27 **Abstract**

28 The southeastern Atlantic (SEA) and its associated cloud deck, off the west coast of  
29 central Africa, is an area where aerosol-cloud interactions can have a strong radiative  
30 impact. Seasonally, extensive biomass burning (BB) aerosol plumes from southern Africa  
31 reach this area. The NASA ObseRvations of Aerosols above Clouds and their  
32 intEractionS (ORACLES) study focused on quantitatively understanding these  
33 interactions and their importance. Here we present measurements of cloud condensation  
34 nuclei (CCN) concentration, aerosol size distribution, and characteristic vertical updraft  
35 velocity ( $w^*$ ) in and around the marine boundary layer (MBL) collected by the NASA P-  
36 3B aircraft during the August 2017 ORACLES deployment. BB aerosol levels vary  
37 considerably but systematically with time; high aerosol concentrations were observed in  
38 the MBL ( $800\text{-}1000\text{ cm}^{-3}$ ) early on, decreasing mid-campaign to concentrations between  
39  $500\text{-}800\text{ cm}^{-3}$ . By late August and early September, relatively clean MBL conditions were  
40 sampled ( $<500\text{ cm}^{-3}$ ). These data then drive a state-of-the-art droplet formation  
41 parameterization, from which the predicted cloud droplet number and its sensitivity to  
42 aerosol and dynamical parameters are derived. Droplet closure was achieved to within  
43 20%. Droplet formation sensitivity to aerosol concentration,  $w^*$ , and the hygroscopicity  
44 parameter,  $\kappa$ , vary and contribute to the total droplet response in the MBL clouds. When  
45 aerosol concentrations exceed  $\sim 900\text{ cm}^{-3}$  and maximum supersaturation approaches  
46 0.1%, droplet formation in the MBL enters a “velocity-limited” droplet activation regime,  
47 where cloud droplet number responds weakly to CCN concentration increases. Below  
48  $\sim 500\text{ cm}^{-3}$ , in a “clean” MBL, droplet formation is much more sensitive to changes in  
49 aerosol concentration than to changes in vertical updraft. In the “competitive” regime,

50 where the MBL has “intermediate” pollution (500-800 cm<sup>-3</sup>), droplet formation becomes  
51 much more sensitive to hygroscopicity ( $\kappa$ ) variations than for clean and polluted  
52 conditions. Higher concentrations increase the sensitivity to vertical velocity by more  
53 than ten-fold. We also find that characteristic vertical velocity plays a very important role  
54 in driving droplet formation in a more polluted MBL regime, in which even a small shift  
55 in  $w^*$  may make a significant difference in droplet concentrations. Identifying regimes  
56 where droplet number variability is primarily driven by updraft velocity and not aerosol  
57 concentration is key for interpreting aerosol indirect effects, especially with remote  
58 sensing. Droplet number responds proportionally to changes in characteristic velocity,  
59 offering the possibility of remote sensing of  $w^*$  under velocity-limited conditions.

60

61 **1. Introduction**

62 Aerosol particles affect the planetary radiative balance by directly absorbing and  
63 scattering radiation. They also provide the nuclei upon which cloud droplets and ice  
64 crystals form; variations thereof can profoundly impact cloud formation, precipitation,  
65 and the hydrological cycle (Boucher et al., 2013; Myhre et al., 2013). These aerosol  
66 impacts are thought to be important but uncertain modulators of regional and global scale  
67 climate. The interactions of aerosols with clouds are especially uncertain, and affect  
68 estimates of equilibrium climate sensitivity and transient climate response to greenhouse  
69 gas concentrations (Seinfeld et al., 2016, IPCC 2013).

70 Only a fraction of aerosol can affect clouds; those aerosols that can activate to  
71 form cloud droplets (termed cloud condensation nuclei, CCN) must satisfy a certain  
72 range of physical size and chemical composition for the levels of water vapor  
73 supersaturation that develop in cloud-forming air parcels (Köhler, 1936; Seinfeld and  
74 Pandis, 2006). The properties and dynamical development of warm and mixed-phase  
75 clouds are sensitive to the number of cloud droplets formed. It is now established that  
76 anthropogenic emissions have strongly modulated global CCN and droplet number since  
77 the industrial revolution (e.g., Boucher et al., 2013; Raatikainen et al., 2013). Much work  
78 remains, however, to reduce the uncertainty associated with this forcing on climate (e.g.,  
79 Seinfeld et al., 2016).

80 Appropriately capturing the variability in droplet number, and its sensitivity to  
81 aerosol (which is at the heart of aerosol-cloud interactions) requires a good description of  
82 aerosol size distribution and hygroscopicity (e.g., Fanourgakis et al., 2019), especially in  
83 boundary-layer clouds where liquid clouds and their radiative cooling dominates. Key

84 towards achieving this goal is to capture the source characteristics of major aerosol types,  
85 and their chemical/microphysical evolution throughout their atmospheric residence.  
86 Biomass burning (BB) aerosol has emerged as a major source of regional and global  
87 aerosol, contributing up to 64% of global surface CCN concentrations (Spracklen et al.,  
88 2011). The influence of BB is expected to increase in importance as the combustion of  
89 biomass (natural and anthropogenic) is expected to accelerate in the future, especially in  
90 Africa, while anthropogenic emissions decrease (Bond, et al. 2013, Andela et al., 2017).

