22 **Highlights**

- 23 1. Particles from a GDI-engine vehicle and their ageing were studied.
24 2. GDI-engine vehicles contribute significantly to both primary and secondary
25 organic particles.
26 3. Higher contents of organic particles were emitted under hot stabilized running and
27 hot start states.
28 4. Sulfate and secondary organic aerosol form on the surface of primary particles after
29 ageing.
30 5. Particles aged rapidly by catalyzed acidification under high pollution levels in
31 Beijing.
32
33
34

35 **Abstract:**

36 Air pollution is particularly severe in developing megacities, such as Beijing,
37 where pollutants from vehicles equipped with modern gasoline direct injection (GDI)
38 engines must be paid enough attention. This study presents the characteristics of
39 individual particles emitted by a GDI gasoline vehicle and their ageing in a smog
40 chamber under the Beijing urban environment, as part of the Atmospheric Pollution &
41 Human Health (APHH) research programme. Using electron microscopy, we identified
42 the particles emitted from a commercial GDI-engine vehicle running under various
43 conditions, namely cold start, hot start, hot stabilized running, idle, and acceleration
44 states. Our results show that most of the particles were organic, soot and Ca-rich ones,
45 with small quantities of S-rich and metal-containing particles. In terms of grain size,
46 the particles exhibited a bimodal distribution in number vs size, with one mode at 800–
47 900 nm, and the other at 140–240 nm. The amounts of organic particles emitted under
48 hot start and hot stabilized states were higher than those emitted under other conditions.
49 The amount of soot particles was higher under cold start and acceleration states. Under
50 the idle state, the proportion of Ca-rich particles was highest, although their absolute
51 number was low. In addition to quantifying the types of particles emitted by the engine,
52 we studied the ageing of the particles during 3.5 hours of photochemical oxidation in
53 an environmental chamber under the Beijing urban environment. Ageing transformed
54 soot particles into core-shell structures, coated by secondary organic species, while the
55 content of sulfur in Ca-rich and organic particles increased. Overall, the majority of
56 particles from GDI-engine vehicles are organic and soot particles with submicron or

57 nanometric size. The particles are highly reactive; they react in the atmosphere and
58 change their morphology and composition within hours via catalyzed acidification that
59 involves gaseous pollutants under high pollution levels in Beijing.

60

61 **1. Introduction**

62 Air pollution caused by $PM_{2.5}$ in megacities such as Beijing, the capital city of
63 China, is of public and academic concern due to its environmental impacts (Bond et al.
64 2013, Huang et al. 2014, Liu et al. 2017,) and adverse health effects (Chart-asa and
65 Gibson 2015, Shao et al. 2017). PM (particulate matter) emissions from vehicles are
66 one of the most significant sources of airborne particles in the urban atmosphere, and
67 contribute up to 31% of primary particulate emissions of $PM_{2.5}$ in Beijing (Yu et al.
68 2013). Moreover, secondary aerosol formation associated with traffic emissions is a
69 major process leading to the rapid increase of $PM_{2.5}$, which results in severe haze
70 episodes (Huang et al. 2014). Although emissions from gasoline engines are relatively
71 lower than those from diesel engines (Alves et al. 2015), the number of gasoline-
72 powered vehicles in urban areas greatly exceeds that of diesel-powered vehicles. The
73 total number of vehicles in China reached 310 million in 2017, about 70% of these were
74 powered by gasoline engines (National Bureau of Statistics of China, 2018). There are
75 two main types of gasoline engines, namely conventional multipoint port fuel injection
76 (PFI) engines and gasoline direct injection (GDI) engines. In recent years, the demand
77 for engines with high efficiency and low fuel consumption has led to an increasing use
78 of GDI engines in light-duty passenger cars. The market share of GDI-engine vehicles

79 has increased dramatically over the past decade and was estimated to reach 50% of new
80 gasoline vehicles sold in 2016 (Zimmerman et al. 2016). In Beijing and northern China,
81 the vehicle emissions become a more concerned issue in terms of air pollution when
82 the emission from coal combustion are seriously compressed after the Action for
83 Comprehensive Control of Air Pollution in Beijing since 2017 (Chen et al. 2019, Zhang
84 et al. 2019).

