23 **Abstract.** Aerosol-planetary boundary layer (PBL) interaction was proposed as an
24 important mechanism to stabilize the atmosphere and exacerbate surface air pollution.
25 Despite the tremendous progress made in understanding this process, its magnitude and
26 significance still have large uncertainties and vary largely with aerosol distribution and
27 meteorological conditions. In this study, we focus on the role of aerosol vertical
28 distribution on thermodynamic stability and PBL development by jointly using
29 micropulse lidar, sunphotometer, and radiosonde measurements taken in Beijing.
30 Despite the complexity of aerosol vertical distributions, cloud-free aerosol structures
31 can be largely classified into three types: well-mixed, decreasing with height, and
32 inverse structures. The aerosol-PBL relationship and diurnal cycles of the PBL height
33 and $PM_{2.5}$ associated with these different aerosol vertical structures show distinct
34 characteristics. The vertical distribution of aerosol radiative forcing differs drastically
35 among the three types with strong heating in the lower, middle, and upper PBL,
36 respectively. Such a discrepancy in heating rate affects the atmospheric buoyancy and
37 stability differently in the three distinct aerosol structures. Absorbing aerosols have the
38 weak effect of stabilizing the lower atmosphere under the decreasing structure than
39 under the inverse structure. As a result, the aerosol-PBL interaction can be strengthened
40 by the inverse aerosol structure, and can be potentially neutralized by the decreasing
41 structure. Moreover, aerosols can both enhance and suppress the PBL stability, leading
42 to both positive and negative feedback loops. This study attempts to improve our
43 understanding of the aerosol-PBL interaction, showing the importance of the
44 observational constraint of aerosol vertical distribution for simulating this interaction

45 and consequent feedbacks.

46 **1. Introduction**

47 Aerosols have a critical impact on the earth's climate through aerosol-cloud
48 interactions (ACI) and aerosol-radiation interactions (ARI). They also continue to
49 contribute toward the considerable uncertainty in quantifying and interpreting the
50 earth's changing radiation budget and hydrological cycles (Charlson et al., 1992;
51 Ackerman et al., 2004; Boucher et al., 2013; Z. Li et al., 2011, 2017a; J. Guo et al.,
52 2017, 2019a). Despite the great advances made in the past decades in observational and
53 modeling studies of aerosol effects, it is still a challenge to accurately quantify aerosol
54 effects on the climate system due to inadequate understanding of some mechanisms and
55 strong variations in aerosol type, loading, and vertical distribution (Haywood and
56 Boucher, 2000; Jacobson et al., 2001; Carslaw et al., 2013; J. Huang et al., 2015; J. Guo
57 et al., 2016a; Z. Li et al., 2016; Wei et al., 2019a, 2019b). Aerosols can interact with
58 thermodynamic stability through ARI (Atwater, 1971; Bond et al., 2013). Absorbing
59 aerosols can stabilize the atmosphere (Ramanathan et al., 2001; Y. Wang et al., 2013;
60 Ding et al., 2016) and may also enhance convection and precipitation under certain
61 conditions (Menon et al., 2002; Z. Li et al., 2017).

62 Thermodynamic stability in the planetary boundary layer (PBL) dictates the PBL
63 development (Stull, 1988; W. Zhang et al., 2018), thereby dominating the vertical
64 dissipation of surface pollutants to some degree. Aerosols, in turn, have important
65 feedbacks on the stability in the PBL, depending on aerosol properties, especially those
66 of light-absorbing aerosols (e.g., black, organic, and brown carbon). However, due to
67 large uncertainties in aerosol radiative forcing, it remains a challenge to quantify the

68 impact of aerosols on thermodynamic stability and PBL development. Conventionally,
69 increasing the aerosol absorption tends to stabilize the atmosphere, leading to a reduced
70 PBL height (PBLH). A more stable atmosphere and lower PBLH will, in turn, increase
71 the surface aerosol loading, which is the well-established positive feedback loop in the
72 aerosol-PBL interaction (e.g., H. Wang et al., 2015; Ding et al., 2016; Petäjä et al., 2016;
73 Dong et al., 2017; Zou et al., 2017; Q. Huang et al., 2018; Z. Wang et al., 2018; H. Wang
74 et al., 2019). However, such a positive feedback loop may not be real for all situations
75 and is subject to confounding factors such as aerosol type, aerosol vertical distribution,
76 soil moisture, and PBL regime (J. Guo et al., 2019b; Lou et al., 2019). Geiß et al. (2017)
77 reported the ambiguous relationship between surface aerosol loading and PBLH, while
78 our previous study revealed weak correlations between surface pollutants and the PBLH
79 in mountainous or clean regions (Su et al., 2018). Lou et al. (2019) showed that aerosols
80 have a positive correlation with the PBLH under stable PBL conditions, indicating the
81 importance of thermodynamic conditions in the PBL.