91       Almost one third of annual global biomass burning emissions originate from  
92 regional fires across the savannah and woodlands of sub-Saharan Africa, and one fourth  
93 originate from southern Africa (van der Werf et al., 2010). From approximately June until  
94 October, these intense BB emissions are subsequently transported over the southeast  
95 Atlantic (SEA) region (Adebiyi and Zuidema, 2016; Garstang et al., 1996), greatly  
96 elevating CCN levels above background concentrations (Ross, et al., 2003) and  
97 interacting with low-level marine boundary layer clouds that are abundant in the SEA  
98 (e.g., Seager et al., 2003; Grosvenor et al., 2018; Zuidema et al., 2018). The SEA  
99 experiences a structure transition from marine stratocumulus to trade wind cumulus  
100 clouds, so the coincidence of large BB aerosol plumes implies a potentially large role for  
101 aerosol-cloud interactions to affect cloud radiative properties over a globally-relevant  
102 system, potentially modulating the extent of each regime and the transition itself  
103 (Yamaguchi et al., 2015; Zhou et al., 2017). The microphysical influence of BB aerosol  
104 on clouds, however, is non-linear, as increasing aerosol levels enhance the competition of  
105 CCN for water vapor, to the point where droplet formation may be insensitive to CCN  
106 concentration level (e.g., Rissman et al., 2004; Ruetter et al., 2009; Bougiatioti, et al.,

107 2016). Dynamical adjustments (primarily vertical velocity) may also respond to CCN and  
108 cloud droplet number changes - therefore it is important to quantify all these links, as  
109 model-assessments of BB aerosol-cloud-climate interactions in the SEA critically rely on  
110 them. Constraints, however, on such links are virtually nonexistent for this region of the  
111 globe.

112 This study analyzes data collected in August 2017 on the NASA ObseRvations of  
113 Aerosols above CLouds and their intEractionS (ORACLES) campaign, and provides a  
114 systematic mapping of CCN concentration, aerosol size distribution, hygroscopicity, and  
115 cloud vertical velocity in the SEA. The in-situ measurements are then coupled with a  
116 state-of-the-art droplet parameterization to determine the in-cloud maximum  
117 supersaturation ( $S_{max}$ ) achieved in the cloud updrafts and its response to aerosol changes.  
118 The data then is used to quantify the sensitivity of droplet formation to variations in  
119 vertical velocity and aerosol. We also explore whether the presence of BB aerosol  
120 correlates with shifts in the cloud vertical velocity driving droplet formation. These  
121 perturbations in BB aerosol availability, linked with vertical updraft dynamics, and  
122 predicted cloud droplet formation allow for understanding the drivers of droplet  
123 formation in the SEA cloud deck, and the degree to which BB influences droplet  
124 formation in the boundary layer.

125

## 126 **2. Methods**

### 127 **2.1 Observational Data Set**

128 A complete description and overview of the project is provided by Redemann, et  
129 al. (in preparation). All measurements were taken aboard the National Aeronautics and

130 Space Administration (NASA) P-3B aircraft from August 12<sup>th</sup> through 31<sup>st</sup> as part of the  
131 ORACLES 2017 campaign. The aircraft was based at the International Airport  
132 (0.3778°N, 6.7131°E) of São Tomé, an island off the west coast of central Africa. A map  
133 of MODIS satellite fires for the month of August 2017 can be found in Figure 1. The  
134 burning area is largely savanna grassland and the subsequent smoke plume travels  
135 westward over the SEA region. This work focuses on data collected on eight different  
136 research flights in the 2017 campaign during which instrumentation providing all relevant  
137 aerosol microphysical and cloud-scale dynamics data performed optimally. Flight paths  
138 for all data used in this work can be found in Figure 1. Most flights followed a “routine”  
139 route going out to 5°E longitude and then due South. Each flight included legs at varying  
140 altitudes to capture the characteristics of the plume, the marine boundary layer (MBL),  
141 and the cloud deck. This work primarily focuses on the aerosol measured below-cloud in  
142 the MBL, as that is the aerosol that will participate in cloud droplet activation.

## 143 **2.2 Instrumentation**

144 A summary of the relevant measurements obtained at each flight can be found in  
145 Table 1. A solid diffuser inlet, characterized previously as having a 4 $\mu$ m dry diameter  
146 cut-off (McNaughton, et al. 2007), was used to sample aerosol onboard the aircraft. A  
147 Droplet Measurement Technologies (DMT; CCN-100) Continuous Flow Streamwise  
148 Thermal Gradient Chamber (CFSTGC; Roberts and Nenes, 2005) was used to measure  
149 CCN concentrations using a DMT constant pressure inlet operated at 600 mbar pressure.  
150 Since CCN measurements are highly sensitive to fluctuations in pressure and their effect  
151 on generated supersaturation (Raatikainen, et al. 2014), a flow orifice and active control  
152 system were used upstream of the instrument to ensure that the pressure remained

153 constant, despite fluctuations in ambient pressure with altitude. The instrument was  
154 operated in both “standard” mode, where supersaturation (SS%) was stepped between  
155 0.1, 0.2, and 0.3% by changing the temperature gradient in the droplet growth chamber,  
156 and in “scanning flow CCN analysis” (SFCA) mode (Moore and Nenes, 2009), where  
157 supersaturation was varied from 0.1% to 0.4% by cycling the flow in a sinusoidal pattern  
158 from 300 to 1000 cm<sup>3</sup> min<sup>-1</sup> while maintaining a constant temperature gradient in the  
159 growth chamber. Aerosol particles that activated into droplets sized greater than 0.5µm  
160 were then counted as CCN by the optical particle counter located at the exit of the  
161 CFSTGC growth chamber.

