21

22 **Abstract.** Characterizing vertical profiles of aerosol optical properties is important because only relying
23 on the surface or column-integrated measurements is unable to unambiguously constrain the radiative
24 impacts of aerosol. This study presents series of vertical profiles of in-situ measured multi-wavelength
25 optical properties of aerosols during three pollution events in Nov. to Dec. 2016 over Beijing region. For
26 all pollution events, clean periods (CP) before pollution initialization showed higher scattering Ångström
27 exponent and smaller asymmetry parameter (g), and relatively uniform vertical structures. The heavy
28 pollution (HP) periods showed increased particle size, causing these parameters to vary in the opposite
29 way. During the transition periods (TP), regional transport of aged aerosols at upper level was found. The
30 AERONET aerosol optical depth (AOD) matched the in-situ measurements within 10 %, however the
31 AERONET absorption optical depth (AAOD) was 10-20 % higher than in-situ measurements, and this
32 positive discrepancy increased to 30 % at shorter wavelength. The absorption of brown carbon (BrC) was
33 identified by increased absorption Ångström exponent (AAE), and the heating rate of black carbon (BC)
34 and BrC was calculated by computing the wavelength-dependent absorption coefficient and actinic flux
35 by the radiative transfer model. BC and BrC had heating rate up to 0.18 K/h and 0.05 K/h in the planetary
36 boundary layer (PBL) respectively during the pollution period. The fraction of BrC absorption increased
37 from 12 % to 40 % in the PBL from CP to HP period. Notably, higher contribution of BrC heating was
38 found above the PBL under polluted condition. This study gives a full picture of shortwave heating
39 impacts of carbonaceous aerosols during different stages of pollution event, and highlights the increased
40 contribution of BrC absorption especially at higher level during pollution.

41

42 1. Introduction

43 The optical properties of aerosol, which is how aerosol scatters or absorbs solar radiation, have caused
44 important radiative impacts on earth system (IPCC2013). The optical properties depend on the particle
45 size (Bergin et al., 2001), refractive index (Ebert et al., 2002; Quinn, 2002) and mixing state of aerosols.
46 There are still large uncertainties in evaluating the radiative forcing of aerosol especially in east Asia
47 region due to lack of information on vertical distribution of these parameters (Liao and Seinfeld, 1998;
48 Ramanathan et al., 2001; Li et al., 2017). Previous studies showed that the surface observation or column-
49 integrated measurements may not provide sufficient information to derive vertical profiles of aerosol
50 optical properties (Andrews et al., 2011; Rosati et al., 2016). Modelling studies found the radiative forcing
51 impact is sensitive to the aerosol vertical distribution (Haywood et al., 1998), and especially for the
52 absorbing aerosol such as black carbon (BC) will exert different climatic impacts depending on the
53 location of aerosol layer (Yu et al., 2002; Ban-Weiss et al., 2011; Wilcox et al., 2016). Even though most
54 aerosol was contained inside the planet boundary layer (PBL), the climatic sensitivity to absorbing aerosol
55 rapidly increases with altitude (Ramanathan et al., 2001; Hodnebrog et al., 2014; Nazarenko et al., 2017).
56 Absorbing aerosol above the PBL has the potential to suppress the PBL development and enhance the
57 inversion cap at top of the PBL (Ding et al., 2016; Wang et al., 2018c), further execrating the pollution.
58 However, this impact depends on the location of the absorbing layer which may also promote the
59 convection by heating the layer above (Koch and Del Genio, 2010; Yu et al., 2019). It is therefore
60 important to characterize the vertical profile of absorbing component in the atmosphere in order to
61 understand its influence on atmospheric thermodynamics.

62 The North China Plain (NCP) has raised great attention in recent decade because of the severe air pollution
63 and high frequency of haze days. The causes of pollution have been widely investigated through surface
64 measurements (Zhang et al., 2013; Zhang et al., 2015; Zhong et al., 2018), however only limited studies
65 have considered the evolution of pollutants in vertical direction (Tian et al., 2019; Wang et al., 2018a). It
66 was found the surface aerosol concentration over Beijing not only depended on the emission but the
67 vertical structure of aerosol distribution was largely dependent on local and synoptic meteorological
68 conditions (Ran et al., 2016a; Zhao et al., 2019), and regional transport will introduce enhanced aerosol

69 loadings to high level (Liu et al., 2018). The vertical distribution of aerosol optical properties, however
70 have not been in detail investigated, which will provide important insights to improve the understanding
71 on the aerosol-PBL interactions hence the causes of pollution (Li et al., 2017).

72 This study chose three typical pollution events occurring in wintertime over Beijing, and performed
73 successive flights on daily basis for each event. The vertical profiles of multi-wavelength aerosol optical
74 properties were in-situ characterized, accounting for all stages during pollution events from pollution
75 starts, full development and cease. The directly measured optical parameters were used as inputs for
76 radiative transfer calculation, hereby the heating rate of light-absorbing aerosols, including black and
77 brown carbon (BrC) was estimated. The results here for the first time provide a full picture of vertical
78 profiles of aerosol optical properties over Beijing region during the heavy pollution events.

