23

24 Key points:

- 25 1. Planetary boundary layer (PBL) mixing is the determinant factor in modeling the
26 diurnal cycle of surface PM_{2.5} concentration over East China
- 27 2. PBL mixing coefficient instead of PBL height is the key factor controlling the simulated
28 diurnal cycle of surface PM_{2.5} concentration in WRF-Chem
- 29 3. The PBL mixing during the night over East China may be underestimated by WRF-
30 Chem; Increase of PBL mixing during the night can significantly reduce the modeling
31 biases of surface PM_{2.5} concentration and also the modeling sensitivity to the PBL
32 configuration
- 33 4. The diurnal cycle and injection height of anthropogenic emission have impacts on
34 simulating diurnal cycle of surface PM_{2.5} concentration but smaller than that from PBL
35 mixing

36

37 **Abstract**

38 Diurnal variation of surface $PM_{2.5}$ concentration (diurnal $PM_{2.5}$) could dramatically affect
39 aerosol radiative and healthy impact, and can also well reflect the physical and chemical
40 mechanisms of air pollution formation and evolution. So far, diurnal $PM_{2.5}$ and its modeling
41 capability over East China have not been investigated, and therefore, are examined in this study.
42 Based on the observations, the normalized diurnal amplitude of surface $PM_{2.5}$ concentrations
43 averaged over East China is the weakest (~ 1.2) in winter, and reaches ~ 1.5 in other seasons.
44 The diurnal $PM_{2.5}$ shows the peak concentration during the night in spring and fall and during
45 the daytime in summer. The simulated diurnal $PM_{2.5}$ with WRF-Chem and its contributions
46 from multiple physical and chemical processes are examined in the four seasons. The simulated
47 diurnal $PM_{2.5}$ with WRF-Chem is primarily controlled by planetary boundary layer (PBL)
48 mixing and emission variations, and significantly overestimates the observations during the
49 night. This modeling bias is likely primarily due to the inefficient PBL mixing of primary $PM_{2.5}$
50 during the night. The simulated diurnal $PM_{2.5}$ is sensitive to the PBL schemes and vertical layer
51 configurations with WRF-Chem. The PBL mixing coefficient instead of PBL height is found
52 as the critical factor determining the PBL mixing of pollutants in WRF-Chem. The increase of
53 lower limit of PBL mixing coefficient during the night can significantly reduce the modeling
54 biases in diurnal $PM_{2.5}$ and also the mean concentrations, particularly at the major cities of East
55 China. It can also reduce the modeling sensitivity to the PBL vertical layer configurations. The
56 diurnal variation and injection height of anthropogenic emissions also play roles on simulating
57 diurnal $PM_{2.5}$, but the impact is relatively smaller than that from the PBL mixing. This study
58 underscores that more efforts are needed to improve the boundary mixing process of pollutants
59 in models with observations of PBL structure and mixing fluxes in addition to PBL height, in
60 order to simulate reasonably the diurnal $PM_{2.5}$ over East China. The diurnal variation and
61 injection height of anthropogenic emissions are also necessary to be included to simulate the
62 diurnal $PM_{2.5}$ over East China.

63

64

65 1. Introduction

66 The Yangtze River Delta (YRD) region of East China hosts the economic engine and a
67 major portion of the Chinese population. During the past two decades, the rapid economic
68 growth has resulted in significant elevated surface air pollutants over East China, especially
69 particulate matter (PM), also called aerosols. Previous studies have indicated that exposure to
70 the high concentrations of PM_{2.5} (fine particulate matter with aerodynamic diameter less than
71 2.5 μm) can cause many health issues such as lung cancer (LC), ischemic heart disease(IHD),
72 asthma, and nervous system breakdown (e.g., Seaton A et al., 1995; Davidson C I et al., 2005;
73 Pope III C A et al., 2006; Ho et al., 2018; Li T et al., 2018; Liu T et al., 2018). It has become
74 the fourth risk factor of deaths in China and 11.1% of all deaths are attributable to the ambient
75 elevated concentration of particulate matter (Gakidou et al., 2017). Besides the health impacts,
76 atmospheric aerosol can also influence the radiative energy budget of the Earth's system
77 through interacting with radiation, and serving as cloud condensation nuclei (CCN) and ice
78 nuclei (IN) and hence modifying cloud microphysics (e.g., Ackerman T P., 1977; Dickerson R
79 R et al., 1997; Jacobson M. Z., 1998).

80 Many studies have investigated spatial and temporal variations of atmospheric aerosol
81 over China in last decades. The PM_{2.5} concentrations are higher in North China than in South
82 China. The highest surface PM_{2.5} concentrations appear in winter and the lowest in summer,
83 and the highest and lowest surface PM_{2.5} concentration of a day often occurs in the evening and
84 afternoon, respectively (e.g., Gong et al., 2007; Fu et al., 2008; Hu et al., 2014; Wang ZF et al.,
85 2014; Wang YG et al., 2014; Wang YJ et al., 2014; Geng et al., 2015; Xie et al., 2015; Zhang
86 and Cao, 2015; Zhang H et al., 2015). Moreover, modeling analysis can help understand the
87 chemical and physical processes affecting aerosol formation and evolution (e.g., Ying et al.,
88 2009; Zhang et al., 2010; Liao et al., 2014; Wang YX et al., 2014; Wang YJ et al., 2014; Hu et
89 al., 2016; Li et al., 2016; Yang et al., 2016; Hu et al., 2017; Zhao B et al., 2017). Yang et al.
90 (2016) reproduced an increasing trend of winter PM_{2.5} concentrations averaged over East China
91 for 1985-2005 with the GEOS-Chem model, and found that the variations in anthropogenic
92 emissions dominated the increase of winter surface PM_{2.5} concentrations over East China and
93 the variations in meteorological fields also played an important role in influencing the decadal
94 increase in winter PM_{2.5} concentrations over East China. Hu et al., (2017) investigated the
95 spatial and temporal distribution of secondary organic aerosol (SOA) in China in 2013 with
96 the WRF-CAMQ model and found that the formation of SOA from biogenic emissions was
97 significantly enhanced due to anthropogenic emissions.

98 Most of previous modeling studies focused on understanding the mechanisms driving PM
99 variation on daily or seasonal scales or/and evaluating the simulation of daily and monthly
100 mean PM concentrations over East China. Few studies evaluated the model performance in
101 simulating diurnal cycle of surface PM concentration and investigated the mechanisms
102 underneath. However, the model capability of capturing diurnal cycle of surface PM
103 concentration is critical for revealing mechanisms of PM formation and evolution and may also
104 affect simulating mean concentration. Some studies also found that diurnal variation of surface
105 PM concentration can affect the daily average radiative forcing (e.g., Arola A et al., 2013;
106 Kassianov E et al., 2013; Kuang Y et al., 2015; Wang Z et al., 2015; Song et al., 2018). Based
107 on the ground-based data collected in Hefei from 2007 to 2013, Wang Z et al. (2015)
108 demonstrated that using daily averaged aerosol properties to retrieve the 24-h average direct
109 aerosol radiative forcing can have positive biases of up to 7.5 W m^{-2} for the cases. Arola et al.
110 (2013) found that the aerosol optical depth (AOD) diurnal cycles have significant impacts on
111 the daily mean aerosol radiative forcing.