162 A DMT Ultra High Sensitivity Aerosol Spectrometer (UHSAS) was also operated  
163 on the same 600mbar constant pressure inlet as the CFSTGC to detect the aerosol  
164 concentration from 80 to 1000 nm (Table 1). Comparison of UHSAS with DMA  
165 distributions revealed that the UHSAS counting efficiency dropped below about 80 nm  
166 (Howell et al., in preparation), which should not strongly affect our subsequent analysis –  
167 as particles larger than 80nm diameter contribute the exclusive majority of CCN that  
168 activate into droplets for the conditions considered. The aerosol size distribution was  
169 combined with CCN measurements to calculate the hygroscopicity parameter,  $\kappa$ , of the  
170 observed aerosol (Petters and Kreidenweis, 2007), following a procedure adopted in  
171 numerous studies (e.g., Kalkavouras et al., 2019; Bougiatioti et al., 2016; Moore et al.,  
172 2011; Lathem et al., 2013) where integration of the particle size distribution from the  
173 largest resolved bin in the UHSAS down to a characteristic size,  $d_{crit}$  (also known as the  
174 “critical diameter”), matches the measured CCN concentration. The hygroscopicity then

175 is obtained from from  $d_{crit}$  and the instrument supersaturation, following Kalkavouras et  
176 al. (2019).

177 Vertical winds on the P-3B were measured with the Turbulent Air Motion  
178 Measurement System (TAMMS) (Thornhill et al., 2003). Fast-response flow-angle,  
179 pressure, and temperature sensors combined with a GPS corrected inertial navigation  
180 system (INS) provide 50 Hz inputs to compute 20 Hz averaged vertical winds via the full  
181 air motion equations from Lenschow (1986). The updraft velocities are then used as an  
182 input to calculate cloud droplet number concentration via a Gaussian distribution of  
183 updraft velocities (Section 2.3).

184 An Aerodyne High-Resolution Time-of-Flight Aerosol Mass Spectrometer (HR-  
185 ToF-AMS) (DeCarlo, et al., 2006) was used to monitor bulk chemical composition of  
186 sampled aerosol throughout all flights. The bulk chemical composition acquired is then  
187 used to calculate the “bulk”  $\kappa$  (Petters and Kreidenweis, 2007), based on the mass  
188 fraction of organics and sulfate in the aerosol – assuming that the hygroscopicity of the  
189 organic fraction,  $\kappa_{org}=0.1$ , and of sulfate,  $\kappa_{sulfate}=0.6$ . We have also ignored the effects of  
190 insoluble material – such as black carbon – as it constitutes a small volume fraction of the  
191 aerosol and has a negligible influence on hygroscopicity. The bulk-derived  $\kappa$  allows for  
192 comparison with the directly calculated  $\kappa$  from the CFSTGC and UHSAS measurements,  
193 even if the AMS-derived values correspond to larger sizes than the CCN-derived  $\kappa$ .  
194 Nevertheless, strong agreement is found between the two  $\kappa$  values (Table 1; Figure S1),  
195 thus confirming that the internal mixture assumption inherent to CCN-derived  
196 hygroscopicity applies, and, that the composition varies little over the size range between  
197  $d_{crit}$  (~100-200nm) and the peak of the mass distribution resolved by the AMS. It should

198 also be noted that all of the AMS data was in high-sensitivity mode; the AMS heater was  
199 operated at an indicated 600 °C, which was tested and proved optimal for the ORACLES  
200 BB Organic Aerosol plume. The data were processed using the standard AMS software  
201 (Squirrel, version 1.41).

202 A Droplet Measurement Technologies (DMT) Cloud Droplet Probe (CDP) was  
203 used to measure the cloud droplet number from 2 to 50 micron in diameter. The CDP was  
204 modified according to Lance et al. (2010) to reduce coincidence problems. The total  
205 cloud droplet number ( $N_d$ ) from the CDP is compared against the predicted  $N_d$  from the  
206 cloud droplet parameterization. These comparisons are done in flights with mostly  
207 stacked legs in the MBL and clouds; occasionally, flights where aerosol and cloud were  
208 immediately before or after each other were used (but not stacked).

### 209 **2.3 Predicted Cloud Droplet Number**

210 The droplet activation process is the direct microphysical link between clouds and  
211 aerosol. Every aerosol particle, to activate and form a cloud droplet, requires exposure to  
212 a “critical” supersaturation (or above) for enough time to grow past a “critical” wet size  
213 (Nenes et al., 2001) that ensures unconstrained growth. Applying this principle to  
214 ambient clouds is confounded by the complex relationship of supersaturation with aerosol  
215 size distribution, hygroscopicity, and the characteristic vertical updraft velocity. State-of-  
216 the-art cloud droplet parameterizations (e.g., Ghan et al., 2011; Morales and Nenes,  
217 2014), however, resolve this relation and determine the cloud droplet number ( $N_d$ ),  
218 maximum available supersaturation ( $S_{max}$ ), and sensitivity of  $N_d$  to changes in aerosol  
219 concentration ( $N_a$ ), vertical updraft velocity ( $w$ ), and CCN activity ( $\kappa$ ).

