**Abstract.** The amount of ice injected up to the tropical tropopause layer has a strong radiative impact on climate. In the tropics, the Maritime Continent (MariCont) region presents the largest injection of ice by deep convection into the upper troposphere (UT) and tropopause level (TL) (from results presented in the companion paper Part 1). This study focuses on the MariCont region and aims to assess the processes, the areas and the diurnal amount and duration of ice injected by deep convection

- 5 over islands and over seas using a  $2^{\circ} \times 2^{\circ}$  horizontal resolution during the austral convective season of December, January and February. The model presented in the companion paper is used to estimate the amount of ice injected ( $\Delta$ IWC) up to the TL by combining ice water content (IWC) measured twice a day in local time in tropical UT and TL by the Microwave Limb Sounder (MLS; Version 4.2) from 2004 to 2017, and precipitation (Prec) measurement from the Tropical Rainfall Measurement Mission (TRMM; Version 007) averaged at high temporal resolution (1 hour). The horizontal distribution of  $\Delta$ IWC estimated
- 10 from Prec ( $\Delta IWC^{Prec}$ ) is presented at 2° × 2° horizontal resolution over the MariCont.  $\Delta IWC$  is also evaluated by using the number of lightning events (Flash) from the TRMM-LIS instrument (Lightning Imaging Sensor, from 2004 to 2015 at 1-h and  $0.25^{\circ} \times 0.25^{\circ}$  resolutions).  $\Delta IWC^{Prec}$  and  $\Delta IWC$  estimated from Flash ( $\Delta IWC^{Flash}$ ) are compared to  $\Delta IWC$  estimated from the ERA5 reanalyses ( $\Delta IWC^{ERA5}$ ) with the vertical resolution degraded to that of MLS observations ( $\langle \Delta IWC^{ERA5} \rangle$ ). Our study shows that, while the diurnal cycles of Prec and Flash are consistent with each other in timing and phase over land but
- 15 different over offshore and coastal areas of the MariCont, the observational  $\Delta$ IWC range between  $\Delta$ IWC<sup>*Prec*</sup> and  $\Delta$ IWC<sup>*Flash*</sup>, interpreted as the uncertainty of our model to estimate the ice injected, is smaller over land (they agree to within - 6 to - 22 %) than over ocean (to within 6 to - 71 %) in the UT and TL. The impact of the vertical resolution on the estimation of  $\Delta$ IWC is higher in the TL (difference between  $\Delta$ IWC<sup>*ERA5*</sup> and  $\langle \Delta IWC^{$ *ERA5* $} \rangle$  of 32 to 139 %) than in the UT (difference of 9 to 33 %). Considering estimates of  $\Delta$ IWC from all the methods,  $\Delta$ IWC is estimated in the UT between 4.2 and 10.0 mg m<sup>-3</sup> over
- 20 land, and between 0.3 and 4.4 mg m<sup>-3</sup> over sea, and, in the TL, between 0.5 and 3.7 mg m<sup>-3</sup> over land and between 0.1 and 0.7 mg m<sup>-3</sup> over sea. Finally, based on IWC from MLS and ERA5, Prec and Flash, this study highlights that 1)  $\Delta$ IWC over land (> 4 mg m<sup>-3</sup>) has been found to be larger than  $\Delta$ IWC over sea (< 4 mg m<sup>-3</sup>), and 2) small islands with high topography present the largest  $\Delta$ IWC such as the Java Island (7.7 to 9.5 mg m<sup>-3</sup> in the UT).

# 25 1 Introduction

55

In the tropics, water vapour (WV) and ice cirrus clouds near the cold point tropopause (CPT) have a strong radiative effect on climate (Stephens et al., 1991) and an indirect impact on stratospheric ozone (Stenke and Grewe, 2005). WV and water ice crystals are transported up to the tropopause layer by two main processes: a three-dimensional large-scale slow process (3-m month  $^{-1}$ ), and a small-scale fast convective process (diurnal timescale) (e.g. Fueglistaler et al., 2009; Randel and Jensen,