79 **2. Instrumentation and data analysis**

80 A Kingair 350ER turbo aircraft in Beijing weather modification office was employed for the in-situ
81 measurements over Beijing during the 2016 winter in this study. Meteorological parameters including the
82 temperature, relative humidity, pressure, wind direction and wind speed with a time resolution of 1 s were
83 measured by the Aircraft Integrated Meteorological Measurement System (AIMMS-20, Aventech
84 Research Inc, Canada), which was calibrated annually. The aerosol instrumentation inside the cabin was
85 connected to an isokinetic inlet (Model:1200, Brechtel Inc, USA), which can deliver particle with a high
86 transport efficiency (90%) for sub-micrometer particles. The maintained room temperature in the cabin
87 had drying effects when the temperature inside was higher than outside the cabin, in addition to which, a
88 silicate direr was utilized ahead of all instruments to maintain the sampling RH lower than 40%.

89 In-situ measurements of aerosol optical properties were performed during three pollution events over
90 Beijing in Nov. 15th to Dec. 21th 2016, including 14 flights covering the start, development and cease
91 stage for each pollution event. All flights were conducted around midday when the PBL was well
92 developed. Table 1 summarizes the information of each flight. The in-cloud data in this study was
93 screened out according to in-situ measured RH and liquid water content, thus only the out-of-cloud data
94 is reported here.

95 2.1 Aerosol optical properties

96 The aerosol scattering (σ_{sca}) and hemispheric backscattering (σ_{bsca}) coefficients at $\lambda=450$ nm, 525 nm, and
97 650 nm were measured by an integrating nephelometer (Aurora3000, Ecotech Inc, Australia), and the
98 flowrate of Aurora3000 was maintained at 4 L/min during flight. The baseline of Aurora3000 in real time
99 was corrected for Rayleigh scattering of gas molecule at different air pressure (Fig. S1). In addition, the
100 σ_{sca} and σ_{bsca} at all wavelengths were corrected for truncation affects (Anderson and Ogren, 1998; Müller
101 et al., 2009).

102 The scattering Ångström exponent (SAE) measures the wavelength dependence of σ_{sca} assuming a power
103 relationship with λ , expressed as:

$$104 \quad SAE = -\frac{\ln(\sigma_{\lambda_1}/\sigma_{\lambda_2})}{\ln(\lambda_1/\lambda_2)}, \quad (1)$$

105 where σ_{λ_l} denotes the σ_{sca} at λ_l , the value of SAE could also be used to reflect particles size with larger
106 particles showing a smaller SAE (Carrico et al., 1998).

107 The asymmetry parameter (g) is obtained from measured backscattering fraction according to the
108 empirical function from Andrews et al. (2006).

$$109 \quad g = -7.143889 \cdot \beta^3 + 7.4633439 \cdot \beta^2 - 3.9356 \cdot \beta + 0.9893, \quad (2)$$

110 where β is the hemi-spherical backscatter fraction ($\sigma_{bsca}/\sigma_{sca}$) measured by the Aurora3000.

111 The absorbing coefficient (σ_{abs}) at different wavelengths (370, 470, 520, 590, 660, 880, and 950nm) was
112 measured by an Aethalometer (AE33, Magee Scientific Inc, USA) (Hansen, 2005; Drinovec et al., 2015).
113 The flowrate of AE33 was maintained at 4 L/min below 3000 m. The shadowing effect of the AE33 was
114 corrected by the two spot measurements with different attenuation (Drinovec et al., 2017). The multiple
115 scattering artifact of AE33 was corrected by measuring the ambient aerosol in parallel with photoacoustic
116 spectrometer (PASS3, DMT Inc, USA) which is independent of the filter artifacts. The PASS3 was
117 calibrated using the NO₂ and BC standard. (Arnott et al., 2005). Fig. S2 shows the two weeks' ambient
118 measurements between AE33 and PASS3 at three overlapped wavelengths. Multiple scattering correction
119 factor of 2.88 was consistently found at three λ , which was applied to correct the AE33 measurement.

120 The absorbing Ångström exponent (AAE), which can weight the absorption at different wavelength, is
121 calculated using power fitting at seven wavelengths.

$$122 \quad \sigma_{abs}(\lambda) = \sigma_{abs,0} \left(\frac{\lambda}{\lambda_0} \right)^{AAE}, \quad (3)$$

123 We estimated the σ_{abs} of brown carbon (BrC) assuming that BC is the only absorber at $\lambda=950$ nm, then
124 the absorption of BC at other wavelengths was extrapolated by assuming an AAE of 1 (Kirchstetter et al.,
125 2004; Lack et al., 2013; Massabò et al., 2015), and the contribution of BrC at each wavelength was
126 obtained by subtracting the BC absorption from the total absorption (Schnaiter et al., 2005; Liu et al.,
127 2015). It should be noted that previous studies point out the AAE_{BC} may be less than 1, thus assuming
128 $AAE_{BC}=1$ may lead to underestimation of BrC contribution (Gyawali et al., 2009; Lack and Cappa, 2010;
129 Feng et al., 2013). We therefore consider the results reported here is the lower bound of BrC contribution.

130 The single scattering albedo (SSA) is the ratio of the scattering coefficient over the extinction coefficient
131 (σ_{ext}) at a given wavelength.