112 Previous studies have observed evident diurnal variations of surface PM over East China
113 (e.g., Gong et al., 2007; Gu et al., 2010; Pathak R K et al., 2011; Feng et al., 2014; Hu et al.,
114 2014; Huang et al., 2014; Ma et al., 2014; Zhang and Cao, 2015; Chen et al., 2016; Tao et al.,
115 2016; Zhao et al., 2016; Chen et al., 2017; Jia et al., 2017; Guo H et al., 2017; Guo J et al.,
116 2017;). Zhang and Cao (2015) used a long-term dataset of surface $\text{PM}_{2.5}$ concentration
117 measured at 190 cities of China, and found that the diurnal variation of the $\text{PM}_{2.5}$ -to-CO ratio
118 consistently displayed a pronounced peak during the afternoon, reflecting a significant
119 contribution of secondary PM formation. Guo H et al. (2017) investigated the diurnal cycle of
120 $\text{PM}_{2.5}$ in China with the observations obtained at 226 sites of China during the period of January
121 of 2013 to December of 2015 and found the surface $\text{PM}_{2.5}$ concentration reached the maximum
122 in the morning over the YRD region.

123 Diurnal variation of surface PM concentration can be controlled by many factors including
124 emissions, chemical reactions, and meteorology (e.g., Wang et al., 2006; Huang et al., 2010;
125 Wang et al., 2010; Menuet et al., 2012; Qi et al., 2012; Quan et al., 2013; Tiwari et al., 2013; Li
126 et al., 2014; Pal et al., 2014; Sun et al., 2015; Zhang and Cao, 2015; RR Rodelas et al., 2019;
127 Xu et al., 2019). Wang et al. (2010) found that simulations with hourly emission inventory can
128 reproduce the diurnal variation patterns and magnitude of AOD better than simulations with
129 daily emission inventory. Xu et al. (2019) compared the diurnal cycles of aerosol species
130 between 2014 and 2016 observed by Aerodyne high-resolution aerosol mass spectrometer in

131 Beijing and found that the increase of secondary inorganic nitrate, sulfate, and ammonium
132 throughout the day in 2016 were mainly caused by the enhanced photochemical production.
133 With the dataset of PBL height derived from the space-borne and ground-based lidar, Su et al.
134 (2018) investigated the relationship between PBL height and surface PM concentrations across
135 China and found nonlinearly negative responses of PM to PBL height evolution over polluted
136 regions, especially when the PBL height is shallow and PM concentration is high.

137 Since very few studies evaluated the modeling performance of diurnal cycle of surface
138 PM concentration over East China and investigated the mechanisms underneath, this study
139 investigates the WRF-Chem (Weather Research and Forecasting model coupled with
140 Chemistry) simulation of diurnal variation of PM_{2.5} over East China. WRF-Chem (Grell et al.,
141 2005) is an online-coupled meteorology and chemistry model that simulates meteorological
142 fields and air pollutant concentrations simultaneously. It has been widely used for studying the
143 temporal and spatial variation of aerosols (e.g., Jiang et al., 2012; Zhou et al., 2014; Bei et al.,
144 2016; Wang et al., 2016; Zhang et al., 2016; Zhong et al., 2016; Li et al., 2017; Zhao et al.,
145 2017; Zhou et al., 2017; Liu S et al., 2018; Ni et al., 2018) and their meteorological and climatic
146 impacts over East China (e.g., Gong et al., 2007; Ding et al., 2013; Wu et al., 2013; Gao et al.,
147 2014; Chen et al., 2014; Zhao et al., 2014; Zhang B et al., 2015; Zhang L et al., 2015; Huang
148 et al., 2016; Liu et al., 2016; Pet ä et al., 2016; Zhao B et al., 2017). Most of the previous
149 modeling studies with WRF-Chem over China investigated the influencing factors on spatial
150 distribution and monthly or seasonal variation of PM. None of them focused on the
151 performance of simulating diurnal variation of PM with WRF-Chem.

152 The study will examine the observed characteristics of diurnal variation of surface PM_{2.5}
153 concentration over the YRD region of East China in four seasons of 2018. The WRF-Chem
154 simulations are conducted for one month of each season over East China as shown in Fig 1a,
155 and the simulated diurnal cycle of surface PM_{2.5} concentration will be evaluated through
156 comparing with hourly observations of surface PM_{2.5} concentration released by the Ministry of
157 Environmental Protection (MEP) of China for 190 stations over the YRD region of East China
158 in 2018. The model is also used to investigate the mechanisms driving the diurnal cycle of
159 surface PM_{2.5}. This study will focus on the impacts from meteorology and anthropogenic
160 emissions on the diurnal variation of surface PM_{2.5} concentration. For meteorology, we will
161 focus on the PBL mixing process that has been found largely controlling the diurnal variation
162 of surface pollutant concentrations (Liu M et al., 2018). For emissions, based on the findings
163 of Wang et al. (2010) and Yang et al. (2019), the diurnal variation and injection height of
164 emission will be investigated. The rest of the paper is organized as follows. The detailed

165 introduction of WRF-Chem model and numerical experiments, anthropogenic emissions, and
166 observations will be presented in Section 2. The examination of simulated diurnal variation of
167 surface PM_{2.5} concentrations and the impacts of PBL mixing and emission will be discussed in
168 Section 3. The conclusions can be found in Section 4.

169

170 **2. Methodology**

171 **2.1 Models and experiments**

172 2.1.1 WRF-Chem

173 In this study, the version of WRF-Chem updated by University of Science and Technology
174 of China (USTC version of WRF-Chem) is used. This USTC version of WRF-Chem includes
175 some additional capabilities such as the diagnosis of radiative forcing of aerosol species, land
176 surface coupled biogenic VOC emission, aerosol-snow interaction compared with the
177 publically released version (Zhao et al., 2013a,b, 2014, 2016; Hu et al., 2019). Particularly, in
178 order to understand the modeling mechanisms driving the diurnal variations of surface PM_{2.5}
179 concentration over East China, this study updates the USTC version of WRF-Chem to include
180 the diagnosis of contribution to surface PM_{2.5} concentration from individual process including
181 transport, emission, dry and wet deposition, PBL mixing, and chemical production/loss through
182 estimating the difference of surface PM_{2.5} concentration before and after individual process
183 during the simulation.