220 In this study, we utilize the Nenes and Seinfeld (2003) parameterization with  
221 improvements introduced by Fountoukis and Nenes (2005), Barahona et al., (2010) and  
222 Morales and Nenes (2014). In applying the droplet parameterization, we integrate over  
223 the distribution of vertical velocities within the boundary layer – by utilizing the  
224 “characteristic vertical velocity” approach of Morales and Nenes (2010). In this  
225 approach, instead of numerically integrating over a probability density distribution  
226 (PDF), the parameterization is applied at a “characteristic” velocity,  $w^*$ , that yields the  
227 same result as the integrated value over the PDF. To derive  $w^*$ , the measured updrafts  
228 (positive vertical winds),  $w$ , are taken from all segments just below cloud in a given  
229 flight, then fit to a Gaussian distribution with zero mean;  $w^*=0.79\sigma_w$ , where  $\sigma_w$  is the  
230 width of the vertical velocity spectrum (Morales and Nenes, 2010). Stratocumulus clouds,  
231 such as those sampled in this study, are well characterized by a Gaussian distribution of  
232 vertical velocities with a mean close to zero (Morales and Nenes, 2010). A comparison  
233 between the predicted  $N_d$  from the parameterization and the measured  $N_d$  from the CDP  
234 can be found in Figure S2. The parameterized  $N_d$  was, on average, within 20% of the  
235 measured  $N_d$ , which is within the difference range of previous droplet closure studies  
236 (e.g., Meskhidze et al., 2005; Fountoukis et al., 2007; Morales et al., 2011).

237

### 238 **3. Results and Discussion**

#### 239 **3.1 Marine Boundary Layer Air Mass Characterization**

240 Characteristic vertical profiles of CCN concentrations from 0.1 to 0.4%  
241 supersaturation for flights used in this work are shown in Figure 2. Earlier flights (RF01 –  
242 RF03) have lower BB plume heights, relatively little vertical variation of concentration

243 within the plume, and high CCN concentrations in the marine boundary layer (MBL).  
244 Later flights (RF08 – RF12) show distinct layering in the plume, a higher plume cap  
245 altitude, and lower MBL concentrations. Hereon we focus on aerosol concentrations in  
246 the MBL, being the relevant aerosol providing CCN for BL cloud formation. A summary  
247 of the MBL aerosol concentrations, CCN-derived  $\kappa$  (averaged over all the  
248 supersaturations measured), and characteristic vertical updraft velocity ( $w^*$ ) is provided  
249 for all flights in Table 1. Flights are classified according to the observed MBL aerosol  
250 concentrations from the UHSAS into categories defined, for the purposes of this work, as  
251 “polluted” (exceeding  $800 \text{ cm}^{-3}$ ), “intermediate” ( $500\text{-}800 \text{ cm}^{-3}$ ), and “clean” (below  
252  $500 \text{ cm}^{-3}$ ). MBL aerosol concentration is higher earlier on in August and decreases as the  
253 mission progresses. The average CCN-derived  $\kappa$  for the MBL aerosol is fairly consistent,  
254 ranging from 0.2 to 0.4, and agrees well with the  $\kappa$  estimated from the bulk MBL aerosol  
255 elemental composition as measured by the aerosol mass spectrometer, implying that the  
256 aerosol is chemically uniform throughout the ultrafine aerosol size range (Figure S1).

257 Characteristic vertical updrafts are higher earlier in August, averaging  $0.4 \text{ ms}^{-1}$ ,  
258 and decrease to around  $0.3 \text{ ms}^{-1}$  later in the campaign. A decrease in MBL aerosol  
259 concentration is also seen during this time, with earlier flights seeing aerosol  
260 concentrations reaching up to  $1000 \text{ cm}^{-3}$  and later decreasing to  $200 \text{ cm}^{-3}$ . The average  
261 BB plume aerosol concentrations aloft range from around  $1250 \text{ cm}^{-3}$  to  $3000 \text{ cm}^{-3}$ , but  
262 show no distinct trends throughout the month. However, an interesting trend can be found  
263 in comparing the altitudes of the bottom of the BB plume and the top of the MBL cloud  
264 deck with the characteristic vertical updraft velocities – a lower  $w^*$  of  $0.3 \text{ ms}^{-1}$  coincides  
265 with observation of a clean, low-aerosol “gap” between the top of the MBL clouds and

266 the bottom of the BB plume. In higher  $w^*$  flights ( $0.4 \text{ ms}^{-1}$ ), the BB plume extends all the  
267 way down to the top of the MBL cloud layers. In these flights, the BB plume is observed  
268 to have one single, well-mixed layer throughout, while the later flights ( $w^* \sim 0.3 \text{ ms}^{-1}$ ) are  
269 characterized by two distinct layers in the plume.