132 All the data related to volume concentration was corrected for standard temperature and pressure (STP,
133 1013.25hpa , 273.15K). In addition to the aircraft measurements, a micro pulse lidar (MPL, Sigma Inc,
134 USA) was employed to measure the temporal evolution of aerosol extinction vertical profiles, and the
135 vertical wind profile was measured by a wind profile radar with a vertical resolution of 150 m. Column
136 aerosol optical properties during the aircraft observation period were obtained from Aerosol Robotic
137 Network (AERONET) sun-photometer network (Che et al., 2009; Xia et al., 2008), where the site
138 (AERONET BEIJING_PKU) was about 10 km away from the location of vertical profiles.

139 **2.3 Radiative transfer calculation**

140 The atmospheric irradiance and actinic flux are calculated using the pseudo-spherical version of the
141 Discrete Ordinates Radiative Transfer Code (DISORT), as implemented in the libRadtran software
142 package (Emde et al., 2016). The aircraft in-situ measured vertical profiles of AOD, single scattering
143 albedo (SSA) and g are used as inputs. The other input parameters for the radiative transfer calculation is
144 summarized in Table S1. The direct, upward diffuse, and downward diffuse irradiance and actinic flux

145 (AF, in mWm^{-2}) at $\lambda=250\text{-}2550$ nm are calculated. The spectral instantaneous absorbing power of BC
146 (A_{BC}) or BrC (A_{BrC}) can be calculated by multiplying the absorption coefficient of BC (or BrC) and AF at
147 specified λ , then integrating all λ will obtain the total absorbing power, expressed as:

$$148 \quad A_{BC \text{ or } BrC} = \int_{250\text{nm}}^{2550\text{nm}} AF(\lambda) \cdot \sigma_{BC \text{ or } BrC}(\lambda) d\lambda, \quad (4)$$

149 By assuming no radiative loss of solar energy and the heat absorbed by aerosol is fully transferred to the
150 surrounding air, the instantaneous heating rate of BC or BrC to ambient air is hence calculated as:

$$151 \quad H_{BC,BrC} = A_{BC,BrC}/(\rho \cdot C_p), \quad (5)$$

152 where ρ and C_p are the air mass density and heat capacity, respectively.

153 3. Results and discussions

154 3.1 Overview and the pollution events

155 Three pollution events from Nov. 15th to 18th (Case 1), Dec. 10th to 12th (Case2), and Dec. 16th to 19th
156 (Case 3) in 2016 were captured. Fig. 1 shows the temporal evolution of surface $\text{PM}_{2.5}$, AOD (AAOD)
157 constrained by in-situ aircraft measurements and from AERONET, and vertical profiles of σ_{ext} and wind
158 information during Case 1 pollution event. The other two events are shown in Fig. S3 and Fig. S4. Aircraft
159 vertical profiles were performed on daily basis as the flight time indicated by vertical bars (Fig. 1). Each
160 pollution event was classified as pollution initialization, development and peak pollution periods,
161 corresponding to the pollution levels as clean period (CP, $\text{PM}_{2.5, \text{surface}} < 35 \mu\text{g}/\text{cm}^3$), transition period (TP,
162 $35 \mu\text{g}/\text{cm}^3 < \text{PM}_{2.5, \text{surface}} < 200 \mu\text{g}/\text{cm}^3$) and heavy pollution (HP, $\text{PM}_{2.5, \text{surface}} > 200 \mu\text{g}/\text{cm}^3$). For the
163 results here, a total of 14 profiles and 3, 5 and 6 profiles was observed for LP, TP and HP period,
164 respectively (as detailed in Table. 1). As Fig. 1b shows, wind shear in both wind speed and direction
165 appeared on top of PBL, consistent with the lidar vertical distribution of σ_{ext} (Fig. 1c). During LP, wind
166 profiles (Fig. 1b) showed dominant northwesterly wind with high wind speed throughout the column,
167 enhancing the pollutant dispersion in more developed PBL (Fig. 1c). During TP, the southerly air flow
168 dominated and the $\text{PM}_{2.5}$ underwent a rapid increase from 30 to $100 \mu\text{g m}^{-3}$ in several hours. During HP,
169 the windspeed was relatively low at all altitude, maintaining the $\text{PM}_{2.5}$ at a high level. Some flights

170 experienced boundary cloud (i.e., flight 20161117AM, flight 20161117PM and flight 20161118), which
171 is indicated by the intensive extinction on top of the PBL (Fig. 1c).

172 Fig. 2 summarized the in-situ measured meteorological parameters at different stages of pollution events.
173 The height of PBL (PBLH) was determined by considering a variety of factors. Firstly, a stable potential
174 temperature (θ) (Fig. 2d-f) with vertical gradient $d\theta/dz < 5$ K/km in the PBL indicated an sufficient
175 convective mixing (Su et al., 2017), with an apparent positive gradient above the PBL indicating a stable
176 layer (Petra Seibert, 2000). Secondly, there is usually a temperature inversion on top of the PBL (Fig. 2a-
177 c). During the CP, the weak temperature inversion (~ 0.15 K/100m) on top of the PBL allowed pollutants
178 to penetrate the PBL and disperse in a higher atmospheric column (Fig. 2b). This inversion was
179 significantly enhanced for the TP and HP periods, to 0.9K/100m and 0.7K/100m respectively. The large
180 increase of the inversion during flight 20161211 was caused by regional transport from the south, when
181 lower-latitude warmer air mass was imposed onto the measurement point (Tian et al., 2019). Additionally,
182 the PBLH decreased gradually as pollution continued during the pollution event, in line with the enhanced
183 aerosol concentration in the PBL. The moisture had similar features that a lower moisture content showed
184 when lower pollution level and vertically efficiently dispersed, whereas stronger inversion also trapped
185 the moisture inside the PBL, leading to a positive vertical gradient with the maximum RH showing on
186 top of the PBL. There were some regional transport influences under TP, resulting in enhanced RH when
187 air mass was advected from the south (Fig. 2f).