85 The number, mass and size distribution of particles emitted from GDI-engine
86 vehicles have been studied (Khalek et al. 2010, Baral et al. 2011, Maricq et al. 2011).
87 The size distribution usually has an accumulation mode with the maxima in the
88 diameter range of 100–300 nm. Major components of the particles include elemental
89 carbon (EC), organic carbon, and ash (Giechaskiel et al. 2014). Besides particulate
90 matter, the engines emit gaseous hydrocarbon compounds. These compounds might
91 form particles, or be adsorbed on the surface of particle aggregates, leading to the
92 growth of the particles in the engine emission (Luo et al. 2015). Relatively high particle
93 emissions by GDI-engine vehicles have prompted studies on the effects of engine
94 operating parameters and fuel composition on the characteristics of the particles (Hedge
95 et al. 2011, Szybist et al. 2011). It has been found that, in general, emissions under the
96 cold start condition make up the major contribution to the total amount of PM emissions
97 from GDI engines (Chen and Stone 2011). Studies have also demonstrated that the
98 highest particle emissions from GDI engines in number concentration occur under the
99 acceleration state during transient vehicle operations (Chen et al. 2017).

100 Studies have also shown that gasoline vehicles are an important source of

101 secondary aerosol precursors in urban areas (Suarez-Bertoa et al. 2015). Secondary
102 aerosols can be formed via gas-phase reactions of volatile organic compounds and
103 multiphase and heterogeneous processes of primary particles (Zhu et al. 2017).
104 Experiments performed in environmental chambers demonstrated that the mass of
105 secondary aerosols derived from precursors could exceed that of directly-emitted
106 aerosols (Jathar et al. 2014). The occurrence of secondary aerosols on particles could
107 change the properties of particles in size, mass, chemical composition, morphology,
108 optical and hygroscopic parameters. These changes, in turn, might affect the
109 environmental impact of the particles significantly, for instance in terms of visibility,
110 human health, weather, and energy budgets (Peng et al. 2017). In general, the ageing
111 processes of primary particles in the atmosphere are studied to understand their climate
112 effects (Niu et al. 2011). However, the lack of data on primary particles emitted by
113 gasoline engines hinders a deep understanding of the roles and activities of the particles
114 in ambient air pollution and relevant environmental effects.

115 APHH-Beijing aimed to explore the sources and processes affecting urban
116 atmospheric pollution in Beijing. Details regarding this project are given in Shi et al.
117 (2018). To address one of the aims of the AIRPOLL-Beijing (Source and Emissions of
118 Air Pollutants) and AIRPRO-Beijing (The integrated Study of AIR Pollution Processes),
119 we employed a dedicated experiment to investigate the characteristics of the individual
120 particles, in terms of the number concentration, size distribution, emitted from a GDI-
121 engine vehicle during a real-world driving cycle for chassis dynamometer test, i.e., the
122 Beijing driving cycle (BDC). Various test modes were introduced to accurately evaluate

123 the emission from light- or medium-duty vehicles. Furthermore, experiments were
124 conducted in an environmental chamber to investigate the ageing processes of particles
125 emitted by GDI-engine vehicles in ambient air in Beijing. We utilized a transmission
126 electron microscope equipped with an Oxford energy-dispersive X-ray spectrometer
127 (TEM-EDX) to identify the morphology, size and elemental composition of particles
128 emitted by the GDI-engine vehicle when it was running under different states. Particles
129 before and after a 3.5-hour ageing in the chamber were compared on the basis of the
130 TEM-EDX analysis. The TEM-EDX analysis could provide the information on the
131 internal inhomogeneity, mixing state and surface characteristics of individual particles
132 and has been used to analyze the aerosol particles (Li and Shao 2009, Adachi and
133 Buseck 2015, Shao et al. 2017). The experimental design allows for the study of the
134 physical and chemical characteristics of the particles emitted from the GDI-engine
135 vehicles, as well as their ageing in a simulated urban atmosphere. The purposes of this
136 study are to evaluate the individual characteristics and the ageing process of primary
137 particles emitted by a GDI-engine vehicle, to investigate the ageing processes of such
138 particles in the atmosphere, and to deepen the understanding of the environmental
139 impact of gasoline-powered vehicle emissions.