- 30 2013). Many studies have already shown the impact of convective processes on the hydration of the atmospheric layers from the upper troposphere (UT) to the lower stratosphere (LS) (e.g. Liu and Zipser, 2005; Jensen et al., 2007; Dauhut et al., 2018; Dion et al., 2019). However, the amount of total water (WV and ice) transported by deep convection up to the tropical UT and LS is still not well understood. The vertical distribution of total water in those layers is constrained by thermal conditions of the CPT (Randel et al., 2006). During deep convective events, Dion et al. (2019) have shown that air masses transported up to
- 35 146 hPa in the UT and up to 100 hPa in the tropopause layer (TL) have ice to total water ratios of more than 50% and 70%, respectively, and that ice in the UT is strongly spatially correlated with the diurnal increases of deep convection, while WV is not. Dion et al. (2019) hence focused on the ice phase of total water to estimate the diurnal amount of ice injected into the UT and the TL over convective tropical areas, showing that it is larger over land than over ocean, with maxima over land of the Maritime Continent (MariCont), the region including Indonesian islands. For these reasons, the present study is focusing on
- 40 the MariCont region in order to better understand small-scale processes impacting the diurnal injection of ice up to the TL.

A method to estimate the amount of ice injected into the UT and up to the TL over convective areas and during convective seasons has been proposed by Dion et al. (2019). This method provides an estimation of the amplitude of the diurnal cycle of ice in those layers using the twice daily in local times Ice Water Content (IWC) measurements from the Microwave Limb Sounder (MLS) instrument and the full diurnal cycle of precipitation (Prec) measured by the Tropical Rainfall Measurement

- 45 Mission (TRMM) instrument, at one hour resolution. The method first focuses on the increasing phase of the diurnal cycle of Prec (peak to peak from the diurnal Prec minimum to the diurnal Prec maximum) and shows that the increasing phase of Prec is consistent in time and in amplitude with the increasing phase of the diurnal cycle of deep convection, over tropical convective zones and during convective season. The amount of ice ( $\Delta$ IWC) injected into the UT and the TL is estimated by relating IWC measured by MLS during the growing phase of the deep convection to the increasing phase of the diurnal cycle of Prec. Dion
- 50 et al. (2019) conclude that deep convection over the MariCont region is the main process impacting the increasing phase of the diurnal cycle of ice in those layers.

The MariCont region is one of the main convective center in the tropics with the wettest troposphere and the coldest and driest tropopause (Ramage, 1968; Sherwood, 2000; Hatsushika and Yamazaki, 2001). Yang and Slingo (2001) have shown that, over the Indonesian area, the phase of the convective activity diurnal cycle drifts from land to coastlines and to offshore areas. Even though those authors have done a comprehensive study of the diurnal cycle of precipitation and convection over the MariCont, the diurnal cycle of ice injected by deep convection up to the TL over this region is still not well understood.

2

Millán et al. (2013) have tentatively evaluated the upper tropospheric diurnal cycle of ice from Superconducting Submillimeter-Wave Limb-Emission Sounder (SMILES) measurements over the period 2009-2010 but without differentiating land and sea over the MariCont, which caused their analysis to show little diurnal variation over that region. Dion et al. (2019) have 1)

- 60 highlighted that the MariCont must be considered as two separate areas: the MariCont land (MariCont\_L) and the MariCont ocean (MariCont\_O), with two distinct diurnal cycles of the Prec and 2) estimated the amount of ice injected in the UT and the TL. Over these two domains, it has also been shown that convective processes are stronger over MariCont\_L than over MariCont\_O. Consequently, the amount of ice injected in the UT and the TL is greater over MariCont\_L than over MariCont\_O.
- Building upon the results of Dion et al. (2019), the present study aims to improve their methodology by i) studying smaller study zones than in Dion et al. (2019) and by distinguishing island and sea of the MariCont, ii) comparing the sensitivity of our model to different proxies of deep convection and iii) comparing the amount of ice injected in the UT and the TL inferred by our model to that of ERA5 reanalyses. Based on space-borne observations and meteorological reanalyses,  $\Delta$ IWC is assessed at a horizontal resolution of 2° × 2° over 5 islands (Sumatra, Borneo, Java, Sulawesi and New Guinea) and 5 seas
- 70 (West Sumatra Sea, Java Sea, China Sea, North Australia Sea, and Bismarck Sea) of the MariCont during convective season (December, January and February, hereafter DJF) from 2004 to 2017.  $\Delta$ IWC will be first estimated from Prec measured by TRMM-3B42. A sensitivity study of  $\Delta$ IWC based on the number of flashes (Flash) detected by the TRMM Lightning Imaging Sensor (TRMM-LIS), an alternative proxy for deep convection as shown by Liu and Zipser (2008), is also proposed. Finally, we will use IWC calculated by the ERA5 reanalyses from 2005 to 2016 to estimate  $\Delta$ IWC in the UT and the TL over each
- rs study zone and compare it to  $\Delta$ IWC estimated from Prec and Flash.