188 3.2 Vertical profile of σ_{ext} , σ_{sca} and σ_{abs}

189 Fig. 3 shows the vertical distribution of aerosol optical properties including extinction (σ_{ext}), scattering
190 (σ_{sca}) and absorbing (σ_{abs}) coefficient. Different structures of vertical profiles were observed for CP, TP
191 and HP periods. During CP, aerosol concentration was low and showed uniform mixing inside the PBL,
192 with the σ_{ext} , σ_{sca} and σ_{abs} ranging from 220-270 Mm^{-1} , 180-240 Mm^{-1} , and 30-50 Mm^{-1} , respectively. The
193 backward trajectories for the CP showed that the air masses were from the northwestern low emission
194 region (Fig. S5). TP showed about 4-fold increase of σ_{ext} compare to the CP. During TP, the σ_{ext} , σ_{sca} and
195 σ_{abs} had large variation inside the PBL, ranging from 325-1435 Mm^{-1} , 300-1275 Mm^{-1} , and 45-160 Mm^{-1} ,
196 respectively, and the mean PBLH decreased to 200-500 m. During these pollution accumulation periods

197 (before the pollution reached peak level), two contrast vertical structures showed. One showed well-
198 mixing in the PBL but declined concentration in the free troposphere (FT) (e.g. flight 20161115PM and
199 20161210) (Fig. 3a). The other one had the increased aerosol layer on top of the PBL, and showed positive
200 vertical gradient for all optical properties at certain level (e.g. flight 20161116 AM, 20161211 and
201 20161216) (Fig. 3b). The former was because of the mostly cleaner northwesterly air mass and higher
202 wind speed influencing the layer above the PBL, while the latter resulted from the southwesterly regional
203 transport (Tian et al., 2019).

204 During HP period, most flights showed consistent exponentially-declined vertical profile patterns, and
205 the PBLH was even lower than that in TP (Fig. 2f). The stronger temperature inversion (Fig. 2c) and lower
206 wind speed (Fig. 1b) inside the PBL led to high stability of the PBL and promoted the pollutant
207 accumulation. The aerosol concentration was largely enhanced towards the surface and sharply declined
208 above the PBL. Interestingly, the absorption showed higher degree of negative vertical gradient than the
209 scattering at $\lambda=440\text{nm}$, which reflected the different sources and mixing ratios of absorbing and non-
210 absorbing aerosols. The surface emission tends to contain more primary sources of absorbing particles
211 such as BC and BrC, while enhanced secondary aerosol formation at upper level may add additional
212 aerosol extinction.

213 The vertical profiles of σ_{sca} and σ_{abs} during HP can be fitted as:

$$214 \quad \sigma_{sca} = \sigma_{sca,0} \cdot \exp(-a * H); \quad a = 0.0012 \pm 0.0001, \quad (6)$$

$$215 \quad \sigma_{abs} = \sigma_{abs,0} \cdot \exp(-b * H); \quad b = 0.0015 \pm 0.0001, \quad (7)$$

216 where σ_0 represent the surface value of σ_{sca} and σ_{abs} , and H is the altitude. The a and b are the parameter
217 define the changing rate with the altitude. This parameterization could be used to represent the vertical
218 structure of optical properties under heavy pollution condition.

219 **3.3 Vertical profile of SSA, SAE, AAE and g**

220 Fig. 4 shows the vertical profiles of aerosol single scattering albedo (SSA) for all the flights under
221 different stages of pollution events. Overall, the SSA showed two modes inside the PBL. Under the CP,

222 SSA for most flights was populated at 0.85, and had less variation throughout the column in the PBL.
223 Flight 20161115AM showed a strong elevation of SSA (0.94) at 2200 m (Fig. 4a), which may be
224 influenced by a dust layer (as further discussed in the following). SSA showed positive vertical gradient
225 for the TP and HP inside the PBL, i.e. from the surface to the PBLH, the mean SSA increased from 0.85
226 to 0.91 and from 0.87 to 0.92 for TP and HP period, respectively. This indicates the reduced fraction of
227 absorbing particles, in turn suggesting an enhancement of secondary production of non-absorbing
228 particles. There were a few profiles featuring with large enhancement of SSA (>0.95 , for flight 20161211)
229 at high altitude (Fig. 4b), and backtrajectory analysis (Fig. S5) showed that these resulted from regional
230 transport when more aged pollutants were advected to a high altitude. The SSA in the FT was mostly
231 higher than that in the PBL and maintained at 0.9-0.95 for TP and HP, meaning a lower absorbing particle
232 fraction at higher altitude. Comparing among different stages during pollution event, it could be
233 concluded that at the initialization stage of pollution when the total PM was relatively low, a lower SSA
234 exhibited, while the increase of pollution level added more secondary species, hence increasing SSA. This
235 trend consistent with previous ground studies in Beijing (He et al., 2009; Jing et al., 2011).