140 **2. Material and methods**

141 **2.1 Test vehicle, fuels, and test procedure**

142 The GDI-engine vehicle utilized in the experiment complies with the China Phase
143 4 (equivalent to Euro 4) standard. It uses a three-way catalyst to reduce gaseous
144 emissions. The GDI (model GDI-1.4-T) in the test vehicle is recognized as a
145 representative of leading-edge designs of gasoline engines, having advanced engine

146 technologies, that combine turbocharging and GDI together with a downsized
147 displacement. Vehicles equipped with such GDI engines constitute the majority of light-
148 duty vehicles in China, especially in large cities like Beijing. Details of the engine used
149 in this study are listed in Table S1. The fuel used in the experiment is a commercial
150 gasoline blend of common quality in China. The properties of the fuel were measured
151 by SGS-CSTC Standards Technical Services Co., Ltd., China, and are listed in Table
152 S2. The fuel has a Research Octane Number (RON) of 93 and is a fifth-stage gasoline.
153 It contains, in volume, 36.7% of aromatics and 15.4% of olefins; it also has 6% of sulfur
154 in mass. The experiments were conducted within repeated Beijing driving cycles
155 (BDCs). One BCD included a 200-s “cold start” phase followed by an 867-s “hot
156 stabilized running” phase. The conditions during a BDC in the experiments are
157 illustrated in Figure S1a. The cold start state was achieved by starting the vehicle with
158 a period of small accelerations, while the hot stabilized running state had multiple
159 periods of large acceleration and a maximum velocity of 50 km h⁻¹.

160 All tests were performed on a Euro 5/LEV2/Tier 2-capable test cell on a 48-inch
161 single-roll chassis dynamometer at the State Key Laboratory of Automobile Safety and
162 Energy Conservation at Tsinghua University. The test procedure for each run was as
163 follows: fuel change, BDC preparation, soak, cold start BDC test, and hot start BDC
164 test. After fuel change and BDC preparation, the test vehicle was then conditioned with
165 an overnight soak for more than 10 h. The soak room temperature was maintained
166 between 20 and 30 °C. Due to the limitation of the facilities and available running time,
167 a hot start test was conducted within 5 mins after the cold start test. A dilution unit was

168 applied to dilute the exhaust from the tailpipe into 1/10 in volume using synthetic air
169 composed of 79% N₂ and 20% O₂, in order to obtain the concentrations suitable for
170 subsequent measurements and suppress possible coagulation. The number
171 concentration of the emitted particles was monitored by a Combustion Fast Particle
172 Size Spectrometer Differential Mobility Spectrometer 500 (DMS 500). The maximum
173 measurable number concentration of DMS 500 was 10¹¹ (dN/dlogDp/cc) after the
174 dilution (Petzold et al. 2011). For the analyses of individual particles, 6–8 samples were
175 collected during one BDC test. At least one sample was collected under each running
176 state (i.e. cold start, hot start, idle state, acceleration state, or hot stabilized running
177 state). The driving cycle test was repeated at least twice. Two or more samples were
178 obtained for each running state. A single-stage cascade impactor was mounted to the
179 exit of the tailpipe after the dilution unit. The emitted particles were collected onto 300-
180 mesh copper TEM grids, which were covered with a carbon-coated formvar film. The
181 flow rate was 1.0 L min⁻¹, and the cut-off diameter of the impactor for 50% collection
182 efficiency was 0.25 μm if the density of the particles was 2 g cm⁻³. For each sample, the
183 collection time was 60 s.

184 **2.2 Environmental chamber experiments**

185 Particles from the GDI-engine vehicle were introduced into an environmental
186 chamber and exposed to sunlight. The chamber, made of perfluoroalkoxy (PFA) Teflon
187 in order to achieve a high transmission of ultraviolet light, had an internal volume of
188 1.2 m³. Ambient sunlight was used as the driving force for photochemical reactions in
189 the chamber, in an environment close to actual open air. Before the experiments, the
190 chamber was cleaned by flushing with zero air for approximately 12 hours and

191 illuminated with sunlight, to remove residues that could influence the experiments.
192 H₂O₂ (1 mL, 30%), together with the vehicle emission, was injected into the chamber
193 to generate OH exposure. After the injection, the experiments were conducted from
194 approximately 13:00 to 17:00 local time under sunshine, with the relative humidity kept
195 around 50%. The global solar radiation when the tests were carried out was
196 approximately 318 W m⁻². After 3.5 h of ageing, the particles in the chamber were
197 collected onto mesh TEM grids using the impactor. The collection time for each sample
198 was 120 s. The schematic diagram of the experimental system is presented in Figure
199 S1b.