The observational datasets used in our study are presented in Sect. 2. Method is reviewed in Sect. 3. The amount of ice  $(\Delta IWC)$  injected up to the TL estimated from Prec is evaluated in Sect. 4. Diurnal cycles of Prec and Flash are compared to each other over different areas of the MariCont in Sect. 5. Results of the estimated  $\Delta IWC$  injected up to the UT and the TL over five islands and five seas of the MariCont are presented and compared with the ERA5 reanalyses in Sect. 6. Results are

80 discussed in Sect. 7, and conclusions are drawn in Sect. 8. This paper contains many abbreviations and acronyms. To facilitate reading, they are compiled in the Acronyms list.

# 2 Datasets

This section presents the instruments and the reanalyses used for this study.

### 2.1 MLS Ice Water Content

85 The Microwave Limb Sounder (MLS, data processing algorithm version 4.2) instrument on board NASA's Earth Observing System (EOS) Aura platform (Waters et al., 2006; Livesey et al., 2018) launched in 2004 provides ice water content (IWC<sup>MLS</sup>, mg m<sup>-3</sup>) measurements. MLS data processing provides IWC<sup>MLS</sup> at 6 levels in the UTLS (82, 100, 121, 146, 177 and 215 hPa). Although optimal estimation is used to retrieve almost all other MLS products, a cloud-induced radiance technique is

used to derive the IWC<sup>MLS</sup> (Wu et al., 2008, 2009). We have chosen to study only two levels: an upper and a lower level

- 90 of the TTL. Because the level at 82 hPa does not provide enough significant measurements of IWC to have a good signal-tonoise, we have selected: 1) 100 hPa as the upper level of the TTL (named TL for tropopause level), and 2) 146 hPa as the lower level of the TTL (named UT for upper troposphere). MLS follows a sun-synchronous near-polar orbit, completing 233 revolution cycles every 16 days, with daily global coverage every 14 orbits. The instrument crosses the equator twice a day at fixed times, measuring IWC<sup>MLS</sup> at 01:30 local time (LT) and 13:30 LT. The vertical resolution of IWC<sup>MLS</sup> is 4 and 5 km
- at 146 and 100 hPa, respectively. In our study, high horizontal resolution is now possible because we consider 13 years of MLS data, allowing the IWC<sup>*MLS*</sup> measurements to be averaged within bins of horizontal resolution of  $2^{\circ} \times 2^{\circ}$  (~ 230 km<sup>2</sup>). We select IWC<sup>*MLS*</sup> during all austral convective seasons DJF between 2004 and 2017. The IWC measurements were filtered following the recommendations of the MLS team described in Livesey et al. (2018). The resolution of IWC<sup>*MLS*</sup> (horizontal along the path, horizontal perpendicular to the path, vertical) measured at 146 and 100 hPa is  $300 \times 7 \times 4$  km and  $250 \times 7 \times 5$  km,
- respectively. The precision of the measurement is  $0.10 \text{ mg m}^{-3}$  at 146 hPa and 0.25 to 0.35 mg m<sup>-3</sup> at 100 hPa. While the accuracy is 100% for values less than 10 mg m<sup>-3</sup> at both levels, it is strongly reduce by averaging on the study period and over the study zones. The valid range is 0.1-50.0 mg m<sup>-3</sup> at 146 hPa and 0.02-50.0 mg m<sup>-3</sup> at 100 hPa (Wu et al., 2008).

# 2.2 TRMM-3B42 Precipitation

The Tropical Rainfall Measurement Mission (TRMM) was launched in 1997 and provided measurements of Prec until 2015.

- 105 TRMM is composed of five instruments, three of them are complementary sensor rainfall suite (PR, TMI, VIRS). TRMM had an almost circular orbit at 350 km altitude performing a complete revolution in one and a half hour. The 3B42 algorithm product (TRMM-3B42) (version V7) has been created to estimate the precipitation and extend the precipitation product through 2019. TRMM-3B42 is a multi-satellite precipitation analysis. The analysis merges microwave and infrared space-borne observations and included TRMM measurements from 1997 to 2015 (Huffman et al., 2007, 2010; Huffman and Bolvin,
- 110 2018). Work is currently underway with NASA funding to develop more appropriate estimators for random error, and to introduce estimates of bias error (Huffman and Bolvin, 2018). Prec data are provided at a 0.25° × 0.25° (~ 29.2 km<sup>2</sup>) horizontal resolution, extending from 50° S to 50° N (https://pmm.nasa.gov/data-access/downloads/trmm, last access: April 2019). Prec from TRMM-3B42 products does not differentiate between stratiform and convective precipitation. In our study, Prec from TRMM-3B42 is selected over the austral convective seasons (DJF) from 2004 to 2017 and averaged to a horizontal grid of
- 115  $2^{\circ} \times 2^{\circ}$  to be compared to IWC<sup>*MLS*</sup>. The TRMM-3B42 data have been averaged over a 1-hour interval from 0 to 24 hours. TRMM-3B42 data are provided in Universal Time that we converted into local time (LT). Details of the binning methodology of TRMM-3B42 is provided by Huffman and Bolvin (2018).