236 The SAE reflects the particle size with larger size having a smaller SAE. A decreasing SAE was shown
237 for increasing pollution levels inside the PBL (Fig. 4), i.e., from CP to HP, the SAE in the PBL showed
238 an average value of 1.74, 1.45, and 1.21, respectively. For most of the profiles, SAE showed enhancement
239 at higher altitude. This means smaller particle sizes at high level, which may result from a higher
240 scavenging efficiency for larger particles where smaller particle remained un-scavenged in the upper level
241 (Liu et al., 2009). These was exception for flight 20161211, when regional advection transported larger
242 and aged particles to the higher altitude. The particle size also corresponded with asymmetry parameter
243 (g , Fig. 4j-i), with larger particle presents more fraction of forward scattering (larger g).

244 AAE reflects the degree of absorption towards shorter wavelength, such as the presence of BrC will
245 enhance the absorption in the UV. A lower AAE 1.2 ± 0.2 was shown for the CP (Fig. 4g), but increased
246 to 1.56 ± 0.3 for TP in the PBL (Fig. 4h), and additional higher mode of AAE showed at 1.8-2.0 for the
247 HP period (Fig. 4i). There was weak variation of AAE for CP throughout the column, but became largely
248 spreading for TP, i.e., with either positive or negative vertical gradient at different levels. Notably, the
249 AAE showed consistent positive vertical gradient for most of the HP profiles (Fig. 4i). This implied the

250 enhancement of BrC contribution at higher altitude for polluted troposphere. Flight 20161115AM showed
251 a notably increased AAE up to 2 at altitude 2 km (Fig. 4g), which may reflect the influence from dust
252 (Cazorla et al., 2013). The ground AAE had strong seasonal variation with winter normally showing a
253 higher AAE due to higher emissions of solid fuel burning (Sun et al., 2017; Wang et al., 2018b). However,
254 there is still lack of results on the vertical characteristics of AAE due to limited measurements, and the
255 results here highlight the enhancement of BrC at high level, mainly for polluted environment.

256 **3.4 Comparison of column integrated and in-situ constrained AOD/AAOD**

257 To compare the AOD and AAOD between AERONET and that constrained by aircraft in-situ
258 measurements, the AERONET data was chosen to match with the aircraft profiles in time (± 3 h) and
259 location (within 10 km) (the PEK site). The comparison was performed at overlapped wavelength (440nm,
260 675nm, and 870nm) between AERONET and aircraft instruments. As Fig. 5a-c shows, high correlation
261 ($R^2 > 0.95$) was found between columnar and in-situ measurement. In particular, the correlation was most
262 unit under dry condition ($RH < 40\%$), while the AERONET was about 10-20% higher than in-situ
263 measurement when $RH > 60\%$. Improved agreement between both may be achieved by considering the
264 particles hygroscopic growth, which requires composition measurement to constrain this factor but this
265 was not available in this study.

266 Fig. 7d-f shows at three wavelengths the AAOD had lower correlations between both methods compare
267 to AOD, with $R^2 = 0.75, 0.58,$ and 0.49 at 440 nm, 675 nm, and 870nm, respectively. The columnar AAOD
268 was overall about 10-25 % higher than in-situ measurement. This is consistent with previous findings that
269 the retrieved AAOD from AERONET was biased higher when compared to in-situ measurement
270 (Andrews et al., 2017). Note that there was better agreement during CP, when lower pollution level and
271 lower RH (shown in blue dots). This suggests a lower moisture and less AOD interface may improve the
272 agreement of AAOD. As previous studies pointed out that the retrieval of the AERONET was sensitive to
273 the variation of aerosol vertical distribution (Torres et al., 2014). We speculate that the better agreement
274 for CP was due to the vertically homogeneous distribution of aerosol optical properties, and larger bias
275 for CP and HP periods might be caused by the significant variations of the vertical profiles. Other factors
276 like the particle hygroscopic growth under higher RH may introduce factors in enhancing the absorption,

277 e.g. more lensing effect on BC absorption via thicker and moisture coating (Wu et al., 2017). Though this
278 study is not able to rule out the exact influencing factor in causing this discrepancy, a 25 % overestimation
279 of the AERONET AAOD under polluted condition was shown for the dataset here.

280 **3.5 Heating impacts of BC and BrC**

281 Fig. 6 showed vertical profiles of irradiances from radiative transfer calculation using in-situ
282 measurements as model inputs (Table S1). The results show that the presence of aerosols reduced the
283 direct irradiance reaching the surface (Fig. 6a-c) but increased the upward diffuse (Fig. 6d-f) and
284 downward diffuse irradiances, especially above the PBL (Fig. 6g-i). The direct irradiance on the surface
285 ranged from 1×10^9 to 3.5×10^9 mW m⁻², with an average of 2.2×10^9 mW m⁻² during CP (Fig. 6a), which
286 was about two-fold and three-fold larger than that during TP (Fig. 6b) and HP period (Fig. 6c), respectively.
287 The combined direct, diffuse upward and downward irradiance which forms the actinic flux (AF), showed
288 enhancement above the PBL and reduced within the PBL (Fig. 7a-c), but to what extent the enhancement
289 or reduction occurred depends on the aerosol vertical profile. The vertical gradient of AF was slightly
290 modified by aerosol loadings during CP, whereas for the TP and HP, aerosol effects caused AF about two
291 times smaller within the PBL and 20 % larger above the PBL, leading to an increased vertical gradient of
292 AF.