82 Among others, numerical models are one of the viable methods used to determine
83 aerosol impacts on stability and PBL (e.g., J. Wang et al., 2014; Ding et al., 2016; Y.
84 Wang et al., 2018; Zhou et al., 2018). The aerosol optical depth (AOD), a measure of
85 aerosol columnar loading, is usually taken into account in model simulations. However,
86 the aerosol vertical distribution in models is generally prescribed and may differ greatly
87 from the real situation. With observational constraints, the role of aerosol vertical
88 distributions in aerosol-PBL interactions warrants further investigation.

89 Ample observational datasets for Beijing are available, including aerosol vertical

90 distributions derived from lidar, optical properties derived from the sunphotometer,
91 profiles of meteorological variables from radiosonde (RS), and surface PM_{2.5} and
92 meteorological parameters. Based on these measurements, a radiative transfer model is
93 used to simulate the vertical profiles of aerosol radiative forcing that are employed to
94 investigate the impact of aerosols on buoyancy in the lower atmosphere.

95 The paper is structured as follows. Section 2 introduces the datasets and methods
96 used. Section 3 presents analyses of aerosol-PBL interactions under different aerosol
97 vertical structures. Section 4 discusses the results with a brief summary.

98

99 **2. Data and Method**

100 **2.1. Site description**

101 We utilized data from multiple sources in Beijing, a megacity located in the North
102 China Plain. As one of the most densely populated and urbanized regions in the world,
103 Beijing is a polluted region with high concentrations of absorbing aerosols (Y. Zhang
104 et al., 2019). The micropulse lidar (MPL) located in Beijing was operated continuously
105 by Peking University (39.99°N, 116.31°E) from March 2016 to December 2018, with
106 a temporal resolution of 15 s and a vertical resolution of 15 m. Due to incomplete laser
107 pulse corrections, the near-surface lidar blind zone is ~0.15 km. Background subtraction,
108 saturation, after-pulse, overlap, and range corrections are applied to raw MPL data to
109 calculate the normalized signals (Yang et al., 2013; Su et al., 2017a). MPL data on
110 raining days are excluded. Level 1.5 AOD and single-scattering albedos (SSA) are
111 employed at multiple wavelengths (i.e., 0.44, 0.5, 0.67, 0.87, and 1.02 μm) from the

112 Beijing RAD1 (40°N, 116.38°E) Aerosol Robotic Network (AERONET) site from 2011
113 to 2018 under cloud-free conditions (Holben et al., 1998; Smirnov et al., 2000; Y. Zhang
114 et al., 2017). The RS station (39.80°N, 116.47°E) in Beijing, operated by the China
115 Meteorological Administration, is ~25 km from the MPL site. The variables observed
116 at the RS station include meteorological data and profiles of water vapor, temperature,
117 pressure, and wind. The vertical resolution of the RS is altitude dependent and generally
118 less than 8 m (J. Guo et al., 2016b; W. Zhang et al., 2018). The RS is routinely launched
119 at 0800 Local Time (LT) and 2000 LT each day and is also launched at 1400 LT in the
120 summer (June-July-August). RS measurements are collected during 2011–2018. To
121 reduce small-scale biases and to obtain a picture of the regional variation in particulate
122 matter with the diameter smaller than 2.5 μm ($\text{PM}_{2.5}$), we acquire mean $\text{PM}_{2.5}$ data from
123 twenty environmental monitoring stations located within 20 km from the lidar site,
124 including one station at the Beijing Embassy of the United States. Figure 1 shows the
125 topography of Beijing. The green square indicates the MPL site, and the yellow triangle
126 indicates the AERONET station. The brown star represents the RS station, and the red
127 pink dots represent the $\text{PM}_{2.5}$ sites.