184 The Model for Simulating Aerosol Interactions and Chemistry (MOSAIC, Zaveri and
185 Peter, 1999; Zaveri et al., 2008) and the CBM-Z (carbon bond mechanism) photochemical
186 mechanism (Zaveri and Peters, 1999) are used. The MOSAIC aerosol scheme includes physical
187 and chemical processes of nucleation, condensation, coagulation, aqueous phase chemistry,
188 and water uptake by aerosols. All major aerosol components including sulfate, nitrate,
189 ammonium, black carbon, organic matter, sea salt, mineral dust, and other inorganics (OIN)
190 are simulated in the model. Aerosol size distributions are represented by eight discrete size bins
191 through the bin approach (Fast et al., 2006). Dry deposition of aerosol mass and number is
192 simulated following the approach of Binkowski and Shankar (1995), which includes both
193 particle diffusion and gravitational effects. Wet removal of aerosols by grid resolved stratiform
194 clouds/precipitation includes in-cloud removal (rainout) and below-cloud removal (washout)
195 by impaction and interception, following Easter et al. (2004) and Chapman et al. (2009). In this
196 study, cloud-ice-borne aerosols are not explicitly treated in the model but the removal of
197 aerosols by the droplet freezing process is considered. Convective transport and wet removal

198 of aerosols by cumulus clouds follow Zhao et al. (2013a). Aerosol radiative feedback is coupled
199 with the Rapid Radiative Transfer Model (RRTMG) (Mlawer et al., 1997; Lacono et al., 2000)
200 for both SW and LW radiation as implemented by Zhao et al. (2011). The optical properties
201 and direct radiative forcing of individual aerosol species in the atmosphere are diagnosed
202 following the methodology described in Zhao et al. (2013b). A detailed description of the
203 computation of aerosol optical properties in WRF-Chem can be found in Fast et al. (2006) and
204 Barnard et al. (2010). Aerosol-cloud interactions were included in the model by Gustafson et
205 al. (2007) for calculating the activation and re-suspension between dry aerosols and cloud
206 droplets.

207

208 2.1.2 Numerical experiments

209 In this study, WRF-Chem is conducted with two nested domains (one-way nesting) in one
210 month of each season of 2018 (i.e., January, April, July, October of 2018). The outer quasi-
211 global domain with 360×145 grid cells ($180^\circ \text{W} \sim 180^\circ \text{E}, 67.5^\circ \text{S} \sim 77.5^\circ \text{N}$) at the $1^\circ \times 1^\circ$ horizontal
212 resolution is used to provide the chemical boundary to the inner domain with 112×105 grid
213 cells ($109.0^\circ \text{E} \sim 124.9^\circ \text{E}, 24.0^\circ \text{N} \sim 38.9^\circ \text{N}$) at the horizontal resolution of 15 km over East China
214 covering the entire YRD region as shown in Figure 1a. More details about the quasi-global
215 WRF-Chem simulation can be found in Zhao et al. (2013a) and Hu et al. (2016). To better
216 resolve the PBL structure and mixing and examine the modeling sensitivity to vertical
217 configuration within PBL, two experiments (CTL1 and CTL2, Table 1) are configured with 40
218 vertical layers but have different distributions (as shown Fig. 1b). One configuration (L1) has
219 roughly 20 layers below 2 km above the ground, and the other has about 10 layers below 2 km
220 (Fig. 1b). In both CTL1 and CTL2, MYNN2 PBL scheme (Nakanishi and Niino, 2006) is used.
221 To demonstrate the modeling sensitivity to PBL parameterizations, the experiment CTL3 is
222 conducted as the way similar to CTL2 but with the YSU PBL scheme (Hong et al., 2006). Two
223 additional sensitivity experiments (EXP1 and EXP2, Table 1) are also conducted
224 corresponding to the experiments CTL1 and CTL2, respectively, except that the PBL mixing
225 coefficient is modified (see details in Section 3.2.2). All these WRF-Chem experiments use the
226 Morrison two-moment cloud microphysics (Morrison et al., 2009), Kain-Fritsch convective
227 scheme (Kain et al., 2004), CLM land surface scheme, and RRTMG longwave and shortwave
228 radiation schemes. The meteorological initial and lateral boundary conditions are derived from
229 the NCEP Final reanalysis data with $1^\circ \times 1^\circ$ degree resolution and 6-hour temporal resolution.
230 The modeled u component and v component wind and atmospheric temperature are nudged

231 towards the reanalysis data only to the layers above the PBL with nudging coefficients of 3×10^{-4}
232 s^{-1} with a nudging timescale of 6-hour (Stauffer and Seaman, 1990; Seaman et al., 1995).

233

234 2.1.3 Emissions

235 Anthropogenic emissions for the outer quasi-global simulation are obtained from the
236 Hemispheric Transport of Air Pollution version-2 (HTAPv2) at $0.1^\circ \times 0.1^\circ$ horizontal resolution
237 and a monthly temporal resolution for year 2010 (Janssens-Maenhout et al., 2015), except that
238 emissions over China within the domains are from the Multi-resolution Emission Inventory for
239 China (MEIC) at $0.1^\circ \times 0.1^\circ$ horizontal resolution for 2015 (Li M et al., 2017), which is also
240 used for the inner domain simulation over East China. Figure 1a shows the spatial distributions
241 of emissions of primary $\text{PM}_{2.5}$, NO_x , and SO_2 over East China. The default anthropogenic
242 emission inventories assume no diurnal variation of emissions and that all emissions are near
243 the surface (e.g., first model layer). Since diurnal variation of emissions and injection height
244 of power plant emissions may have impacts on diurnal variation of surface pollutants, the
245 experiments discussed above apply the diurnal profiles of anthropogenic emissions from five
246 individual sector (i.e., agriculture, industry, transport, energy, and residential) following
247 Olivier et al. (2003) and Wang et al. (2005) as shown in Fig. 1c and vertical distributions of
248 anthropogenic power plant emissions following Wang et al. (2010) as shown in Table 2. As
249 shown in Fig. 1c, emissions from all sectors show peak values during the daytime, and the
250 diurnal variations from agriculture, residential, and transportation are much stronger than those
251 from industry and power plant. The emissions from power plant are distributed from the bottom
252 to a height of ~ 900 m with more than 90% below 500 m. Two sensitivity experiments,
253 EXP1_E1 and EXP1_E2, are conducted as the way similar to EXP1 except that EXP1_E1
254 assumes no diurnal variation of anthropogenic emissions and EXP1_E2 assumes all power
255 plant emissions are placed near the surface (i.e., the first model layer). Comparing EXP1 with
256 EXP1_E1 and EXP1_E2 can examine the impact of diurnal variation and injection height of
257 anthropogenic emissions on diurnal cycle of surface $\text{PM}_{2.5}$, respectively. All these experiments
258 are summarized in Table 1. Biomass burning emissions are obtained from the Fire Inventory
259 from NCAR (FINN) with hourly temporal resolution and 1 km horizontal resolution
260 (Wiedinmyer et al., 2011), and are vertically distributed following the injection heights
261 suggested by Dentener et al. (2006) from the Aerosol Comparison between Observations and
262 Models (AeroCom) project. Sea-salt emission follows Zhao et al. (2013a), which includes
263 correction of particles with radius less than $0.2 \mu\text{m}$ (Gong, 2003) and dependence of sea-salt

264 emission on sea surface temperature (Jaeglé et al., 2011). The vertical dust fluxes are calculated
265 with the GOCART dust emission scheme (Ginoux et al., 2001), and the emitted dust particles
266 are distributed into the MOSAIC aerosol size bins following a theoretical expression based on
267 the physics of scale-invariant fragmentation of brittle materials derived by Kok (2011). More
268 details about the dust emission scheme coupled with MOSAIC aerosol scheme in WRF-Chem
269 can be found in Zhao et al. (2010, 2013a).