200

201 **2.3 TEM/EDX and scanning transmission electron microscopy (STEM) analyses**

202 The particles in the samples were examined using a Tecnai G2 F30 field emission
203 high-resolution transmission electron microscope (FE-HRTEM). This microscope is
204 also equipped with an Oxford EDX and a STEM unit with a high-angle annular dark-
205 field detector (HAADF). The EDX can detect elements with the atom number larger
206 than 5 (B) in a single particle. The HAADF can detect the distribution of a certain
207 element by mapping the distribution of the element in a particle. The TEM was operated
208 with the acceleration voltage of 300 kV. EDX spectra were firstly collected for 20 live
209 seconds to minimize the influence of radiation exposure and potential beam damage
210 and then for 90 live seconds for a range of possible elements. Copper was excluded
211 from the analysis because of interference from the TEM grids which are made of copper.

212 To ensure the representativeness of the analyzed particles, more than 150 particles
213 from at least 3 random areas were analyzed from the center and periphery of the

214 sampling spot on each grid. All individual particles larger than 50 nm in the selected
215 areas were analyzed. The TEM images were digitized using an automated fringe image
216 processing system to project the surface areas of the particles. The equivalent spherical
217 diameter of a particle was calculated from its projected area, expressed as the square
218 root of $4A/\pi$, where A is the projected area.

219 **3. Results**

220 **3.1. Particle morphology, elemental composition and size**

221 A total of 2880 particles were analyzed from the GDI-engine vehicles. Most of the
222 particles were in the sub-micrometer size range. Based on morphology and elemental
223 composition of the particles, the majority of them were identified as soot, organic and
224 Ca-rich particles, a smaller amount was identified as S-rich or metal-rich particles (Fig.
225 1). The method of particle classification is similar to that adopted by Okada et al. (2005)
226 and Xing et al. (2019). In the following description, “X-rich” means that the element
227 “X” occupies the largest proportion in the element composition of the particles. Figure
228 2 illustrates the number-size distributions of the relative concentration ($dN/d\log D$) of
229 primary particles from the GDI-engine vehicle, where N is the relative number fraction
230 and D is the equivalent diameter. The particles were in the range of 60–2500 nm and
231 displayed a bimodal distribution, with one mode in the 140–240 nm range, and another
232 in the 800–900 nm range. Particles smaller than 250 nm were largely underestimated
233 because of the loss during the particle collection. Therefore, there should have been
234 more particles in the smaller mode range than shown in Figure 2.

235 It should be noted that organic particles were mainly composed of C and O
236 elements, and contained a small amount of inorganic elements Ca, P, S and Zn.

237 Elemental mapping of the organic particles exhibited the presence of Ca, P, S and Zn in
238 some of the particles, showing the mixture state of organic and inorganic materials (Fig.
239 1f). It has been reported that such particles could be related to the combustion of fuels
240 or lubrication oil (Rönkkö et al. 2013). In addition to these primary organic particles,
241 the GDI-engine vehicle emitted precursor gases, which produced secondary organic
242 particles via gas-phase reactions, and multiphase and heterogeneous processes on the
243 primary particles. A group of spherical particles were found in the environmental
244 chamber (Fig. 1g). These particles became semi-transparent or transparent to an
245 electron beam, which is characteristic of organic materials, liquid water, or their
246 evaporation residues either mixed or not mixed with electron absorptive materials. We
247 regard these particles as secondary organic particles because the humidity in the
248 chamber during the experiment was kept much below saturation (relative humidity
249 around 50%). Therefore, these particles were expected to mainly consist of secondary
250 organic materials, which should have been produced via gas phase reactions or on the
251 surface of pre-existing particles (Hu et al. 2016). No other elements, except C and O,
252 were identified in these particles, which is consistent with the above inference. Similar
253 particles were also encountered in other environmental chamber experiments studying
254 emissions from light-duty gasoline vehicles (Jathar et al. 2014).