128 **2.2. Statistical analysis methods**

129 The statistical significance is tested by two independent statistical methods, namely,
130 the least-squares regression and the Kendall' tau (MK) test (Mann, 1945; Kendall, 1975;
131 J. Li et al., 2016). Least-squares regression typically assumes a Gaussian data
132 distribution in the trend analysis, whereas the MK test is a nonparametric test without
133 any assumed functional form. The latter is more suitable for data that do not follow a

134 certain distribution. To improve the robustness of the analysis, a relationship is
135 considered significant when the confidence level is above 99% for both the least-
136 squares regression and the MK test. Hereafter, “significant” indicates that the
137 correlation is statistically significant at the 99% confidence level.

138 We primarily use the linear-fit method to build relationships between different
139 parameters. The Pearson correlation coefficient derived from the linear regression
140 analysis measures the degree to which the data fit a linear relationship. However,
141 following our recent work (Su et al., 2018), inverse fitting [$f(x) = A/x + B$] is used
142 to establish the relationship between PBLH and $PM_{2.5}$. The magnitude of the correlation
143 coefficient (R^\dagger) is designed to measure the degree to which the data fit an inverse
144 relationship. Since the relationship between the PBLH and $PM_{2.5}$ is non-linear, the
145 inverse fitting better characterizes this relationship.

146 **2.3. PBLH and buoyancy derived from RS**

147 The RS vertical resolution varies according to the balloon ascending rate. The RS
148 records measurements every 1.2 s, which represents an approximate vertical resolution
149 of 5–8 m. Prior to the retrieval of the PBLH, we further resample RS data to achieve a
150 vertical resolution of 5 hPa with linear interpolation. We follow a well-established
151 method developed by Liu and Liang (2010) to derive the PBLH based on profiles of the
152 potential temperature gradient that takes into account different stability conditions. In
153 this study, we only focus on PBLs driven by buoyancy, so PBLs driven by low-level
154 jets are excluded using RS-derived wind profiles (Liu and Liang, 2010; Miao et al.,
155 2018).

156 The static stability of the atmosphere is determined by the buoyancy force, which
157 is expressed as (Wallace and Hobbs, 2006)

$$158 \quad B = \frac{d^2z}{dt^2} = \frac{T' - T}{T}g = -g\Delta z \frac{1}{\theta} \frac{d\theta}{dz} \quad , \quad (1)$$

159 where z is the height of the air parcel, and t indicates the time. T' represents the
160 temperature of the parcel, T represents the temperature of the environment, and θ is
161 the virtual potential temperature of the environment. An atmospheric layer is convective
162 if the buoyancy is above zero and stable when the buoyancy is below zero. If the
163 buoyancy is near zero, the atmosphere is neutral. We calculated buoyancy with a
164 vertical resolution of 30m. Based on the identification method for PBL type (Liu and
165 Liang, 2010; W. Zhang et al., 2018), we present profiles of buoyancy forcing for stable,
166 neutral, and convective PBLs (Figure 2a). Results shown are averages from 3069
167 radiosonde measurements, of which 438 cases are convective PBLs, 714 cases are
168 neutral PBLs, and 1916 cases are stable PBLs. The strongest upward or downward
169 forcing occurs near the surface. Figures 2b-c further show the height-dependent
170 correlation coefficients between buoyancy and PBLH/PM_{2.5} with an interpolation
171 window of 0.2 km. Note that the PBLH and surface PM_{2.5} are fixed for the entire column,
172 and the buoyancy is height dependent. Due to the insufficient development of the PBL,
173 we do not use RS data at 0800 LT here. To exclude the impact induced by the dragging
174 effects of rainfall, we only consider cases without precipitation within the past 24 hours.
175 Strong upward buoyancy can uplift the PBLH and mitigate surface pollutants,
176 especially in the lower atmosphere. Thus, we vertically average the buoyancy forcing
177 profiles within the lowest 1 km (red line in Figures 2b-c), defined as the lower-

178 atmosphere buoyancy (LAB). As shown in Figures 3a-b, LAB and PM_{2.5} are negatively
179 correlated, and LAB and PBLH are positively correlated. LAB also has a significant
180 negative correlation with absorbing aerosol optical depth (Figure 3c). This may be due
181 to the stabilizing effect of absorbing aerosols on the atmosphere, widely reported in
182 many previous studies (H. Wang et al., 2015; Ding et al., 2016; Petäjä et al., 2016; Dong
183 et al., 2017; Z. Li et al., 2017b; X. Huang et al., 2018).