270

271 **2.2 Observations**

272 The ground observations of hourly surface PM_{2.5} mass concentration in January, April,
273 July, and October of 2018 are obtained from the website of the Ministry of Environmental
274 Protection of China (MEP of China). Since this study focuses on the YRD region of East China,
275 190 stations over East China are selected for analysis. The locations of these 190 stations are
276 shown in Fig. 1a within the black box (116.0 °E~122.5 °E, 29.0 °N~33.0 °N). Besides regional
277 average analysis, four cities (Fig. 1a) as the Center (Shanghai, 121.45 °E and 31.21 °N) and sub-
278 Center (Nanjing, 118.78 °E and 32.06 °N; Hefei, 117.25 °E and 31.85 °N; Hangzhou, 120.08 °E
279 and 30.21 °N) of the YRD city cluster are also selected for further analysis at urban areas.

280

281 **3. Results**

282 **3.1 Modeling diurnal cycle of surface PM_{2.5} concentration**

283 In order to investigate the diurnal cycle of surface PM_{2.5} concentration, this study defines
284 an index to better show the diurnal variation. The diurnal index (DI) is defined as the value of
285 each hour divided by the minimum value within 24-hour on monthly average. The peak DI
286 within 24-hour represents the amplitude of diurnal variation. Figure 2 shows the diurnal index
287 of surface PM_{2.5} concentration within 24-hour averaged over the YRD region of East China (as
288 shown as the black box in Fig. 1a) for January, April, July, October of 2018 from the WRF-
289 Chem experiments and observations. The experiment CTL1 uses the MYNN PBL scheme and
290 finer boundary layer configuration (L1 in Fig. 1b). The simulation results are 3-hourly and
291 sampled at the observational sites as shown in Fig. 1a. On regional average, the observed
292 variation of DI is the weakest in winter with the peak value around 1.2 among the four seasons.
293 The observed DI reaches the maximum of 1.5 in autumn. In spring and autumn, the observed
294 diurnal variation of DI is similar, showing two peaks in the morning and night, respectively,
295 and reaching the minimum in the afternoon, which is consistent with previous findings with
296 observations over East China (e.g., Zhang and Cao., 2015; Liu et al., 2016; Guo et al., 2017). In

297 summer, different from other seasons, the observed diurnal variation of DI shows the single
298 peak around 1.4 near the noon time. The CTL1 experiment can generally reproduce two peaks
299 in spring and autumn, however, the CTL1 simulation overestimates the observed peak DI in
300 the two seasons, particularly in autumn. The experiment generally captures the seasonality of
301 DI of surface $PM_{2.5}$ concentration that is higher DI in spring and autumn and the weakest DI in
302 winter, except that in summer the experiment significantly overestimates the DI during the
303 night and produces opposite diurnal pattern with the minimum DI near the noon time. The
304 spatial distributions of DI over East China are also generally consistent between observations
305 and simulations and show similar seasonality (Figure S1 in the supporting material). The area
306 with higher surface $PM_{2.5}$ concentration generally has higher DI (Figure S2 in the supporting
307 material), particularly from the simulation.

308 Therefore, the DI distribution at the four cities as the Center (Shanghai) and sub-Center
309 (Nanjing, Hefei, Hangzhou) of the YRD city cluster in East China (as shown in Fig. 1a) are
310 further analyzed. Figure 3 shows the diurnal index of surface $PM_{2.5}$ concentration within 24-
311 hour averaged over the four cities for January, April, July, October of 2018 from the WRF-
312 Chem experiments and observations. The observed diurnal variation of DI in these four cities
313 are consistent with that on regional average of East China. The diurnal variation of DI is more
314 evident in the two inland cities (Hefei and Nanjing) than the two coastal cities (Hangzhou and
315 Shanghai). Consistent with the results based on regional average, the CTL1 experiment can
316 generally capture the diurnal variation of DI of surface $PM_{2.5}$ in the four cities, but
317 overestimates the DI in the night, particularly in spring and autumn. In summer, again, the
318 CTL1 significantly overestimates the DI during the night and produces the opposite diurnal
319 pattern compared to observations. In general, the CTL1 produces even higher DI during the
320 night in the four cities than regional average, which results in larger diurnal amplitudes in the
321 four cities than regional average. The CTL1 can generally simulate stronger diurnal variation
322 in the two inland cities than in the two coastal cities.

323 The analysis above for both regional average and city average indicates that the CTL1
324 simulation has high positive biases of DI during the night. In order to understand the modeling
325 biases and the mechanisms driving the simulated diurnal variations of surface $PM_{2.5}$
326 concentration over East China, the contribution to diurnal variation of surface $PM_{2.5}$
327 concentration from individual process including transport, emission, dry and wet deposition,
328 mixing, and chemical production/loss is estimated. The contribution is calculated as the
329 difference of surface $PM_{2.5}$ concentration before and after individual process during the
330 simulation. Figure 4 shows the contribution of individual process to the variation of surface

331 PM_{2.5} concentration every 3-hour in Hefei from the WRF-Chem experiments averaged for
332 January, April, July, and October of 2018. The 3-hourly tendency of surface PM_{2.5}
333 concentration is also shown. The contributions and tendencies are divided by monthly mean
334 surface PM_{2.5} concentration for each month. The results for the other three cities (Nanjing,
335 Hangzhou, Shanghai) are similar to that of Hefei and are shown in the supporting material
336 (Figure S3a-c). Process contribution analysis is verified by comparing the variations of surface
337 PM_{2.5} concentration with the sum of the contribution from each individual process. As shown
338 in Figure S4, the sum contributions of all processes are consistent with the variations in surface
339 PM_{2.5} concentration following the principle of mass balance.