293 The vertical profiles of absorbing power and heating rate of BC are shown in Fig. 7d-f. The results
294 indicated that the atmospheric heating of BC was mainly inside the PBL for all cases, but exhibited
295 different vertical structure for CP (Fig. 7d), TP (Fig. 7e), and HP period (Fig. 7f). Vertically
296 homogeneously BC heating rates of 0.05 K/h was found inside the PBL during CP (Fig. 7d). During the
297 regional transport cases (flight20161211 and flight20161216) for TP, positive vertical gradient (increase
298 with increasing altitude) of BC heating rates was observed, and as high as 0.1 K/h heating rate could occur
299 at top of the PBL height (Fig. 7e). During the HP period, negative heating rate (decrease with increasing
300 altitude) of BC was found except from one flight on 20161212 in Case 2, and the BC heating rate at the
301 surface could reach as high as 0.15 K/h (Fig. 7f). The reason causing negative vertical gradient of BC
302 heating rate was the higher degree of negative gradient of σ_{abs} (Fig. 3i) than the positive gradient of AF
303 (Fig. 7).

304 The contribution of BrC to absorbing power and heating rates was computed as the integrated portion of
305 absorption over visible wavelength (370–950nm in this study) by subtracting the BC absorption. Fig. 7g-
306 i shows the vertical profile of BrC heating rate. Continuously increase of BrC heating rate in the PBL was
307 observed from CP to HP, with mean heating rate of 0.02 K/h, 0.03 K/h, and 0.05 K/h during CP, TP and
308 HP respectively. Though the BC was the main contributor to the heating in the PBL, the heating of BrC
309 was more evenly distributed and could be comparable with the BC heating rate at high altitude especially
310 during HP period (Fig. 7i).

311 The vertical gradient of the overall heating rate from absorbing components, i.e. increase or decrease
312 heating rate with altitude, will importantly determine the influence on atmospheric stability. If the heating
313 occurred near surface (Case 3), the lower layer will be heated leading to enhanced convective mixing
314 (Sühring et al., 2014;Petaja et al., 2016); whereas if heating above the PBL (Case 2), an increase of
315 temperature inversion will occur hence inhibiting the PBL development trapping the pollutants in the PBL
316 (Wilcox et al., 2016).

317 **3.6 The importance of BrC heating effects**

318 Fig. 8 shows the measured absorption coefficient of BrC and BC inside and above the PBL at different λ
319 for CP, TP and HP period, respectively. The results suggested that both σ_{abs} of BC and BrC increased with
320 the pollution level, e.g. the σ_{abs} at $\lambda=440\text{nm}$ was 42.8 Mm^{-1} and 7.2 Mm^{-1} on average in the PBL and
321 above the PBL respectively under HP period, and was 4.7 Mm^{-1} and 1.3 Mm^{-1} for LP. The contribution of
322 BrC to total σ_{abs} was found to increase from CP to HP period (Fig. 8c, f). This is in line with previous
323 studies in urban Beijing that more BrC contribution to total absorption was found under higher pollution
324 level (Xie et al., 2019;Ran et al., 2016b), suggesting the important role of BrC on absorption under
325 polluted condition.

326 The BrC contribution to total heating rate showed notably different vertical structures. During CP, all
327 profiles showed consistently low BrC contribution throughout the column, with about 7 % at the surface
328 and 9 % in the FT (Fig. 8g). This means the low primary emission or the emission after being diluted by
329 clean air mass had not contained important fraction of absorbing organics. During TP, BrC contribution

330 inside the PBL increased to 22 % and showed considerable variation at higher level (Fig. 8h). During HP
331 period, the surface contribution was comparable with that in TP, but showed remarkably enhanced BrC
332 heating contribution at higher altitude, with a vertically increasing rate of 1.5 %/m in the PBL and reached
333 as high as 45 % in the LFT. The higher heating contribution of BrC at higher altitude means the BrC
334 absorption played an important role in heating at upper level, which may enhance the temperature
335 inversion at the level hereby inhibiting the convective mixing under the heated layer.