255

256 **3.2 Number fractions of particles**

257 Figure 3 illustrates the numbers of accumulation mode particles emitted by
258 burning one kilogram of fuel during the cold start and hot start driving cycles. PM
259 emissions at the start-up stage under both cold and hot start states were higher than the

260 emissions under the states when the engine was fully warmed and the vehicle operation
261 was stabilized. The PM emission was the highest under the hot stabilized running state
262 (2.3×10^{10} particles (kg fuel)⁻¹), followed by those under the hot start (1.2×10^{10} particles
263 (kg fuel)⁻¹), cold start (7.1×10^9 particles (kg fuel)⁻¹), and acceleration running states
264 (2.9×10^9 particles (kg fuel)⁻¹). The emission was the lowest under the idle running state
265 (7.4×10^8 particles (kg fuel)⁻¹) (Fig. S2).

266 Under all the running states, we found similarities in particles morphologies and
267 types. However, the proportions of particle types differed considerably (Fig. S3). The
268 fractions of organic particles were high under hot stabilized and hot start states. Soot
269 particles were abundant under cold start and acceleration states. A relatively higher
270 fraction of Ca-rich particles was found under idle state, compared to those under other
271 running states.

272 We estimated the number of different type particles in the emission under the
273 running states by burning one kilogram of fuel (Fig. 4). Organic particles in the
274 emission under the hot stabilized running state (2.3×10^9 particles (kg fuel)⁻¹) and the
275 hot start running state (3.6×10^8 particles (kg fuel)⁻¹) were higher than in the emission
276 under other running states. The number of soot particles were higher under the hot
277 stabilized running state (1.7×10^9 particles (kg fuel)⁻¹) and the cold start state (5.9×10^8
278 particles (kg fuel)⁻¹) than those under other running states. Under the idle state, the
279 relative proportion of Ca-rich particles was the highest, although their absolute number
280 was low (1.4×10^9 particles (kg fuel)⁻¹).

281 Under the cold start state, a significant proportion of the emitted particles were

282 soot particles. This can be attributed to the incomplete vaporization of fuel droplets in
283 the combustion cylinder (Chen et al. 2017). Under the hot start state and the hot
284 stabilized running state, organic particles were predominant. Under these two running
285 states, the engine temperature was high, which enabled the fuel to evaporate and mix
286 with the air easily. With the temperature in the cylinders increasing, the rate of particle
287 oxidation increased, which could cause an increase of organic particles in the emission
288 (Fu et al. 2014). Under the idle state, the fuel consumption was much lower than that
289 under the other running states, which results in the relative contribution of lubricant oil
290 to particles in the emission being higher. The high Ca content in the lubricant oil led to
291 a higher Ca-rich particle emission under this running state. Under the acceleration state,
292 the predominant particle types included soot, organic, and Ca-rich particles. As the
293 acceleration running required a high vehicular speed and engine load, the emissions
294 contained more soot particles than those under other running states.

295 **3.3. Aged particles in the environmental chamber**

296 Secondary organic particles, some soot particles, Ca-rich particles, and primary
297 organic particles were detected in the environmental chamber (Fig. 5). After the ageing
298 process, many soot particles changed into core-shell structures and became coated with
299 secondary species (Figs. 5b and 5c). The morphology and compositions of Ca-rich
300 particles and organic particles (Figs. 5e and 5g) changed, and the aged ones had a higher
301 sulfur (S) content in comparison with the fresh ones (Figs. 5A and B). Approximately
302 80% of the soot particles were present in core-shell structures and coated with
303 secondary species after the 3.5-hour ageing. In contrast, before the ageing, the particles
304 with a core-shell structure were only about 10% of the total. The mean diameter of the

305 soot particles after ageing was around $0.49 \mu\text{m}$, which was much smaller than that
306 before the ageing ($0.65 \mu\text{m}$), indicating the shrinkage of some particles during the
307 ageing (Fig. 5b).

308 **4. Discussion**

309 **4.1. Contribution of GDI-engine vehicle emissions to urban air pollution**

310 Our investigation shows that the GDI-engine vehicle emitted a large amount of
311 soot, organic particles, and Ca-rich particles. Considering the large fraction of vehicles
312 equipped with GDI engines in megacities like Beijing, this indicates a possible
313 substantial contribution of GDI-engine vehicles to urban air pollution. Moreover,
314 organic particles occupied the majority of the particles emitted under hot stabilized
315 running and hot start states. The hot stabilized running state is the most frequent running
316 condition of vehicles, whereas the hot start state is the most frequent condition in
317 congested traffic. This suggests that a substantial number of organic compounds in the
318 air pollution of populated cities might be directly related to vehicle emissions.