340 In Fig. 4, positive value denotes relative increase of surface PM_{2.5} concentration and
341 negative value denotes relative decrease. From the CTL1 experiment, the contributions from
342 emission and chemistry are positive through the day, while the contributions from transport,
343 PBL mixing, wet and dry deposition are negative through the day. The CTL1 simulates the
344 largest variation of tendency in summer and the smallest variation in winter. The tendency is
345 negative from the morning to the afternoon, resulting the simulated minimum surface PM_{2.5}
346 concentration in the afternoon in all seasons, which is consistent with the result shown in Fig.
347 3. It is evident that emission, PBL mixing, and transport are the three main processes
348 controlling the diurnal variation of surface PM_{2.5} concentration, and emission and PBL mixing
349 are the dominant two. Emission increases the surface PM_{2.5} concentration and reaches the
350 maximum near the noon time, while PBL mixing reduces the surface PM_{2.5} concentration and
351 also reaches the maximum reduction near the noon time. The combined effect of emission and
352 PBL mixing is reflected as the overall tendency. Therefore, PBL mixing is the determinant
353 process leading to the simulated minimum DI near the noon time and higher DI during the
354 night. To further demonstrate the contribution of each PM_{2.5} composition to the diurnal
355 variation of surface PM_{2.5} concentration, Figure 5 shows the diurnal variation of surface
356 concentration of each PM_{2.5} composition in Hefei from the WRF-Chem experiments averaged
357 for January, April, July, and October of 2018. The diurnal variations of surface concentrations
358 of OM, BC, and OIN are larger than other components of PM_{2.5}, showing evident higher
359 concentration during the night and minimum near the noon time in all seasons except winter.
360 The sum of OM and OIN contribute to more than half of surface PM_{2.5} concentration. Therefore,
361 it suggests that the PBL mixing of the primary PM_{2.5} determines the simulated diurnal variation
362 of surface PM_{2.5} concentration. The results for the other three cities (Nanjing, Hangzhou,
363 Shanghai) are similar to that of Hefei and are shown in the supporting material (Figure S5a-c).
364

365 3.2 Sensitivity to PBL mixing

366 3.2.1 Sensitivity to the PBL configuration

367 As discussed above, the PBL mixing is very important for modeling diurnal variation
368 of surface $PM_{2.5}$ concentration, and it may be affected by PBL parameterizations and vertical
369 layer configuration within the PBL. Therefore, two experiments, CTL2 and CTL3, are
370 conducted to examine the sensitivity of simulated diurnal variation of surface $PM_{2.5}$
371 concentration to different PBL configurations. The CTL2 uses the MYNN PBL scheme as the
372 CTL1 but is configured with different vertical layer distribution (L2) as shown in Fig. 1b, in
373 which less vertical layers are put within the PBL as described in Section 2.2. The CTL3 uses
374 the YSU PBL scheme and is configured with the L2 vertical layer distribution as the CTL2. As
375 shown in Fig. 2, on regional average, the CTL2 and CTL3 generally simulate similar diurnal
376 and seasonal patterns as that by the CTL1 with the minimum DI near the noon time and the
377 peak DI during the night. The CTL2 simulates lower DI than the CTL1 during the night in all
378 seasons. This indicates that the model with finer vertical resolution within the PBL, which is
379 supposed to better resolve the PBL structure, produces higher positive biases of DI. The CTL3
380 simulates similar diurnal variation of DI as the CTL2 but overestimate the DI during the night
381 to some extent, particularly in summer, which indicates the model with the YSU PBL scheme
382 produces higher positive biases of DI during the night compared to the one with the MYNN
383 PBL scheme. In the four cities as shown in Fig. 3, the CTL2 and CTL3 also simulate similar
384 diurnal and seasonal patterns as that by the CTL1. It is also interesting to note that the
385 difference of DI between CTL2 and CTL1 are larger than that between CTL3 and CTL2, which
386 indicate that the modeling sensitivity of DI to the vertical layer configuration within the PBL
387 is even greater than that to the PBL scheme. Overall, all these three WRF-Chem experiments
388 produce similar positive biases of DI during the night compared to the observations in all
389 seasons over the YRD region of East China, particularly in cities. This is consistent with
390 previous findings about the simulated positive biases of diurnal variation of surface $PM_{2.5}$
391 concentration over East China (e.g., Liu M et al., 2018). The changes of PBL schemes and
392 vertical configurations within the PBL can affect the simulated DI but cannot improve the
393 simulations to reproduce the observations.

394 In order to better understand the modeling sensitivity of DI to the PBL configuration,
395 Fig. 4 and 5 also shows the simulated results for the city of Hefei from the CTL2 and CTL3.
396 Similar as CTL1, the results from CTL2 and CTL3 also show that emission, PBL mixing, and
397 transport are the three main processes controlling the diurnal variation of surface $PM_{2.5}$
398 concentration, and emission and PBL mixing are the dominant two (Fig. 4). Since the number

399 of vertical layer within the PBL in CTL2 and CTL3 is much less than that in CTL1, the
400 thickness of first model layer in CTL2 and CTL3 is about a factor 2 of that in CTL1. With the
401 same emission flux, CTL2 and CTL3 simulate much smaller contribution from emission to the
402 surface $PM_{2.5}$ concentration than does CTL1. Correspondingly, the contribution from PBL
403 mixing to the surface $PM_{2.5}$ concentration in CTL2 and CTL3 is also lower than that in CTL1.
404 The combined effect of emission and PBL mixing results in weaker diurnal variation of surface
405 $PM_{2.5}$ concentration in CTL2 and CTL3 than that in CTL1, as shown by the diurnal variation
406 of overall tendency of surface $PM_{2.5}$ concentration. CTL3 with the YSU PBL scheme simulates
407 stronger diurnal variation of surface $PM_{2.5}$ concentration than does the CTL2 with the MYNN
408 PBL scheme, primarily due to its larger diurnal variation of PBL mixing. With less contribution
409 from emission to the surface $PM_{2.5}$ concentration, CTL2 and CTL3 simulate less primary $PM_{2.5}$
410 (OIN, OM, BC) than does CTL1 (Fig. 5), particularly during the night when the PBL mixing
411 is weak. This leads to the weaker diurnal variation of total surface $PM_{2.5}$ concentration in CTL2
412 and CTL3 as discussed above. The higher DI during the night in CTL3 than CTL2 can also be
413 explained by the higher primary $PM_{2.5}$ during the night due to weaker PBL mixing.

414

415 3.2.2 Sensitivity to the PBL mixing coefficient

416 The results discussed above suggest that, the WRF-Chem simulated diurnal variation of
417 surface $PM_{2.5}$ concentration over East China is largely controlled by the PBL mixing process,
418 and is sensitive to the PBL scheme and vertical layer configuration within the PBL. However,
419 the increase of number of vertical layer within the PBL and use of different PBL schemes
420 cannot reduce the modeling biases in diurnal variation of surface $PM_{2.5}$ concentration. Many
421 previous studies investigated the PBL mixing of pollutants through establishing the
422 relationship between surface pollutant concentration and PBL height. However, it is
423 noteworthy that in most atmospheric models, the mixing of pollutants within the PBL is treated
424 either as full mixing within the PBL height (i.e., uniformly distributed within the PBL height)
425 or as calculated based on the mixing coefficient diagnosed from the PBL scheme. The former
426 method represents the strongest PBL mixing and the surface concentration can be largely
427 influenced by the PBL height. However, the latter one means that the pollutant mixing does
428 not depend explicitly on PBL height.

429 In WRF-Chem, the PBL mixing of pollutants is treated with the second approach. In order
430 to further examine the simulated PBL mixing process in this study, Figure 6 shows the diurnal
431 variation of PBL heights and PBL mixing coefficients below PBL height in Hefei in January,
432 April, July, and October of 2018 from the WRF-Chem experiments CTL1, CTL2, and CTL3.