336 By comparing the BrC heating contribution at the surface, there was an increase from CP to TP, however,
337 not from TP to HP. This suggests the primary emission will increase the BrC fraction from CP to TP, but
338 for even more pollution environment from TP to HP, the primary emission may provide limited further
339 increased fraction of BrC. The primary BrC may result from a range of combustion sources, with the
340 polluted region at the south of Beijing may contain higher fraction of residential coal burning sources
341 (Sun et al., 2017; Xie et al., 2019) which may influence the Beijing region under polluted period. The
342 relatively consistent BrC contribution at ~20 % from TP to HP suggested the relatively uniform BrC
343 profiles for the primary sources. During TP, the BrC contribution above the PBL had rarely been above
344 30 % (Fig. 8h), however during HP, there was further enhancement of BrC contribution up to 45 % above
345 the PBL (Fig. 8i). Note that there was no direct injection of biomass burning plume to the high altitude
346 during the study period, the higher portion of BrC absorption above the PBL during HP may be formed
347 through secondary production in addition to the primary source contribution. As Fig. 7a-c shows, there
348 was more intensive actinic flux received at higher altitude and this will promote the photochemical
349 reactions of gas-phase species, allowing more secondary formation of aerosol which may contain a
350 fraction of BrC (Feng et al., 2013; Nakayama et al., 2013). Previous studies also found promoted BrC
351 formation with light source under certain RH (Nguyen et al., 2012; Updyke et al., 2012; Laskin et al.,
352 2015; Zhao et al., 2015). The positive gradient of BrC heating contribution more likely resulted from
353 enhanced RH from the surface to the top of PBL (Fig. 2i), because increased moisture will promote the
354 aqueous reaction and gas-to-aerosol conversion which may also form part of the BrC observed here
355 (Ervens et al., 2011; Nakayama et al., 2013). The secondary formation of BrC also requires the inorganic
356 or VOC precursors being transported to the high level, therefore the enhancement of BrC mostly occurred
357 under higher pollution level when sufficient gas precursors was transport to the level. The BrC may be

358 also subject to bleaching process and lose the absorbance (Sareen et al., 2013; Lee et al., 2014; Wong et
359 al., 2019), because the profiles in this study were conducted over an urban megacity where the sampled
360 pollutants were fairly young and may have not experienced sufficient ageing time for BrC to be degraded.

361 **4. Conclusions**

362 This study provides detailed characterization of vertical profiles of aerosol optical properties over the
363 Beijing region by continuous aircraft in-situ measurements at different stages during the pollution events.
364 The results combining the direct measurements of scattering and absorption at multiple wavelength, give
365 a full picture of how the optical properties had evolved at different layers during typical pollution event.
366 During clean period for pollution initialization (CP), the aerosols showed relatively uniform
367 characteristics throughout the planetary boundary layer (PBL) and lower free troposphere (FT), such as
368 lowing scattering or absorption coefficient, larger SAE (due to smaller particle size) and lower fraction
369 of brown carbon (BrC) reflected by smaller AAE. The transition period (TP) when pollution was
370 developing had large variation of all optical properties, and enhanced aerosol loadings at higher altitude
371 were encountered when being influenced by regional advection. The fully developed heavy pollution
372 period (HP) featured with the shallow PBL accumulated over 80 % of the scattering and absorption within
373 the PBL, and deceased SAE due to enlarged particles size. Notably the absorption towards shorter
374 wavelength became larger under more polluted environment, especially for the higher altitude.

375 The AOD and AAOD measured by passive remote sensing was for the first time compared with in-situ
376 measurements over this polluted region. AOD showed high correlation between AERONET and in-situ
377 measurement within 10 %, and the most discrepancy between both could be possibly resolved by
378 considering the hygroscopic growth of aerosols under high RH condition. The AAOD however showed
379 10-25 % higher for remote sensing especially at shorter wavelength, consistent with other studies (Müller
380 et al., 2012; Andrews et al., 2017). The possibilities of causing this could be the non-homogeneously
381 vertically structure of optical properties, mixing state of light-absorbing aerosol, and also the particle
382 hygroscopic growth, which are unable to be ruled out only using the results here.

383 The heating rates of aerosols was calculated by the radiative transfer model (DISORT) by using in-situ
384 measured profiles as inputs. BC was the main heating species, having 0.05 K/h, 0.1 K/h and 0.15 K/h

385 heating rate in the PBL during pollution initialization, transition and full development respectively, and
386 showed positive vertical gradient of heating when regional transport The contribution of BrC was found
387 to increase by 20 % throughout the column from CP to HP period, in particular the increased BrC
388 contribution was pronounced at the layer above the PBL during HP, which was proposed to result from
389 the intensive photochemical reactions above the PBL. The BrC present at this layer will have the potential
390 to contribute to the heating at this layer, hence enhancing the temperature inversion on top of the PBL
391 hereby the capping effect to the pollutants trapped in the PBL. Particles at higher altitude may be
392 transported to wider region spatially in both vertical and horizontal directions through convection, which
393 may lead BrC present at this layer to have wilder and longer radiative impacts. Different mechanism of
394 BrC formation at different levels such as above the PBL (where more solar flux received) or within the
395 PBL (where more moisture was constrained) warrants future studies.

Fig. 1. Temporal variations from Nov. 15th to 18th of vertical profiles of wind direction (a), and wind speed (b) measured by wind profile radar; (c) particle extinction measured by MPL lidar; (d) aerosol optical depth (d) and aerosol absorption optical depth (e) from AERONET (asterisk) and derived from aircraft in-situ measurements (open star)(f) surface PM_{2.5} and RH.). The vertical bars denote the periods