184 **2.4. PBLH and aerosol extinction coefficient derived from MPL**

185 MPL data from Beijing were used to retrieve the PBLH during the daytime (0800–
186 1900 LT). Many methods have been developed for retrieving the PBLH from MPL
187 measurements, e.g., the signal threshold (Melfi et al., 1985), the maximum of the signal
188 variance (Hooper and Eloranta, 1986), the minimum of the signal profile derivative
189 (Flamant et al., 1997), and the wavelet transform (Cohn and Angevine, 2000; Davis et
190 al., 2000; Su et al., 2017b; Chu et al., 2019). To derive the PBLH from MPL data, we
191 adopted previous well-established approaches with several refinements, which have
192 already been validated by long-term data collected at the Southern Great Plains site
193 (Sawyer and Li, 2013; Su et al., 2020).

194 We initially identify the local maximum positions (range: 0.25–4 km) in the
195 covariance transform function collocated with a signal gradient larger than a certain
196 threshold. We further estimated the shot noise (σ) induced by background light and dark
197 currents for each profile, and then set the threshold as 3σ . The initial PBLH retrieval
198 (at 0800 LT) is constrained by the PBLH value derived from the morning RS sounding.
199 Then, the following PBLHs are retrieved using a stability-dependent model based on

200 continuity. Boundary layer clouds are identified to diagnose the PBLH for cloudy cases.
201 Figure 3d presents the comparison of summertime PBLH results derived from MPL and
202 RS at 1400 LT, showing good agreement ($R = 0.79$).

203 Multiple studies have provided a well-established algorithm to retrieve the vertical
204 profiles of aerosol extinction coefficient (AEC) from MPL data (e.g., Fernald, 1984;
205 Klett, 1985; Liu et al., 2012). The Klett method is further used to retrieve extinction
206 profiles (Klett, 1985). The column-averaged extinction-to-backscatter ratio (the so-
207 called lidar ratio) is an important parameter in the retrieval process and is constrained
208 using AERONET-derived AOD at $0.5 \mu\text{m}$. The AEC is assumed to be equal within the
209 blind zone. The overall uncertainties from the overlap function, the lidar ratio, the
210 effects of multiple scattering, and noise fall within the range of 20–30% in the retrieval
211 process (He et al., 2006).

212 **2.5. Estimation of the impacts of aerosols on buoyancy**

213 To show vertical profiles of aerosol radiative forcing, the Santa Barbara DISORT
214 Atmospheric Radiative Transfer (SBDART) model (Ricchiazzi et al., 1998) was used
215 to simulate the atmospheric heating rate (dT/dt) induced by aerosols (Liu et al., 2012;
216 Dong et al., 2017). Integrated aerosol inputs include AODs, SSAs (i.e., at 0.44, 0.67,
217 0.87, and $1.02 \mu\text{m}$) retrieved from AERONET measurements, and AEC profiles at 0.5
218 μm obtained from the MPL. We also use Moderate Resolution Imaging
219 Spectroradiometer surface reflectances as an additional input
220 (<https://modis.gsfc.nasa.gov/data/dataproduct/mod09.php>). We further use heating rates

221 induced by aerosols to estimate the impact of aerosols on buoyancy.

222 Theoretically, the rate of change in buoyancy for a certain layer is expressed as

$$223 \quad \frac{dB}{dt} = \frac{d}{dt} \left(\frac{T_0 - \Gamma_d \Delta z - T}{T} g \right) = \frac{\left(\frac{dT_0}{dt} - \frac{dT}{dt} \right) T + \frac{dT}{dt} (\Gamma_d - \Gamma) \Delta z}{T^2} g \quad , \quad (2)$$