433 The black line represents the PBL height while the contour shading represents the PBL mixing
434 coefficients within the PBL height. First of all, the PBL heights simulated from the three
435 experiments all show evident diurnal variation with the maximum in the daytime and the
436 minimum during the night. The simulated PBL heights from CTL1 and CTL2 with the same
437 PBL scheme (MYNN) show very similar diurnal pattern, indicating the vertical layer
438 configuration has small impact on modeling PBL height. Both experiments simulate the largest
439 diurnal variation of PBL height in summer with a changing factor of ~ 10 from ~ 2 km in the
440 afternoon to ~ 200 m in the early morning, and the smallest diurnal variation of PBL height in
441 winter with a changing factor of 2 from ~ 700 m in the afternoon to ~ 350 m in the early morning.
442 It should be noted that the PBL mixing coefficients within the PBL also exhibit evident diurnal
443 variation with a changing factor of ~ 1000 and ~ 50 in summer and winter, respectively, which
444 is much larger than that of the PBL height in all seasons. The CTL3 simulation with the YSU
445 PBL scheme also show that the diurnal variation of PBL mixing coefficient is much larger than
446 that of PBL height. The difference between CTL2 and CTL3 is consistent with the analysis
447 about the simulated diurnal variation of surface $\text{PM}_{2.5}$ concentration, further demonstrating that
448 the WRF-Chem simulated diurnal variation of surface $\text{PM}_{2.5}$ concentration is determined by
449 the PBL mixing coefficient instead of PBL height. For example, in autumn the PBL height
450 during the night is lower in CTL3 than in CTL2, while the DI during the night is lower in CTL3
451 than in CTL2 (Fig. 3) due to the higher PBL mixing coefficient during the night in CTL3 than
452 in CTL2. More WRF experiments with different PBL schemes are conducted and all show
453 similar results that the diurnal variation of PBL mixing coefficient is much stronger than that
454 of PBL height (not shown).

455 With relatively large values of PBL mixing coefficient during the daytime, the emitted
456 pollutants can be mixed up roughly reaching the layer of PBL height. However, weak PBL
457 mixing coefficient during the night results in that the emitted $\text{PM}_{2.5}$ and its precursors will stay
458 near the surface (i.e., within the first layer of model) during the night and cannot be mixed up
459 reaching the PBL height (Fig. S6 in the supporting material). This leads to the large difference
460 of DI between CTL1 and CTL2 with different thickness of first model layer during the night
461 although they simulate similar PBL height. The comparison between simulations and
462 observations (Fig. 2 and 3) suggests the positive modeling biases of DI during the night may
463 be partly due to the underestimation of the PBL mixing during the night. To examine the
464 sensitivity of simulated DI to the PBL mixing coefficient, the sensitivity experiments, EXP1
465 and EXP2, are conducted corresponding to CTL1 and CTL2, respectively, through setting the
466 lower limit of PBL mixing coefficient from $0.1 \text{ m}^2/\text{s}$ (default in the publically released version

467 of WRF-Chem) to $5 \text{ m}^2/\text{s}$ within the PBL. Figure 7 shows the simulated PBL height and mixing
468 coefficients from the two sensitivity experiments, EXP1 and EXP2, in January, April, July, and
469 October of 2018 in Hefei. It shows that the PBL mixing coefficient increases during the night
470 within the PBL compared to the results shown in Fig. 6, while the values during the daytime
471 remain almost the same. The difference of simulated surface $\text{PM}_{2.5}$ between CTL1 and EXP1
472 is relatively small during the daytime, but significant during the night, which is due to that
473 EXP1 can mix up the surface $\text{PM}_{2.5}$ to the PBL height during the night (Fig. S6). It is
474 noteworthy that the lower limit parameter of $5 \text{ m}^2/\text{s}$ is entirely empirical. It is selected to
475 represent the moderate mixing strength between the full PBL mixing and no PBL mixing. A
476 few other values such as $1 \text{ m}^2/\text{s}$ and $10 \text{ m}^2/\text{s}$ are also tested. The results do not change the
477 conclusion found in this study and therefore are not shown.

478 The change of PBL mixing coefficient during the night can significantly affect the diurnal
479 variation of PBL mixing. Figure 8 shows the contribution of individual process to the variation
480 of surface $\text{PM}_{2.5}$ concentration every 3-hour in Hefei simulated by EXP1 and EXP2 averaged
481 for January, April, July, and October of 2018. The 3-hourly tendency of surface $\text{PM}_{2.5}$
482 concentration is also shown. Same as Fig. 4, the contributions and tendencies are divided by
483 monthly mean surface $\text{PM}_{2.5}$ concentration for each month. The results for the other three cities
484 (Nanjing, Hangzhou, Shanghai) are similar to that of Hefei and are shown in the supporting
485 material (Figure S7a-c). Compared to the results from CTL1 and CTL2 shown in Fig. 4, it is
486 evident that the diurnal variation of tendency of surface $\text{PM}_{2.5}$ concentration is significantly
487 reduced in all seasons. This is mainly resulted from the significantly reduced diurnal variation
488 of PBL mixing contribution. Specifically, the PBL mixing contribution during the night is
489 increased. Figure 9 shows the diurnal variation of surface concentration of each $\text{PM}_{2.5}$
490 composition in Hefei simulated by the EXP1 and EXP2 averaged for January, April, July, and
491 October of 2018. The diurnal variations of surface concentrations of OM, BC, and OIN are
492 significantly reduced primarily due to their reduced concentration during the night in EXP1
493 and EXP2, compared to CTL1 and CTL2 (Fig. 5). The results for the other three cities (Nanjing,
494 Hangzhou, Shanghai) are similar to that of Hefei and are shown in the supporting material
495 (Figure S8a-c).

496 The change of PBL mixing and diurnal variation of primary $\text{PM}_{2.5}$ near the surface turn
497 out different DI. Figure 10 shows the diurnal variation of DI of surface $\text{PM}_{2.5}$ averaged over
498 the YRD region of East China for January, April, July, and October of 2018 from the
499 observations and the experiments CTL1, CTL2, EXP1, and EXP2. In general, the simulated
500 DI are reduced significantly during the night in EXP1 and EXP2 much more consistent with

501 the observations compared to the ones in CTL1 and CTL2. In spring, the EXP1 and EXP2
502 slightly underestimate DI during night. Figure 11 shows the diurnal variation of DI averaged
503 over the four cities for January, April, July, October of 2018 from the observations and the
504 experiments CTL1, CTL2, EXP1, and EXP2. As discussed above the diurnal variation of DI is
505 much stronger in cities with relatively more emissions. The simulated DI is also more sensitive
506 to the change of PBL mixing coefficient in these four cities compared to that on regional
507 average. The EXP1 and EXP2 produce much more consistent DI with the observations in the
508 four cities than do CTL1 and CTL2 in all seasons. It is also noteworthy that the difference
509 between EXP1 and EXP2 and that between CTL1 and CTL2 is reduced both on city average
510 and regional average, which indicates that the enhanced PBL exchange coefficient during the
511 night help reduce the modeling sensitivity to the vertical layer configuration. The analysis
512 above suggests that the simulated PBL mixing during the night in the publically-released WRF-
513 Chem may be too weak.