319 Organic particles and soot particles in ambient air are emitted from a range of
320 sources including fossil fuels, biomass burning and urban waste burning (Kanakidou et
321 al. 2005). Table 1 shows the major characteristics of particles in the emissions from
322 different sources. For instance, there is a higher fraction of soot particles and a lower
323 fraction of organic particles in the emissions of GDI-engine vehicles compared to PFI-
324 engine vehicles. Organic particles in emissions from gasoline vehicles are usually
325 enriched in Ca, S and P (Xing et al. 2017, Liati et al. 2018). In comparison, emissions
326 from biomass/wood burning are usually dominated by organic particles, which account

327 for more than 50% of the total amount of particles (Liu et al. 2017). Furthermore,
328 organic particles from biomass/wood burning usually show elevated K content, and
329 thus, this element is frequently used as an indicator for biomass/wood burning organic
330 particles (e.g. Niu et al. 2016). Observations of primary particles directly from coal
331 burning have also demonstrated a predominance of organic particles, soot particles, S-
332 rich particles and mineral particles (Zhang et al. 2018, Wang et al. 2019). Both biomass
333 burning and coal combustion can produce organic particles and almost all the emitted
334 particles contain a certain amount of Si in addition to C and O. Table 1 also shows the
335 elemental concentrations in the organic particles in the emissions from different types
336 of sources. Since the concentrations of minor elements in the organic particles are
337 highly dependent on the sources, they could be used for unambiguous source
338 identification of individual particles in the atmosphere.

339 The present data also permit the compilation of a rough inventory of particle
340 categories and amounts emitted from GDI-engine vehicles under various running
341 conditions (Fig. 4). Combined with statistics on the number of vehicles with GDI
342 engines, the running time and the running conditions on roads within a certain area, it
343 is possible to make an approximate estimate of the amounts of primary particles emitted
344 from GDI-engine vehicles. Such estimate is the basis for accurate source apportioning
345 of particles from vehicles, and it will be very beneficial for studies on the anthropogenic
346 sources of primary particles in urban air. These data could be brought together to better
347 understand the sources of air pollutants in the Beijing megacity and to improve the
348 capability of developing cost-effective mitigation measures.

349 **4.2 Rapid ageing of primary particles in Beijing**

350 The results of chamber experiments indicate that sulfate and secondary organic
351 aerosol (SOA) form on the surface of soot, Ca-rich and organic particles. Moreover, the
352 atmospheric transformation of primary particles emitted by the GDI-engine vehicles
353 could occur within 3.5 hours, indicating the ageing was rapid. Peng et al. (2014) found
354 similar timescales for black carbon transformation under polluted conditions in Beijing.
355 The rapid ageing of primary particles could be caused by several factors, such as the
356 concentration of gaseous pollutants from the vehicles, strength of solar radiation,
357 relative humidity (RH), and O₃ concentration (Guo et al. 2012, Deng et al. 2017, Du et
358 al. 2018). The present experiments were conducted in the atmosphere with relative
359 humidity of approximately 50% and solar radiation of 318 Wm⁻². The total hydrocarbon
360 emission (THC) from the GDI vehicles was 0.297 g km⁻¹. Repeated braking and
361 acceleration in the BDC could cause incomplete combustion and consequently high
362 THC emission. Under a high concentration of gaseous pollutants, primary particles
363 would age rapidly when exposed to solar radiation. Consequently, secondary species
364 including SOA and sulfate were produced on or condensed onto the particles, leading
365 to the coating. Guo et al., (2014) also showed that secondary photochemical growth of
366 fine aerosols during the initial stage of haze development could be attributed to highly
367 elevated levels of gaseous pollutants.