224 where most parameters are defined in the same way as in Eq. (1), and Γ_d (Γ)
225 represents the dry adiabatic lapse rate (environmental lapse rate). We primarily focus
226 on the rate of change in buoyancy during the noontime period (1100–1500 LT), when
227 the PBL is well developed, and aerosol radiative forcing is strong. The rate of change
228 in buoyancy (dB/dt) induced by aerosols is largely determined by the aerosol heating
229 rate, which can be produced by the radiative transfer model. Additional inputs include
230 the environmental lapse rate and temperature, obtained from noontime RS soundings in
231 the summer. For other times, the environmental lapse rate and temperature are obtained
232 from MERRA-2 reanalysis data, which assimilates coarse-resolution RS observations
233 (Rienecker et al., 2011). In this way, we can estimate dB/dt induced by aerosols with
234 a primary focus on the daytime. Note that the errors in MERRA-2 data lead to
235 uncertainties in the estimated dB/dt . A 1–3 K uncertainty in MERRA-2 temperatures
236 (Gelaro et al., 2017) leads to 1–3% relative biases in the estimated dB/dt . Considering
237 the large variation in dB/dt for different aerosol structures, the biases resulting from
238 MERRA-2 data are not a serious issue.

239

240 3. Results

241 3.1. Classification of different aerosol structure scenarios

242 By altering the adiabatic heating rate of the atmosphere, the aerosol vertical
243 distribution is of great importance to the PBL. Based on cloud-free AEC profiles in the
244 PBL, aerosol vertical structures can be classified into three types: well-mixed,
245 decreasing with height, and its inverse, increasing with height. If AEC varies by less
246 than 20% within the lowest 80% of the PBL, it is considered a well-mixed structure.
247 For the other cases, a decreasing structure indicates a peak in AEC near the surface, and
248 the inverse structure indicates a peak in AEC in the middle or upper PBL.

249 To investigate the vertical variation in AEC within the PBL, the evolution of the
250 PBLH has to be taken into account. Following previous studies (Ferrero et al., 2014;
251 Kuang et al., 2017), vertical profiles were normalized by introducing a standardized
252 height (H_s), calculated as follows:

$$253 \quad H_s = \frac{z - PBLH}{PBLH}, \quad (3)$$

254 where z is the height above the ground, and H_s is 0 at the PBL top and -1 at ground
255 level. Figure 4 shows the normalized vertical profiles of AEC derived from MPL data
256 for different aerosol structures around noontime. The number of samples and
257 percentages of decreasing, well-mixed, and increasing aerosol structures are 998 (51%),
258 611 (32%), and 330 (17%), respectively. Since a temperature inversion located at the
259 PBL top traps moisture and aerosols, there is a sharp decrease in the AEC profile from
260 the PBL upper boundary to the free atmosphere. Variations in the aerosol vertical
261 distribution largely depend on different conditions, but share similar features among the

262 different aerosol structure patterns. Despite complex aerosol vertical distributions, these
263 three types of profiles can account for most of the cloud-free cases.

264 **3.2. PBLH and PM_{2.5} under different aerosol structure scenarios**

265 Absorbing aerosols tend to have a positive feedback with the PBLH, and the
266 aerosol vertical distribution plays a critical role in this process. We investigate the
267 relationship between MPL-derived PBLH and PM_{2.5} for absorbing (daily average
268 SSA \leq 0.85) or weakly absorbing (daily average SSA $>$ 0.9) aerosols for
269 increasing/decreasing aerosol structures during 0900–1900 LT (Figure 5). The PBLH-
270 PM_{2.5} relationships can represent the intensity of the aerosol-PBL interaction. In general,
271 there are stronger correlations between PBLH and PM_{2.5} for the inverse aerosol
272 structure. This is likely caused by substantial heating in the upper PBL, facilitating the
273 formation of a temperature inversion and further increasing the stability of the PBL.
274 For the decreasing aerosol structure, aerosols may not significantly redistribute
275 adiabatic energy. Hence, the PBLH-PM_{2.5} correlation is relatively weak. Significant
276 PBLH-PM_{2.5} correlations are found for both absorbing and weakly absorbing cases,
277 indicating that scattering aerosols may also play an important role in the aerosol-PBL
278 interaction, especially for the inverse aerosol structure.

