Hangzhou.

265 Four hourly modeled processes indicated the diurnal fluctuations in loops. Gas chemistry
266 resulted in generation of O₃ nearly above the upper-air height of 2 km in the daytime but caused
267 depletion of O₃ at the near-surface height (<0.3 km) in the nighttime (Fig. 7a). O₃ from the upper
268 layer diffused downward to the ground through vertical diffusion during the study period but was
269 significantly higher in the daytime (Fig. 7b). In addition, as indicated in Fig. 8c and d, several
270 dynamic O₃ circulations were observed between the near-surface and upper-air heights during 24
271 and 25 August and on 02 September 2016. An O₃-rich mass in the lower layer (<1 km) traveled to
272 Hangzhou through horizontal advection, and it was transported from the upper layer to the high
273 layer (approximately 1.5 km) through vertical advection. The mass subsequently reversed and
274 traveled away from Hangzhou in the high layer through horizontal advection in a circular manner.
275 Urban heat island circulations caused the upward and downward flows.

276 **Fig. 8.** (a) Daytime mean (08:00–17:00 LST) variations in simulated surface O₃ change rate (ppb h⁻¹; left y axis)
277 resulting from gas chemistry, vertical diffusion, and horizontal and vertical advection in Hangzhou. (b)
278 Comparison of daytime mean gas chemistry generation (ppb h⁻¹; left y axis) and observed surface-level maximum
279 for daily 8 h concentration of O₃ (O₃-8h; ppb; right y axis) in Hangzhou. China's national standard is
280 approximately 75 ppb (160 µg m⁻³).

281 The daytime mean variations of O₃ at the ground level resulted from atmospheric processes
282 (Fig. 8a). Quantification of these variations revealed major positive contributions from gas
283 chemistry, vertical diffusion, and horizontal advection to surface O₃ formation, with mean
284 production rates of 1.9, 3.3, and 6.7 ppb h⁻¹, respectively, from 24 August to 06 September 2016.
285 Firstly, the trends between the daytime mean values associated with gas chemistry and observed O₃-
286 8h concentration were consistent (Fig. 8b), indicating a trade-off effect among vertical diffusion and
287 horizontal and vertical advection. High O₃ concentrations (i.e., 25 August 2016 O₃-8h: 98 ppb) were
288 accompanied by prolific generation of gas chemicals. Local chemical generation was found to have
289 large positive correlation (Pearson's $r = 0.77$) with O₃ concentrations. Secondly, vertical diffusion

290 may have partially compensated for gas chemistry when the chemical reaction rate was relatively
291 low or negative. For example, on 26 and 27 August and 05 and 06 September 2016, most of the
292 vertical diffusion rates were greater than the chemical production rates. The low O₃ episode on
293 these periods mainly resulted from local chemical consumption. Finally, advection processes were
294 essential and integral to air circulation: horizontal advection exerted remarkably positive effects on
295 surface O₃ concentrations in Hangzhou, and vertical advection exerted dispersion effects.

296 **4. Discussion**

297 This study revealed notable background O₃ concentrations in the upper-air layer in the YRD
298 region. Peripheral downdrafts in large-scale cyclone circulation can transport an O₃-rich mass in the
299 upper troposphere or lower stratosphere downward to the surface (Tang et al., 2011; Hsu and
300 Prather, 2014). This type of O₃ intrusion during this period was reported in southeast China (Ni et
301 al., 2019). Based on our results, we inferred that a considerably high background O₃ concentration
302 in the upper air markedly contributed to surface O₃ pollution; this inference agreed (hemispheric
303 background) with the findings of studies conducted in Europe (Wilson et al., 2012) and the United
304 States (Lin et al., 2012, 2015).

305 We demonstrated that local chemical generation in Hangzhou was enhanced during episodes of
306 high O₃ concentrations before and after the tropical cyclone that occurred during the study period.
307 Chemical generation of O₃ is the net effect of photochemical generation and titration consumption.
308 VOC oxidation (Jenkin et al., 1997; Sillman, 1999) in photochemical reactions provides critical
309 oxidants (i.e., RO₂) that efficiently convert NO to NO₂, resulting in further accumulation of O₃
310 (Wang et al., 2017). In the present study, downward shortwave flux at the ground level (Fig. S3)
311 was more intense on days with high O₃ concentrations than on those with low O₃ concentrations.
312 This strong solar radiation strengthened O₃ photochemical generation. In addition to the stagnant
313 weather conditions, air subsidence in peripheral circulations of tropical cyclones helps to trap heat
314 and pollutants at the surface (Jiang et al., 2015; Shu et al., 2016). Furthermore, a tropical system
315 with calm, hot–dry weather favors the development of an urban heat island, which causes thermal

316 circulations as well as the convergence of the surrounding O₃ and its precursors (Lai and Cheng,
317 2009). The increased temperature also accelerates the photochemical reactions (Narumi et al., 2009;
318 Walcek et al., 1995). In the present study, these enhanced photochemistry processes dominated O₃
319 chemical generation, resulting in high O₃ concentrations. This result was consistent with the results
320 of a previous field study (Su et al., 2017). Low-level O₃ episodes (i.e., 06 September) in Hangzhou
321 were accompanied by a rain band in the YRD region. Rain band–related cumulus clouds blocked
322 solar radiation, thereby weakening O₃ photochemical generation. Consequently, titration
323 consumption dominated the chemical generation process, resulting in low or negative O₃ chemical
324 production.

325 **5. Conclusions**

326 Changes in O₃ concentrations in Hangzhou during the G20 summit were well represented by
327 the WRF-Chem model. Statistical evaluations of meteorological and chemical parameters suggested
328 that the model system results satisfactorily matched the observed data for both the ground and
329 upper-air levels in MICS-ASIA III. The model results revealed that the O₃ concentrations in
330 Hangzhou were highly related to a tropical cyclone over the East China Sea. Throughout the
331 simulation period, large-scale air mass circulations and energy transport by the tropical cyclone
332 probably caused the high upper-air O₃-rich mass in the horizontal and vertical scales of the YRD
333 region; this phenomenon engendered a negative background O₃ concentration. As the tropical
334 cyclone approached, bringing with it a prevailing north wind component, Hangzhou was affected by
335 pollutant transport from North China. After or before the tropical cyclone, peripheral downdraft or
336 air subsidence produced stable and calm weather, with high pressure and temperature and weak
337 wind, and the urban heat island effect was aggravated. The combination of these conditions
338 enhanced the chemical generation process, resulting in a marked increase in surface O₃
339 concentrations. Our study provides scientific insight into urban O₃ formation and dispersion under
340 conditions where short-term emission reduction measures had been applied in East China during a
341 tropical cyclone event.

342

343 **Author contribution**

344 Kun Luo and Xiang Gao designed the experiments. Fei Jiang, Huang Cheng, Jian-ren Fan, Joshua S
345 Fu and Chang-hong Chen edit the manuscript. Zhi-zhen Ni and Yang Gao prepared the manuscript
346 with contributions from all co-authors

347 **Acknowledgments**

348 This work was financially supported by special funds from the Ministry of Environmental
349 Protection of China (No. 201409008-4) and the Zhejiang Provincial Key Science and Technology
350 Project for Social Development (No. 2014C03025). We would like to thank the US National
351 Oceanic and Atmospheric Administration for its technical support in WRF-Chem modeling. High-
352 resolution emission inventories were provided by the Institute of Environmental Science, Shanghai,
353 China, and the official documents of emission control policies were obtained from the Hangzhou
354 Environmental Monitoring Center.