270

### 271 **3.2 Predicted Droplet Number and Maximum Supersaturation**

272 Figure 3a presents predicted droplet number ( $N_d$ ) and CCN (at 0.1%  
273 supersaturation) as a function of total aerosol concentration ( $N_a$ ) for the marine boundary  
274 layer (MBL) legs of all flights. Above an aerosol concentration of  $\sim 600 \text{ cm}^{-3}$ , droplet  
275 number concentration becomes progressively less responsive to further increases in CCN  
276 number (as the incremental change in  $N_d$  is less as CCN increases) and becomes  
277 effectively insensitive ( $\partial N_d / \partial N_a \sim 0$ ) for an aerosol concentration exceeding  $\sim 1000 \text{ cm}^{-3}$ .  
278 The reason behind this increasing insensitivity can be seen in Figure 3b, which presents  
279  $N_d$  against  $N_a$  for all the MBL leg data; the data are colored by supersaturation. For low  
280 values of  $N_a$  and  $N_d$  ( $\sim 200 \text{ cm}^{-3}$ ),  $S_{max}$  tends to be high (just over 0.2%) and the response  
281 of  $N_d$  to increases in aerosol is strong. However, when transitioning from “clean” to  
282 “intermediate” MBL conditions,  $N_d$  is less sensitive to increases in aerosol, because  $S_{max}$   
283 decreases, and mitigates some of the expected droplet number response. Upon reaching  
284 “polluted” conditions ( $> 800 \text{ cm}^{-3}$ ), the decrease in  $S_{max}$  is even stronger, entering into a  
285 regime where any additional aerosol can no longer substantially augment cloud droplets,  
286 owing to the extreme competition of the high CCN concentrations for water vapor. This  
287 water vapor-limited regime occurs when the  $S_{max}$  is less than 0.1% (Figure 3b); given that  
288 water vapor availability is generated through expansion cooling in updrafts, this type of

289 limitation is also known as the “updraft-limited” regime of droplet formation (Ruetter et  
290 al., 2009).

291

### 292 **3.3 Droplet Number Sensitivity**

293 The previous section pointed out the variable sensitivity of droplet number to  
294 aerosol perturbations, depending on the conditions of cloud formation. To further explore  
295 such issues, we explicitly calculate the sensitivities (partial derivatives) of droplet number  
296 in the MBL to changes in aerosol number, characteristic vertical updraft velocity, and  
297 CCN activity, computed by the parameterization using a finite difference approximation.  
298 This is shown in Figure 4 for  $\partial N_d/\partial N_a$  (top panel),  $\partial N_d/\partial w$  (middle panel) and  $\partial N_d/\partial \kappa$   
299 (bottom panel). Results are shown for three flights, corresponding to each pollution class  
300 of Table 1: “polluted” (RF02), “intermediate” (RF09), and “clean” (RF10). Sensitivity of  
301 droplet number to total aerosol concentration ( $\partial N_d/\partial N_a$ ) is fairly comparable between the  
302 two lower concentration conditions and approaches insensitivity ( $\partial N_d/\partial N_a < 0.1$ ) when  
303 the total aerosol concentration exceeds  $1000 \text{ cm}^{-3}$ . Maximum in-cloud supersaturation  
304 decreases steadily as  $N_a$  increases and  $\partial N_d/\partial N_a$  appreciably decreases when  $S_{max}$  drops  
305 below 0.12% (Figure 4, top panel).

306 As  $\partial N_d/\partial N_a$  decreases with increasing levels of aerosol, droplet sensitivity to  
307 vertical updraft velocity,  $\partial N_d/\partial w$ , becomes increasingly important and completely  
308 dominates droplet variability for high aerosol numbers. The reason why droplets become  
309 so sensitive to vertical velocity fluctuations under polluted conditions, is because vertical  
310 velocity drives supersaturation generation; at low supersaturation, when there is very  
311 strong competition for water vapor from the many CCN present (“velocity-limited

312 regime”), any increase in vertical velocity augments supersaturation and droplet number.  
313 For low CCN concentrations, however, supersaturation is high so that fluctuations in  
314 aerosol translate to an almost equal response in droplet number ( $\partial N_d / \partial d N_a \sim 1$ ; Figure 4,  
315 top panel), therefore fluctuations in vertical velocity, hence supersaturation, do not affect  
316 droplet number ( $\partial N_d / \partial w$  small). The low MBL aerosol concentrations lead to the highest  
317 sensitivity of  $N_d$  to  $N_a$  (approaching 100%), creating an “aerosol-limited” condition where  
318 there is sufficient available supersaturation to activate virtually every aerosol added to the  
319 MBL layer. A  $\sim 5x$  increase in  $N_a$  leads to a  $\sim 50\%$  decrease in the sensitivity of  $N_d$  to  $N_a$   
320 to around 40%, with the highest aerosol values corresponding to even lower sensitivities  
321 to aerosol number, approaching below 10% and clearly behavior consistent with a  
322 “velocity-limited” regime.