368 Previous studies demonstrated that inorganic salts, such as sulfate, catalyze
369 carbonyl heterogeneous reactions, and consequently, lead to SOA production (Jang et
370 al. 2002, Jang et al. 2004). Our results showed that sulfate formed on the surface of soot,

371 Ca-rich and organic particles. These aged primary particles favored the formation of
372 secondary aerosols by providing reaction sites and reaction catalysts. Moreover,
373 Mauldin et al. (2012) reported that the VOCs oxidation products could react with SO₂
374 to rapidly produce sulfate. Thus, the rapid ageing of primary particles could also be
375 attributable to the acid-catalyzed mechanism. As the major source of pollutants in urban
376 air, the GDI-engine vehicles supply both primary particles and precursor gaseous
377 species, and the rapid ageing of the particles under certain conditions is very likely the
378 major driving force for the elevation of urban air pollution.

379 **4.3 Implications and perspectives**

380 We highlight the considerable potential contribution of GDI-engine vehicles to
381 both primary and secondary organic aerosols. Organic aerosols (OA) play an important
382 role in the Earth's radiation balance not only for its absorption and scattering of solar
383 radiation but also because they can alter the microphysical properties of clouds (Scott
384 et al. 2014). Particle size, shape, mixing state and composition affect their light
385 scatterings and absorption cross sections, and cloud condensation nuclei activity
386 (Jacobson 2001). Recent measurements indicate that most OA exists as an internal
387 mixture with other aerosols, and the distribution of this mixture depends on the
388 formation mechanism of OA (Zhu et al. 2017). However, some atmospheric models still
389 present the particle population as an external mixture, particularly because the
390 formation of OA is associated with complex and not fully understood mechanisms (Lin
391 et al. 2014). Using external mixture of the aerosols in models will cause the reduced
392 direct effect because of the decrease in total aerosol surface area and the increase of

393 absorption efficiency (Lin et al. 2014).

394 Our results showed that primary organic aerosols (POA) emitted by GDI-engine
395 vehicles could acquire OA and sulfate coatings rapidly, within a few hours, and increase
396 a sizable fraction of total ambient aerosols existing as internal mixtures. In addition, the
397 fast ageing further caused the increase of aged POA in the total OA, consequently,
398 largely modified the properties of the particles such as their optical properties.
399 Structures and compositions are critical to the ability of aerosol particles to absorb and
400 reflect solar radiation (Li et al. 2011). The results of the experiments in the chamber
401 showed that most of the aged POA had a core-shell structure, whereas most of the
402 secondary organic aerosols (SOA) produced by gas-phase reactions had a uniform
403 structure. However, studies on the optical properties of OA have been mainly focused
404 on SOA, and only a few studies dealt with POA. Our results indicate the possible
405 substantial contribution of emissions from the GDI-engine vehicles to POA, especially
406 in traffic congestion. For a better understanding of the roles that traffic emissions play
407 in urban air pollution, further segregation of the aerosol particles such as POA and SOA
408 in model and observation studies is inevitable.

409 **5. Conclusions**

- 410 1. Five types of individual particles emitted by the GDI-engine vehicles were
411 identified, including soot, organic, Ca-rich, S-rich, and metal-rich particles. Among
412 them, soot, organic, and Ca-rich particles were predominant. The particles emitted
413 from GDI-engine vehicles displayed a bimodal size distribution.
- 414 2. The concentrations of the particles under the various running conditions were

415 different. The emission (per unit fuel burned) under the cold start condition was
416 higher than that under hot start condition.

417 3. Large amounts of organic particles were emitted during hot stabilized and hot start
418 states. Under cold start and acceleration states, the emissions were enriched in soot
419 particles. Under idle state, a relatively higher number of Ca-rich particles was
420 emitted, although the absolute number was low.

421 4. After ageing in the environmental chamber, the structure of the soot particles
422 changed into a core-shell structure, and the particles were coated with condensed
423 secondary organic material. Ca-rich particles and organic particles also were
424 modified, and their content of sulfur increased after ageing.

425 5. Ageing of the emitted particles occurred rapidly, within hours. Such rapid ageing
426 could be attributable to an acid-catalyzed mechanism and to the high initial
427 concentrations of gaseous pollutants emitted by the GDI-engine gasoline.