279 Figure 6 presents the averaged diurnal cycles of AEC, PBLH, and PM_{2.5} for
280 different aerosol vertical structures, classified based on the average AEC profiles during
281 noontime. High humidity cases (surface relative humidity $>$ 90%) and strong wind cases
282 (wind speed $>$ 5 m s⁻¹) are excluded. Here, both AEC and PBLH are derived from MPL
283 data. Data are collected on 371 available days, of which 191 days have decreasing

284 aerosol structures, 122 days have well-mixed aerosol structures, and 58 days have
285 inverse aerosol structures. Multiple entangled factors can contribute to the formation of
286 different aerosol structures within the PBL, including synoptic patterns, new particle
287 formation, vertical turbulence, horizontal transport, entrainment rates, to name a few.
288 In general, the inverse structure is characterized by higher aerosol loadings and lower
289 PBLHs, whereas the decreasing structure is characterized by light pollution and a well-
290 developed PBL. In theory, $PM_{2.5}$ should generally decrease with increasing PBLH in
291 the morning due to the dilution effect. This situation is demonstrated clearly for
292 decreasing aerosol structures. However, $PM_{2.5}$ continuously grows during the daytime
293 when an inverse aerosol structure is present, regardless of the PBLH diurnal cycle. Even
294 though many factors control the diurnal variations in aerosols and the PBL, the strong
295 aerosol-stability interaction generates an unfavorable condition for the vertical
296 dissipation of aerosols, so the surface aerosol loading can continuously accumulate due
297 to emissions.

298 The correlations and statistical results concerning the PBLH and $PM_{2.5}$ provide
299 hints about the differences in aerosol-PBL interactions for different aerosol structures.
300 However, these results cannot explain the feedback loop and causality. Therefore, we
301 further use the SBDART model with the constraint of ample observations to investigate
302 the vertical profiles of radiative forcing induced by aerosols and its impacts on
303 atmospheric stability.

304 **3.3. Aerosol radiative forcing for different aerosol structures**

305 Following the description in Section 2.5, we calculate the statistical means of

306 aerosol radiative forcing in the vertical for decreasing, well-mixed, and inverse aerosol
307 structures, derived from the cases presented in Figure 6. Figure 7 shows that the vertical
308 distributions of the heating rate differ drastically among the different aerosol structures.
309 For the inverse aerosol structure scenario, aerosols cause substantial heating in the
310 upper PBL, facilitating the formation of a temperature inversion and further increasing
311 the stability in the PBL. For the decreasing aerosol structure scenario, the abundance of
312 aerosols at the bottom of PBL heats the lower PBL so can potentially enhance
313 convection in the PBL.

314 There are considerable differences in heating rate among the three distinct aerosol
315 structures (Figure 8), which affects the atmospheric buoyancy and stability differently.
316 On average, aerosols generally suppress buoyancy in the lower atmosphere. Such an
317 effect is quite notable for the inverse structure and is insignificant for the decreasing
318 structure with large standard deviations. Absorbing aerosols are not very helpful for
319 stabilizing the lower atmosphere when a decreasing aerosol structure is present, but
320 they play an important role when an inverse aerosol structure is present. As such, we
321 expect the strongest aerosol-PBL interaction to occur for absorbing aerosol cases when
322 an inverse aerosol structure is present, consistent with the results shown in Figure 5.

323 Figure 9 shows schematic diagrams of the interactions between aerosols, stability,
324 and the PBL when decreasing/inverse aerosol structures are present. Overall, both
325 decreasing and inverse aerosol structures can cool the surface and suppress sensible
326 heat, thus stabilizing the PBL. In both cases, aerosols have notable stabilizing effects
327 near the surface.

328 When a decreasing aerosol structure is present, abundant aerosols near the surface
329 generate a stronger aerosol heating rate in the lower PBL than in the upper PBL. Such
330 aerosol radiative forcing lowers the potential temperature gradient ($d\theta/dz$) in the
331 middle and upper PBL and can further strengthen vertical convection in the middle and
332 upper PBL. The opposite aerosol effects on PBL stability lead to a relatively weak
333 aerosol feedback and a relatively weak aerosol-PBL interaction. When an inverse
334 aerosol structure is present, the significant heating effect on the upper PBL facilitates
335 the formation of temperature inversion and further increases the stability and suppresses
336 the PBLH. The notable increase in stability lead to the strong, positive aerosol feedback.