323 Predicted droplet sensitivity to  $\kappa$  displays a unique trend (Figure 4, bottom panel),  
324 becoming stronger initially with increasing aerosol, peaking at intermediate  
325 concentrations and then rapidly dropping towards insensitivity, when supersaturation  
326 approaches 0.1%. This sudden insensitivity to CCN activity aligns with the clouds being  
327 overseeded when supersaturation is starting to be depleted – once supersaturation is not  
328 as readily available, any characteristics of the aerosol cease to play a strong role in  
329 activation. However, prior to reaching the point of being insensitive to aerosol, increased  
330 sensitivity to  $\kappa$  is opposite to the expected trend from  $N_a$  – indicating that the fluctuation  
331 in chemical composition, when droplet formation is in a “competitive” regime (Figure  
332 4c), may be an important contributor to droplet formation – consistent with the findings  
333 of Bougiatioti et al., (2017) for droplet formation in an urban environment in the E.  
334 Mediterranean. We emphasize here that the sensitivity to  $\kappa$  (Figure 4c) is not from its

335 changes over size (which we show above to be small), but rather changes over space and  
336 time.

337

### 338 **3.2.1 Impact of Boundary Layer Turbulence**

339 Throughout the entirety of flights, the maximum predicted droplet number  
340 reaches a plateau, where additional aerosol does not result in any significant increase in  
341  $N_d$ . An example of this behavior is presented in Supplementary Figure S4 (where data of  
342 calculated  $N_d$  is presented for the entire research flight, as opposed to only the segments  
343 in the MBL shown in previous sections). This plateau, owing to the development of  
344 strong water vapor limitations, is termed limiting droplet number,  $N_d^{lim}$ , and should  
345 largely be a function of vertical velocity – precisely because we are in a velocity-limited  
346 regime. This realization implies that much of the droplet number variability (measured or  
347 retrieved) in clouds strongly influenced by BB plumes reflects the underlying shifts in  
348 cloud dynamics associated with each concentration “regime”. Indeed, the characteristic  
349 velocity in the MBL tends to increase as the MBL clouds become progressively polluted  
350 (Figure 5); the higher pollution flights (RF01 and RF02) all fall in mid-August and are  
351 coincident with a higher characteristic vertical updraft velocity of  $\sim 0.4$ , while “clean”  
352 MBL flights coincide with lower vertical updraft velocity values of  $\sim 0.3$  and occur  
353 towards the end of August. “Intermediate” scenario flights are divided between the two  
354 characteristic vertical updraft velocities observed. When the flight-specific characteristic  
355 velocity is then used to calculate the droplet response, it follows a trend with aerosol  
356 levels that magnifies droplet response from what is expected by increasingly adding  
357 pollution alone. In contrast, the aerosol concentration above the MBL is inversely

358 correlated with  $w^*$  (Figure 5), possibly a result of enhanced mixing between the MBL and  
359 the free troposphere (rich in BB aerosol) that is associated with the elevated levels of  
360 turbulence ( $w^*$ ).

361 The impact of increased  $w^*$  on the droplet number is shown for “polluted”,  
362 “intermediate” and “clean” conditions in the inset plot of Figure 6 – which shows  $N_d^{lim}$   
363 for each concentration class for  $w^*$  between 0.1 and 0.6  $\text{ms}^{-1}$ . For polluted conditions,  
364 transitioning from 0.3 to 0.4  $\text{ms}^{-1}$  increases droplet number from 400 to 500  $\text{cm}^{-3}$ , which  
365 is a 20-25% increase. The enhancement is equally important for intermediate and clean  
366 conditions (although less in absolute number), and always comparable to droplet  
367 enhancements from changes in BB concentration.

368

### 369 **3.4 Water-vapor limitations and the lifetime of BB aerosol in the MBL**

370 Above an aerosol concentration of  $\sim 800 \text{ cm}^{-3}$  when water vapor availability is  
371 severely limited,  $N_d$  no longer increases in response to increases in CCN (Figure 3a). An  
372 important consequence is that under such conditions, much of the BBOA does not  
373 activate into cloud droplets and is therefore not lost through wet deposition. Because of  
374 this, the degree of water vapor competition (and supersaturation level) is directly related  
375 to BB lifetime in the MBL.  $\partial N_d / \partial d N_a$  may then be inversely linked to CCN lifetime,  
376 where “velocity-limited” conditions, characterized by the smallest droplet activation  
377 fraction and  $\partial N_d / \partial d N_a$ , also have the largest lifetime and vice versa for “clean” MBL  
378 conditions.

379

380

381 **4. Implications and Conclusions**

382 BB aerosol levels in the SEA varied considerably throughout the 2017 ORACLES  
383 deployment. Earlier in the campaign, high aerosol concentrations were observed in the  
384 MBL (800-1000  $\text{cm}^{-3}$ ), which decreased mid-campaign to concentrations between 500-  
385 800  $\text{cm}^{-3}$ , and in late August and early September, relatively clean MBL conditions were  
386 seen ( $<500 \text{ cm}^{-3}$ ). On 12-13 August, MBL aerosol concentrations exceeded 1000  $\text{cm}^{-3}$ .  
387 From the observed aerosol size distribution and CCN concentrations, we constrained the  
388 aerosol hygroscopicity – which was in agreement with estimates from bulk chemical  
389 composition measurements; together with observed MBL vertical velocity distributions,  
390 we then calculate droplet number concentrations using a state-of-the-art droplet activation  
391 parameterization. Droplet closure was achieved within 20%, consistent with the degree of  
392 closure achieved in past studies.