514 Comparing the simulated surface concentrations of $PM_{2.5}$ components between CTL1 (Fig.
515 5) and EXP1 (Fig. 9), it can be found that the daily average surface $PM_{2.5}$ mass concentration
516 should also be reduced when the diurnal variation is reduced due to the reduction of nighttime
517 surface $PM_{2.5}$ concentration. Figure 12 shows the comparison of monthly mean surface $PM_{2.5}$
518 concentration between the observations and the simulations from CTL1 and EXP1 at each
519 observation site over the YRD region of East China for January, April, July, and October of
520 2018. In all seasons, the CTL1 significantly overestimates the observed surface $PM_{2.5}$
521 concentration with the normalized mean biases (NMB) of 22% (winter) - 109% (summer) on
522 regional average. The EXP1 reduces the NMB to 7% (winter) - 38% (summer) on regional
523 average. In CTL1, the NMB of simulation exceeds 50% at 20%, 35%, 65%, and 60% of
524 observational sites over the YRD region of East China in January, April, July, and October,
525 respectively, which reduces to 0%, 10%, 35%, and 20% of all sites in EXP1. In addition, the
526 EXP1 also increases the spatial correlation between observations and simulated results in all
527 seasons (Fig. 12), although with the improvement of modeling diurnal variation the EXP1 still
528 cannot fully capture the observed spatial variability of surface $PM_{2.5}$ concentration among the
529 observational sites. This may be related to the biases in spatial distributions of emission and
530 model processes contributed to the spatial variability of surface $PM_{2.5}$ concentration, which
531 deserves further investigation in future.

532

533 3.3 Impacts from emission distributions

534 3.3.1 Impacts from emission diurnal variability

535 Besides the meteorology such as PBL mixing as discussed above, the diurnal variation of
536 emissions may also play an important role in determining the DI of surface $PM_{2.5}$ concentration.
537 One sensitivity experiment, EXP1_E1, without diurnal variation of anthropogenic emissions
538 (Fig. 1b) is conducted. Figure 13 shows the spatial distribution of the difference in maximum
539 DI between EXP1 and EXP1_E1 over East China. As removing diurnal variation of emissions
540 will lead to more emissions during the night and thus increase the DI during the night over
541 polluted area, which generally results in larger maximum DI. Therefore, EXP1 has lower
542 maximum DI than EXP1_E1 over most regions of East China in seasons other than winter.
543 EXP1 could have slightly larger maximum DI in winter when the diurnal variation of DI is
544 relatively small (Fig. 2 and 3) and over the relatively clean region (Fig. 1a) in summer. Figure
545 14 shows the diurnal index of surface $PM_{2.5}$ concentration within 24-hour averaged over the
546 four cities for January, April, July, and October of 2018 from observations and the EXP1 and
547 EXP1_E1 experiments. In general, EXP1 shows lower DI than EXP1_E1 during the night, and
548 therefore has smaller diurnal variation of DI in four cities. The largest difference between EXP1
549 and EXP1_E1 in four cities exists in summer and the smallest is in winter. Comparing to the
550 impacts from PBL mixing as shown in Fig. 11, the reduction of diurnal variation of DI by
551 adding diurnal variation of anthropogenic emissions is much smaller.

552 Fig. 13 shows that EXP1 with diurnal variation of emissions could simulate slightly larger
553 diurnal variation of DI over the relatively clean region than EXP1_E1 in winter and summer.
554 The higher DI in EXP1 than EXP1_E1 is primarily in the afternoon and evening (Fig. S9 in
555 the supporting material). One grid over south Anhui is selected for analysis of contributions
556 from different processes in the model to the diurnal variation of surface $PM_{2.5}$ concentration
557 from the experiments EXP1 and EXP1_E1 (Fig. 15). Different from the process contributions
558 over the relatively polluted region (Fig. 8), the contribution from direct local emission to the
559 surface $PM_{2.5}$ concentration is relatively small over the clean region. Instead, the contributions
560 from chemistry, dry deposition, PBL mixing, and transport dominate the diurnal variation of
561 surface $PM_{2.5}$ concentration. The PBL mixing could increase the surface $PM_{2.5}$ concentration
562 during the daytime because of mixing down the pollutants transported from polluted regions
563 above the surface. The diurnal change of surface $PM_{2.5}$ concentration between EXP1 and
564 EXP1_E1 is very similar with slightly difference that results in their slight difference in DI in
565 the afternoon and night.

566

567 3.3.2 Impacts from emission injection height

568 Previous studies suggested that the injection height of emissions from power plants may
569 also affect the diurnal cycle of surface pollutant concentration, particularly for SO₂ (e.g., Wang
570 et al.,2010; Lin et al.,2012; Qi et al.,2012; Xu et al.,2014). Therefore, one sensitivity
571 experiment, EXP1_E2, is conducted with setting the anthropogenic emissions placed only in
572 the first layer of model. Figure 16 shows the spatial distribution of the difference in maximum
573 DI between EXP1 and EXP1_E2 over East China. Over most areas of East China, EXP1
574 simulates lower maximum DI than EXP1_E2, and the difference is primarily in spring and
575 summer. The impact of injection height is negligible in winter. The distribution of impacts
576 correlates highly with the distribution of power plant locations. The reduction of DI of surface
577 SO₂ concentration in EXP1 compared to EXP1_E2 is mainly due to more emissions are placed
578 above the PBL during the night (Fig. S10 in the supporting material). As shown in Table 2,
579 most of power plant emissions are placed below 500 m in EXP1. The larger impact in summer
580 than in winter is mainly due to the higher PBL height during the night in winter (Fig. 7).
581 Therefore, emissions are still placed within the PBL even with the injection height, which
582 results in the small difference of DI of surface SO₂ concentration between EXP1 and EXP1_E2.
583 For surface PM_{2.5} concentration, the impact of emission injection height is even smaller and
584 only distinguishable in summer (Fig. S11 in the supporting material). Overall, impact from the
585 injection height of emission on the diurnal variation of surface PM_{2.5} concentration is much
586 smaller than that from PBL mixing.

587

588 **4. Summary and discussion**

589 In this study, the observed characteristics of diurnal variation of surface PM_{2.5}
590 concentration over the YRD region of East China in four seasons of 2018 is examined based
591 on the hourly surface observations at 190 stations of the region. On regional average, the
592 observed diurnal variation is the weakest in winter and the strongest in autumn. In spring and
593 autumn, the observed patterns of diurnal variation are similar, showing the minimum surface
594 PM_{2.5} concentration in the afternoon, consistent with previous studies (e.g., Zhang and Cao et
595 al.,2015; Liu et al.,2016; Guo et al.,2017). In summer, different from other seasons, the
596 observed diurnal variation shows the maximum surface PM_{2.5} concentration near the noon time.