337 Highly variable aerosol vertical distributions cause large variations in the impact
338 of aerosol on stability, and thus, exert important and highly variable influences on the
339 aerosol-PBL interactions. Although aerosol stabilize PBL for majority cases, aerosol
340 also can suppress the stability in low-atmosphere when aerosol heating effect is much
341 stronger on the near surface than upper PBL, and further lead to a potential negative
342 feedback loop. The positive feedback loop leads to strong aerosol-PBL interactions,
343 whereas negative feedback loop leads to weak aerosol-PBL interactions. It explains the
344 paradox of the different correlations between PBLH and surface pollutants since its
345 magnitude, significance, and even sign reportedly varies or even reverses (Quan et al.,
346 2013; Tang et al., 2015; Geiß et al., 2017; Su et al., 2018).

347

348 **4. Summary and Discussion**

349 Based on integrated aerosol and meteorological measurements made in Beijing, the

350 aerosol-PBL interaction is assessed for different aerosol vertical structures, i.e.,
351 decreasing, well mixed, and inversely increasing with height. The aerosol-PBL
352 relationships and the diurnal cycles of PBLH and $PM_{2.5}$ show distinct characteristics
353 among the different aerosol vertical patterns. For the decreasing aerosol structure, $PM_{2.5}$
354 decreases in the morning with relatively large PBLH growth rates. In this situation,
355 absorbing aerosols are not very helpful in stabilizing the lower atmosphere. For the
356 inverse aerosol structure, $PM_{2.5}$ continuously grows during the daytime with relatively
357 low PBLH growth rates. This phenomenon could be a sign of a strong aerosol-PBL
358 interaction. The aerosol radiative forcing in the vertical for decreasing, well-mixed, and
359 inverse aerosol structures differ drastically with strong heating in the lower, middle, and
360 upper PBL, respectively. Such a difference in heating rate affects the atmospheric
361 buoyancy and stability differently in the three distinct aerosol structures.

362 Turbulent fluxes and eddies in the PBL would spread out and redistribute the
363 radiative effects induced by aerosols. Needed are numerical models to quantify the
364 aerosol-PBL interaction and consequent feedbacks (e.g., Y. Wang et al., 2013; Ding et
365 al., 2016; Z. Wang et al., 2018; Zhou et al., 2018). Aerosol vertical distributions greatly
366 vary on both temporal and vertical scales and critically affect aerosol radiative effects.
367 However, the aerosol vertical distribution is still poorly represented in numerical
368 models, partly due to a lack of observational constraints. This study reveals the
369 important role of the aerosol vertical distribution in the aerosol-PBL interaction, which
370 should be carefully taken into account in both observational analyses and model
371 simulations.

372 This study used column-averaged aerosol properties from AERONET. However,
373 the vertical variations in SSA and aerosol type remains unknown, inducing uncertainties
374 in the estimation of aerosol effects. In the future, we plan to use aircraft data from field
375 campaigns to better account for the influence of different types of aerosols with
376 different properties.

377

378 *Data availability.* Hourly PM_{2.5} data are released by the Ministry of Environmental
379 Protection of China (<http://113.108.142.147:20035/emcpublish>). MERRA-2 reanalysis
380 data are publicly available at
381 <https://disc.gsfc.nasa.gov/datasets?keywords=merra%202&page=1>. AERONET data
382 are publicly available at <https://aeronet.gsfc.nasa.gov>. Meteorological data are provided
383 by the data center of the China Meteorological Administration (<http://data.cma.cn/en>).
384 Other data used in this study are available upon the request from the leading author
385 (tianning@umd.edu).

386

387 *Author contribution.* T. S. and Z. L. conceptualized this study. T. S. carried out the
388 analysis, with comments from other co-authors. C. L., J. L., and W. T. carried out the
389 MPL observations. J. G. provided auxiliary data. W. H., C. S., W. T., J. W., and J. G.
390 provided useful suggestions for the study. T. S. and Z. L. interpreted the data and wrote
391 the manuscript with contributions from all co-authors.

392

393 *Competing interests.* The authors declare that they have no conflict of interest.