393 From the analysis of the dataset, when aerosol concentrations exceed  $\sim 900 \text{ cm}^{-3}$   
394 and maximum supersaturation approaches 0.1%, droplet formation in the MBL begins to  
395 enter a “velocity-limited” droplet activation regime, where cloud droplet number  
396 responds weakly to CCN concentration increases. Lower MBL concentrations (500  $\text{cm}^{-3}$   
397 or less) were observed later in the campaign (late August to early September), thus  
398 leading to a much higher predicted  $S_{max}$  of 0.2%, and much higher fraction of activated  
399 CCN. Under clean conditions, vertical velocity generates ample supersaturation, so  
400 droplet formation is limited by the number of aerosol particles in the MBL. Overall this  
401 leads to a buffering of the  $N_d$  response to aerosol, so that  $N_d$  variability is much less  
402 (down to 1/10 or less) than that seen for the underlying CCN.

403 Droplet formation sensitivity to aerosol concentration, vertical updraft velocity,  
404 and the hygroscopicity parameter,  $\kappa$ , vary and contribute to the total droplet response in  
405 the MBL clouds. Droplet sensitivity to vertical velocity increases an order of magnitude  
406 as aerosol concentration reaches  $1000 \text{ cm}^{-3}$ . This highlights the increased (and eventually  
407 dominant) role that vertical velocity plays in droplet formation in a “polluted” MBL  
408 environment. Below  $\sim 500 \text{ cm}^{-3}$ , in a “clean” MBL, droplet formation is much more  
409 sensitive to changes in aerosol concentration than to the observed changes in vertical  
410 updrafts. In the “competitive” regime, where the MBL has “intermediate” pollution (500-  
411  $800 \text{ cm}^{-3}$ ), hygroscopicity ( $\kappa$ ) variations emerges as an important driver of droplet number  
412 variability, which is something not seen for either “clean” or “polluted” MBL conditions.  
413 Throughout the month of August, a shift is observed in  $w^*$ , from  $\sim 0.45 \text{ m s}^{-1}$  down to  
414  $\sim 0.26 \text{ m s}^{-1}$ , which affects the maximum droplet number that can be generated in the  
415 MBL.  $N_d^{lim}$  is significantly affected by changes in  $w^*$ , especially in higher MBL pollution  
416 conditions, where the effects of increased characteristic vertical updraft velocity  
417 significantly magnifies droplet number concentrations compared to trends seen in  
418 “intermediate” and “clean” MBL environments.

419 Identifying regimes where droplet number variability is primarily driven by  
420 updraft velocity changes, and not aerosol concentration, is key for interpreting aerosol  
421 indirect effects. This is particularly important when using remote sensing data, as can be  
422 seen from the data here: diagnosing aerosol indirect effects using above-cloud aerosol  
423 would give opposite trends from what actually occurs in the MBL – because BB plume  
424 aerosol decreases as the MBL aerosol increases. Nevertheless, the correlations here  
425 between above-cloud and MBL aerosol level might be a useful way to diagnose MBL

426 aerosol – from which  $N_d$  can eventually be determined. Furthermore, when droplet  
427 number is in the velocity-limited regime,  $N_d$  responds proportionally to changes in  $w^*$ ,  
428 offering the possibility of remote sensing of  $w^*$  under these specific conditions (specific  
429 criteria need to be developed to help define when velocity-limited conditions occur, e.g.,  
430 combining collocated in-situ and remote sensing data from field intensives).

431       Very interesting are the trends observed between MBL dynamics, height and the  
432 aerosol levels in the MBL and the BB plume.  $w^*$  is higher earlier in August and decreases  
433 later in the campaign; MBL aerosol concentration correlates with  $w^*$ , while an inverse  
434 correlation is seen for the aerosol in the BB plume above the MBL. A similarly  
435 interesting trend can be found between  $w^*$ , the base altitude of the BB plume and the top  
436 of the MBL cloud deck: higher  $w^*$  corresponds to a BB plume that extends down to the  
437 top of the MBL cloud layers, while lower  $w^*$  is characterized by two distinct layers in the  
438 plume. Although what drives these correlations is not fully understood, it is likely related  
439 to the seasonality of the MBL height and its role in regulating mixing between the MBL  
440 and aloft (also discussed in Zhang et al., 2019). Indeed, the atmosphere is likely less  
441 stable in August, encouraging buoyant parcels (hence larger  $w^*$ ) than in September.  $w^*$   
442 enhancement may also result from enhanced cloud-top radiative cooling driven by LWC  
443 changes between the early and later flights of the campaign – the nearly threefold  
444 increase in cloud droplet number and the expected LWC response, however, suggests that  
445 clouds may actually be thinner (Painemal and Zuidema, 2010; Wood et al., 2012; de  
446 Szoeke et al., 2018). Water vapor in the FT, which is strongly correlated with smoke  
447 occurrence in the FT, would also reduce the longwave emission from the top of the  
448 stratocumulus and thereby reduce the turbulent driving of the PBL. Water vapor in the

449 outflow layers is driven by the proximity of the continental PBL to the warm continental  
450 surface with enhanced evaporation – and is not related to aerosol processes. Absorption  
451 of solar radiation from black carbon in the MBL may also suppress turbulence and  $w^*$   
452 (Wilcox et al., 2016), although our data suggests these effects may not be strong enough  
453 to reverse the trend imposed by any MBL seasonality. A thorough attribution of the link  
454 between  $w^*$ , aerosol, MBL structure and the large scale remains to be carried out, though  
455 results here suggest simple thresholds on these variables could help models determine  
456 how to treat droplet activation in different scenarios.