597 The WRF-Chem experiments are conducted over East China and the simulated diurnal
598 variations of surface PM_{2.5} concentration are compared with the observations. The model
599 generally captures the observed seasonality of diurnal variation of surface PM_{2.5} concentration,
600 except that in summer the model significantly overestimates the diurnal peak during the night

601 and produces opposite diurnal pattern with the minimum concentration near the noon time. The
602 model can generally reproduce the patterns with the minimum noontime concentration in
603 spring and autumn, but overestimates the observed nighttime peaks, particularly in autumn.
604 The modeling biases and the mechanisms driving the diurnal variation of surface $PM_{2.5}$
605 concentration in four seasons are further investigated. Emission and PBL mixing are found to
606 be the two dominant processes controlling the diurnal variation of surface $PM_{2.5}$ concentration
607 over the polluted areas, and the PBL mixing leads to the simulated diurnal pattern of surface
608 $PM_{2.5}$ concentration. More specifically, the simulations suggest that the PBL mixing of the
609 primary $PM_{2.5}$ determines the modelled diurnal variation of surface $PM_{2.5}$ concentration.
610 Although the observation of $PM_{2.5}$ components is not available to evaluate the diurnal variation
611 of primary $PM_{2.5}$, the diurnal variation of surface mixing ratio of CO that is normally used to
612 represent the primary pollutant supports the findings (Fig. S12 in the supporting material).

613 The modeling results are found sensitive to the PBL schemes and the vertical
614 configuration (i.e., the number of model layers within PBL) of simulations. However, none
615 of the PBL schemes in WRF-Chem can reduce the modeling biases in diurnal variation of
616 surface $PM_{2.5}$ concentration. Contrary to the intuition, more model layers within PBL worsen
617 the model performance, which is mainly due to that more layers within PBL makes the first
618 model layer thinner and enlarges the contribution from emission if PBL mixing is not
619 efficient. The analysis indicates that the PBL mixing coefficient instead of the PBL height
620 controls the PBL mixing in WRF-Chem, particularly during the night. Increasing the lower
621 limit of PBL mixing coefficient within the PBL can significantly reduce the modeling biases
622 in diurnal variation of surface $PM_{2.5}$ concentration, primarily during the night. In addition, it
623 can also reduce the modeling sensitivity to the model vertical configuration. The model
624 performance of daily mean surface $PM_{2.5}$ concentration is also largely improved when the
625 biases of diurnal variation are reduced. The diurnal variation of anthropogenic emissions and
626 injection height of power plant emissions can affect the diurnal cycle of surface $PM_{2.5}$
627 concentration to some extent, but the impact is much smaller than that of PBL mixing.

628 This study highlights the importance of modeling PBL mixing coefficient within PBL
629 in models like WRF-Chem that simulates the PBL mixing process based on the mixing
630 coefficient instead of PBL height. Some studies found that other models also overestimated
631 the diurnal variation of observed surface $PM_{2.5}$ concentration over East China (e.g., Cai et
632 al.,2011; Liu M et al.,2018). Our finding suggests that those models may also have the
633 problems in modeling PBL mixing during the night. Many of previous modeling and
634 observation studies focus on investigating the variation of PBL height and its interaction

635 with aerosol concentration (e.g., Sawyer et al., 2015; Ding et al, 2016; Li et al, 2017; Song
636 et al.,2018; Su et al., 2018). However, this study reveals that the PBL mixing flux is more
637 critical than PBL height in terms of understanding the mixing of pollutants within PBL,
638 particularly during the night, which can not only significantly affect the diurnal variation but
639 also the daily mean of surface pollutant concentration. The increase of PBL mixing during
640 the night reduces the modeling biases, which may suggest that the simulated PBL mixing
641 during the night in WRF-Chem is too weak. One possible reason may be due to urban heat
642 island effect that is not accounted in this study, because the observation sites are mostly at
643 urban or sub-urban areas. The test simulations with the current version of WRF-Chem using
644 Noah land surface model with urban effect can increase the nighttime PBL mixing
645 coefficient from 0.1 m²/s to 1-10 m²/s during some cases at urban areas, but the results are
646 sensitive to the urban schemes (not shown), which deserves investigation in future. Another
647 suggestion is that the PBL mixing of pollutants may not be able to follow directly the mixing
648 coefficient diagnosed by PBL parameterization for meteorology, which deserves further
649 investigation. The improvement of modeling PBL height is not enough for understanding
650 the PBL mixing of pollutants. This suggests that the understanding of PBL structure and
651 detailed mixing process are needed. Besides the observation or retrieval of PBL height,
652 observations of PBL characteristics are needed.

653 Although the sensitivity adjustment of PBL mixing coefficient during the night can
654 largely reduce the modeling biases in diurnal variation of surface PM_{2.5} concentration, one
655 evident deficiency is that the model produces opposite diurnal pattern compared with
656 observations in summer. It needs to be noted that the WRF-Chem simulations conducted in
657 this study do not consider the SOA production that still has large uncertainties in
658 mechanisms. One sensitivity experiment with the SOA production shows that the model can
659 better represent the observed diurnal pattern of surface PM_{2.5} concentration in summer
660 showing the maximum concentration in the daytime (Fig. S13 in the supporting material).
661 This indicates that the SOA production may be important for modeling the diurnal variation
662 of surface PM_{2.5} concentration in summer over East China, which suggests more detailed
663 analysis of impact of SOA production on diurnal cycle of surface PM_{2.5} concentration is
664 needed with observations. It is also noteworthy that the impact of SOA production on diurnal
665 variation of surface PM_{2.5} concentration is only significant in summer, likely due to the
666 strong photochemistry activity in summer. Another uncertainty of the results in this study
667 may be related to emissions. Although the diurnal variation and injection height of emission
668 do not contribute significantly to the night time positive biases of surface PM_{2.5}

669 concentration, the emission uncertainties of primary PM may influence the diurnal cycle of
670 surface PM_{2.5}. For example, overestimation of primary PM emission can increase the diurnal
671 variation. Therefore, this study suggests that the long-term measurements of PM_{2.5}
672 components at more stations are needed to further investigate the characteristics of diurnal
673 variation of PM_{2.5}, which can improve our understanding of the impacts of multiple
674 processes, such as chemical production, emissions, and meteorology, on the formation and
675 evolution of air pollution.

676

677 **Data availability**

678 The release version of WRF-Chem can be download from
679 http://www2.mmm.ucar.edu/wrf/users/download/get_source.html. The updated USTC
680 version of WRF-Chem can be downloaded from <http://aemol.ustc.edu.cn/product/list/> or
681 contact chunzhao@ustc.edu.cn. Also, the code modifications will be incorporated the release
682 version of WRF-Chem in future.

683

684 **Author contributions**

685 Qiuyan Du and Chun Zhao designed the experiments, conducted and analyzed the
686 simulations. All authors contributed to the discussion and final version of the paper.

687

688 **Acknowledgements**

689 This research was supported by the Fundamental Research Funds for the Central
690 Universities, and the National Natural Science Foundation of China (grant 41775146). The
691 study used the computing resources from the High-Performance Computing Center of
692 University of Science and Technology of China (USTC). Part of the observation data is from
693 the Qingyue Open Environmental Data Center (<https://data.epmap.org>).