394

395 *Acknowledgements.* This study is supported by the Department of Energy (DOE)
396 Atmospheric System Research program (DE-SC0018996) and the National Science
397 Foundation (AGS1837811 and AGS1534670). The authors would like to acknowledge
398 Prof. Zhengqiang Li for his effort in establishing and maintaining the Beijing RADI
399 AERONET site. We thank the provision of PM_{2.5} data by the Ministry of Environmental
400 Protection of the People's Republic of China and also thank the provision of
401 meteorological and radiosonde data by the China Meteorological Administration. We
402 extend sincerest thanks to the MERRA team for their datasets.

659 **Figure 2.** (a) Averaged vertical profiles of buoyancy forcing in stable, neutral, and
 660 convective PBLs. (b) Height-dependent correlation coefficients between buoyancy and
 661 PBLH. (c) Height-dependent correlation coefficients between buoyancy and surface
 662 $\text{PM}_{2.5}$. Note that the PBLH and surface $\text{PM}_{2.5}$ are fixed for the entire column, and the
 663 buoyancy is height dependent. The buoyancy in the lower atmosphere (< 1 km) has the
 664 most important impact on the PBLH and surface $\text{PM}_{2.5}$. The buoyancy and PBLH are
 665 calculated from RS measurements made at 1400 LT and 2000 LT from 2011 to 2018.

675

676 **Figure 3.** (a) The relationship between lower-atmosphere buoyancy (LAB) and $PM_{2.5}$.

677 (b) The relationship between LAB and $PBLH$. (c) The relationship between absorbing

678 aerosol optical depth ($AAOD$) and LAB . In (a, b, c), the LAB and $PBLH$ are derived

679 from RS measurements made at 1400 LT and 2000 LT, and $AAOD$ is derived from

680 $AERONET$ measurements. The black solid lines indicate the best-fit lines from linear

681 regression. (d) Comparison of $PBLH$ s derived from the MPL and RS at 1400 LT. Each

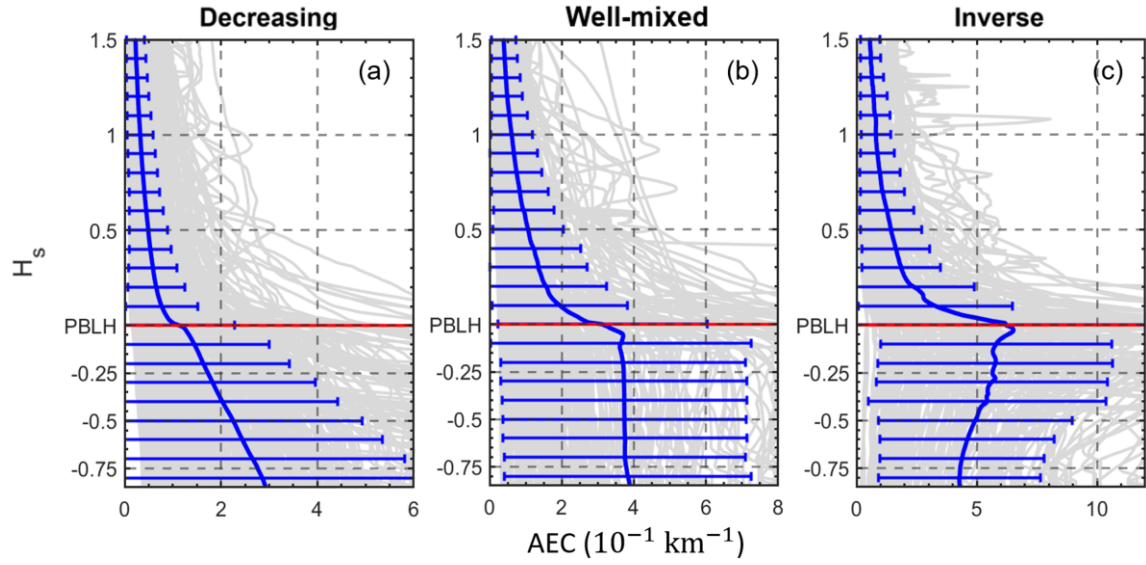

682 panel gives the correlation coefficients (R), sample number (N), and root-mean-square

683 error ($RMSE$). R with an asterisk indicates that the correlation is statistically significant

684 at the 99% confidence level. The color-shaded dots indicate the normalized sample

685 density.