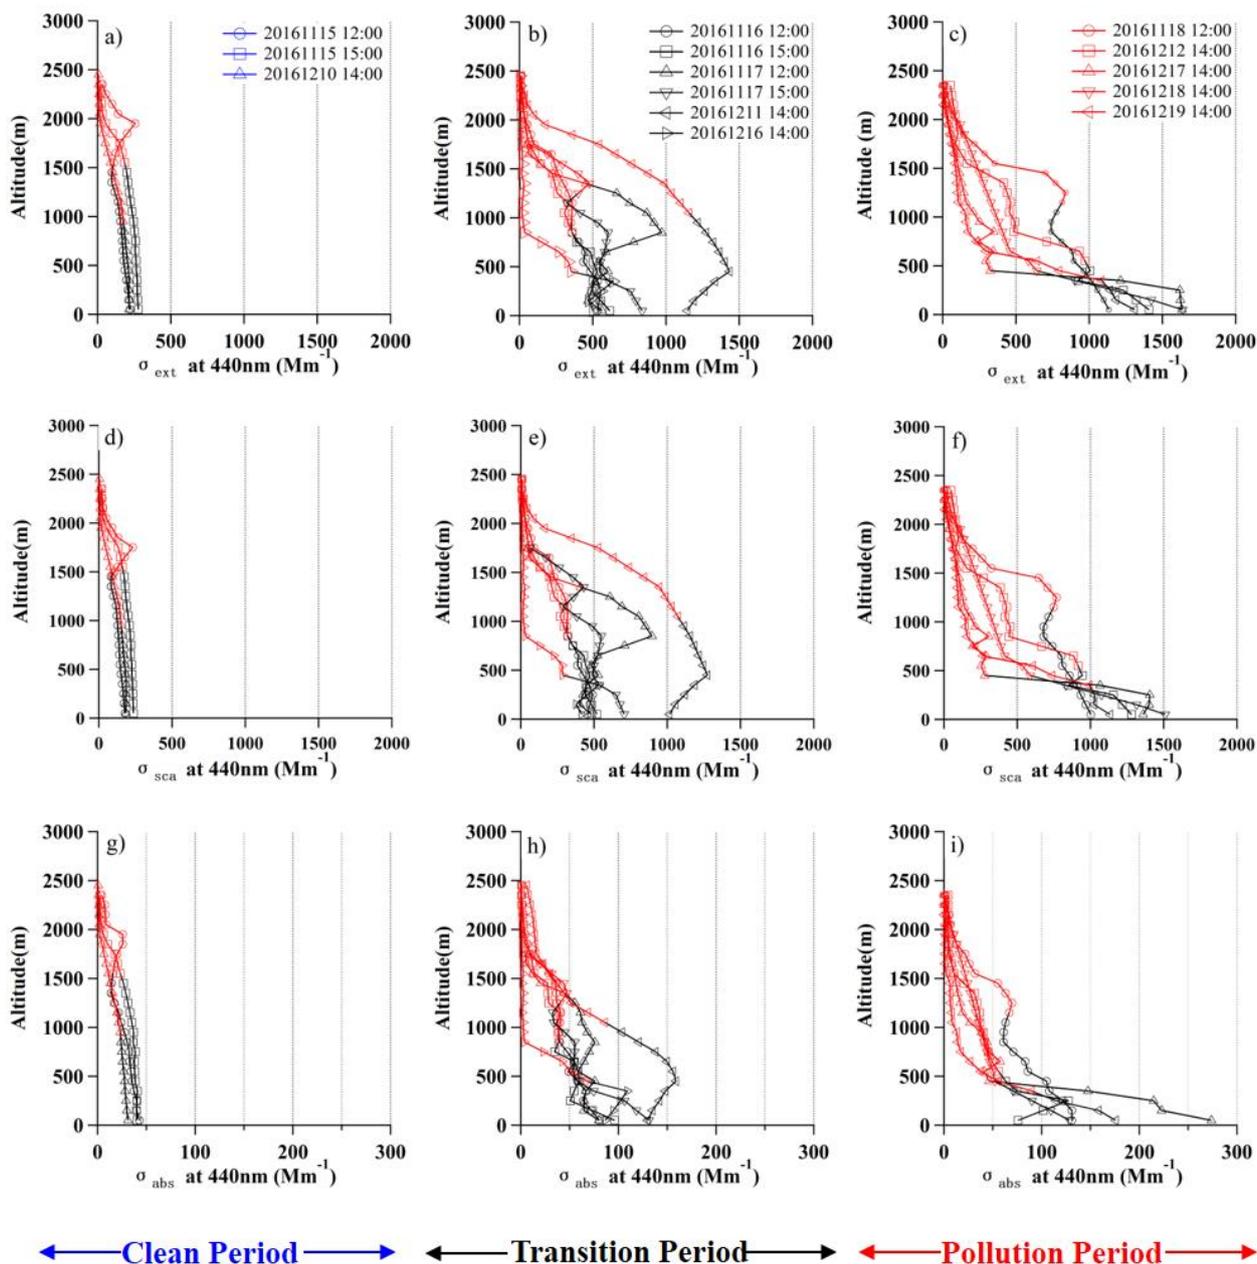

660 of flight profiles, with blue, black and red representing the clean period, transition period and heavy
 661 pollution during a pollution event respectively. The other two pollution events can refer to supplement
 662 Fig. S2 and Fig. S3.

663 Fig. 2. Vertical profiles of temperature (a, b, c), relative humidity (d, e, f) and potential temperature (g,
 664 h, i) for Clean Period, Transition Period and Heavy Pollution period, respectively. The black and red
 665 dots represent for inside the PBL and above the PBL.