457         Although BB aerosol variations can profoundly impact cloud microphysical  
458 characteristics, concurrent variations in vertical velocity must also be considered to fully  
459 understand the drivers of droplet variability, especially when used to evaluate models and  
460 estimates of aerosol-cloud-climate interactions. The small activation fraction of aerosols  
461 under polluted MBL conditions may promote the persistence of aerosol for longer in the  
462 MBL, extending the reach and influence of BB aerosol in the SEA.

727

728 **Tables**

729 **Table 1:** Average marine boundary layer (MBL) aerosol concentrations from the  
 730 UHSAS, CCN activity derived from in-situ CCN measurements ( $\kappa_{CCN}$ ) and bulk chemical  
 731 composition ( $\kappa_{AMS}$ ), and characteristic vertical updraft velocity ( $w^*$ ). Aerosol conditions  
 732 are classified for each flights as “polluted”, “intermediate”, or “clean” based on the MBL  
 733 aerosol concentration.

<b>Flight Number</b>	<b>Date</b>	<b>Pollution Category</b>	<b>Aerosol Number (cm<sup>-3</sup>)</b>	<b>CFSTGC Operation Mode</b>	$\kappa_{CCNc}$	$\kappa_{AMS}$	$w^*$ (ms <sup>-1</sup> )
<i>RF01</i>	12 Aug 17	Polluted	707 ± 104	Both <sup>§</sup>	0.4	-	0.44
<i>RF02</i>	13 Aug 17	Polluted	1012 ± 98	Both <sup>§</sup>	0.4	0.4	0.40
<i>RF03</i>	15 Aug 17	Intermediate	481 ± 109	SFCA <sup>^</sup>	0.4	0.4	0.42
<i>RF08</i>	24 Aug 17	Intermediate	493 ± 40	Both <sup>§</sup>	0.3	0.4	0.32
<i>RF09</i>	26 Aug 17	Intermediate	433 ± 34	CF <sup>*</sup>	0.4	0.4	0.35
<i>RF10</i>	28 Aug 17	Clean	205 ± 21	CF <sup>*</sup>	0.3	-	0.33
<i>RF11</i>	30 Aug 17	Clean	278 ± 24	Both <sup>§</sup>	0.2	0.4	0.24
<i>RF12</i>	31 Aug 17	Clean	195 ± 21	CF <sup>*</sup>	0.4	0.4	0.3 <sup>#</sup>

734 \* CF: Constant Flow operation of the CCN instrument.

735 ^ SFCA: Scanning Flow CCN Analysis operation of the CCN instrument.

736 § Both operation modes (CF, SFCA) of the CCN instrument were used.

737 #  $w^*=0.3 \text{ ms}^{-1}$  assumed when calculating droplet number. This value was selected based  
 738 on the pollution category and date, and the average of corresponding  $w^*$  determined from  
 739 RF10, RF11.

740

741

742

743 **Figures Captions**

744

745 **Figure 1:** Map of ORACLES 2017 research flights used in this work, together with  
746 aerosol optical thickness (AOT) of the August 2017 plume (Meyer et al., 2015). The inset  
747 provides MODIS imagery of savannah fires throughout August 2017. Most flights are in  
748 close proximity to the “routine” flight path of due South along 5°E Longitude.

749

750 **Figure 2:** Vertical profiles (altitude in meters) of CCN concentration ( $\text{cm}^{-3}$ ) from 0.1% to  
751 0.4% supersaturation for all flights in this work.

752

753 **Figure 3:** a) Predicted droplet number ( $N_d$ ;  $\text{cm}^{-3}$ ) and measured CCN ( $\text{cm}^{-3}$ ) at 0.1%  
754 supersaturation as functions of marine boundary layer aerosol concentration ( $N_a$ ;  $\text{cm}^{-3}$ )  
755 for all flights. b)  $N_d$  against  $N_a$  in the MBL for all flights, colored by maximum in-cloud  
756 supersaturation ( $S_{max}$ ).

757

758 **Figure 4:** The sensitivity of droplet number to a) aerosol number ( $\partial N_d / \partial N_a$ ), b)  
759 characteristic velocity ( $\partial N_d / \partial w^*$ ), and, c) hygroscopicity parameter ( $\partial N_d / \partial \kappa$ ) as functions  
760 of  $N_a$  ( $\text{cm}^{-3}$ ). The data is clustered using the “polluted”, “intermediate”, and “clean”  
761 groupings of Table 1.

762

763 **Figure 5:** Characteristic velocity,  $w^*$ , in the MBL as a function of  $N_a$  ( $\text{cm}^{-3}$ ) in the BBOA  
764 plume (blue) and in the MBL (red), for each flight.

765

766 **Figure 6:**  $N_d^{lim}$  ( $\text{cm}^{-3}$ ) for each flight as a function of characteristic vertical updraft  
767 velocity,  $w^*$  ( $\text{ms}^{-1}$ ). Flights are colored by “polluted”, “intermediate”, and “clean”  
768 categories, as defined by MBL concentration. The inset also presents the “asymptotic”  
769 activated droplet number ( $N_d^{lim}$ ;  $\text{cm}^{-3}$ ) for  $w^*$  ranging from 0.1 to 0.6  $\text{ms}^{-1}$ .