641 **List of tables:**

642 Table 1 Comparison of chemical components between various sources including fossil
 643 fuels, biomass burning and urban waste burning

Study	Source	Particle type and relative percentages	Chemical composition of organic particles
This study	GDI-engine vehicles	Organic particles (OM) (32%), Soot (32%), Ca-rich particles (26%), S-rich (5%) and metal-containing particles (4%)	OM with Ca and weak P, S, and Zn
Xing et al. (2019)	PFI-engine vehicles	OM (44%), soot (23%), Ca-rich particles (20%), S-rich (6%) and metal-containing particles (6%).	OM with Ca and weak P, S, and Zn.
Liati et al. (2018)	GDI, PFI and diesel vehicles	Soot, OM (called ash-bearing particles) and ash particles.	OM with Ca, S, P, Fe and minor Zn.
Liu et al. (2017)	Crop residue combustion	OM (27%), OM-K (43%), OM-soot-K (27%), soot-OM (3%).	OM particles with K content.
Liu et al. (2017)	Wood combustion	OM (16%), soot (18%), OM-K (22%), OM-soot-K (15%), soot-OM (29%).	OM particles with K content.
Wang et al. (2019)	Coal burning	OM (38%), soot (40%), S-rich particles (2%), and mineral particles (18%).	OM mainly consisted of C, O and Si.
Zhang et al. (2018)	Residential coal burning	OM (51%), OM-S (24%), soot-OM (23%), S-rich (1%), metal-rich particles (1%), mineral particles (1%).	OM contained C, O, and Si with minor amounts of S and Cl.

644

645

646 **List of figures:**

647

648 Figure 1. TEM images of the individual primary particles emitted from the GDI-engine
649 gasoline vehicle and the secondary organic particle in the chamber after exposure to
650 ambient sunlight for 3.5 hours. (a) soot particle; (b) Ca-rich particle; (c) S-rich particles;
651 (d) Metal-rich particles (Fe); (e) Metal-rich particles (Ti); (f) bright-field-TEM and
652 dark-field-TEM image of organic particles, and others are the mapping of the C, O, P,
653 Ca, S, and Zn in the organic particle; (g) secondary organic particle in chamber.
654

655
656 Figure 2. Size distribution of analyzed particles emitted from the GDI-engine gasoline
657 vehicles. In total, 2880 particles were analyzed from the GDI-engine vehicles. Particles
658 smaller than 0.25 µm should have been underestimated because of the collection
659 efficiency of the impactor.
660
661

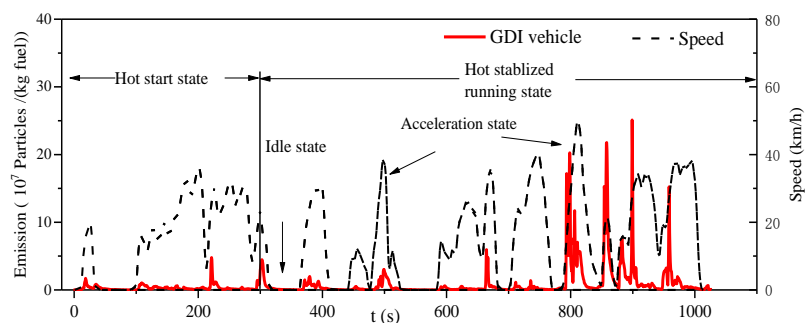

662 (a)

663

664 (b)

665

666 Figure 3. Particles in accumulation mode from the GDI vehicle during cold start (a) and
667 hot start (b) driving cycle. The vehicle speed is also shown for reference. Before the
668 test with cold start, the temperatures of the engine coolant and oil could not differ by
669 more than 2 °C during the soak temperature. The hot start test was conducted within 5
670 mins after the cold start test. The number concentration of particles during the tests was
671 monitored by DMS 500.

672

673

674

675

676 Figure 4. The number of different type particles in the emissions from the GDI vehicle
677 under the different running states by the burning of per unit of fuel, including cold start,
678 hot start, hot stabilization, idle, and acceleration states. Data presented as
679 mean \pm standard deviation, $N = 3$.

680

681

682 Figure 5. TEM images of particles in the chamber after exposure to ambient sunlight
683 for 3.5 hours. (a) Fresh soot particles; (b) Aged soot particles; (c) Aged soot particle (d)
684 Fresh organic particle (e) Aged organic particle (f) Fresh Ca-rich particle (g) Aged Ca-
685 rich particle (A) EDX spectrum for a fresh organic particle and an aged organic particle.
686 (B) EDX spectrum for a fresh organic particle and an aged Ca-rich particle.