# 2.3 TRMM-LIS number of Flashes

The Lightning Imaging Sensor (LIS) aboard of the TRMM satellite measures several parameters related to lightning. According to Christian et al. (2000), LIS used a Real-Time Event Processor (RTEP) that discriminates lightning events from Earth albedo light. A lightning event corresponds to the detection of a light anomaly on a pixel representing the most fundamental detection of the sensor. After spatial and temporal processing, the sensor was able to characterize a flash from several detected events. The observation range of the sensor is between  $38^{\circ}$  N and  $38^{\circ}$  S. The instrument detects lightning with storm-scale resolution of 3-6 km (3 km at nadir, 6 km at limb) over a large region ( $550 \times 550$  km) of the Earth's surface. The LIS horizontal

- 125 resolution is provided at  $0.25^{\circ} \times 0.25^{\circ}$ . A significant amount of software filtering has gone into the production of science data to maximize the detection efficiency and confidence level. Thus, each datum is a lightning signal and not noise. Furthermore, the weak lightning signals that occur during the day are hard to detect because of background illumination. A RTEP removes the background signal to enable the system to detect weak lightning and improves the detection efficiency during the day. LIS is thus able to provide the number of flashes (Flash) measured. The TRMM LIS detection efficiency ranges from 69% near noon
- 130 to 88% at night. The LIS instrument performed measurements between 1 January 1998 and 8 April 2015. To be as consistent as possible to the MLS and TRMM-3B42 period of study, we are using LIS measurements during DJF from 2004 to 2015. As LIS is on the TRMM platform, with an orbit that precesses, Flash from LIS can be averaged to obtain the full 24-h diurnal cycle of Flash over the study period with a 1-h temporal resolution. In our study, Flash measured by LIS is binned at  $0.25^{\circ} \times 0.25^{\circ}$  horizontal resolution to be compared to Prec from TRMM-3B42.

# 135 2.4 ERA5 Ice Water Content

The European Centre for Medium-range Weather Forecasts (ECMWF) Reanalysis 5, known as ERA5, replaces the ERA-Interim reanalyses as the fifth generation of the ECMWF reanalysis providing global climate and weather for the past decades (from 1979) (Hersbach, 2018). ERA5 provides hourly estimates for a large number of atmospheric, ocean and land surface quantities and covers the Earth on a 30 km grid with 137 levels from the surface up to a height of 80 km. Reanalyses such 140 as ERA5 provide a physically constrained, continuous, global, and homogeneous representation of the atmosphere through combining a large number of observations (space-borne, air-borne, and ground-based) with short-range forecasts. Although there is no direct observation of atmospheric ice content in ERA5, the specific cloud ice water content (mass of condensate / mass of moist air) (IWC $^{ERA5}$ ) corresponds to the changes in the analysed temperature (and at low levels, humidity) which is mostly driven by the assimilation of temperature-sensitive radiances from satellite instruments (https://cds.climate.copernicus. eu/cdsapp!/dataset/reanalysis-era5-pressure-levels-monthly-means?tab=form, last access: July 2019). IWCERA5 used in our 145 analysis is representative of non-precipitating ice. Precipitating ice, classified as snow water, is also provided by ERA5 but not used in this study in order to focus only on the injected and non-precipitating ice in the TTL. Furthermore, results from Duncan and Eriksson (2018) have highlighted that ERA5 is able to capture both seasonal and diurnal variability in cloud ice water but the reanalyses exhibit noisier and higher amplitude diurnal variability than borne out by the satellite estimates. The present study uses the IWC<sup>ERA5</sup> at 100 and 150 hPa averaged over DJF from 2005 to 2016 with one-hour temporal resolution. 150 IWC<sup>ERA5</sup> is governed by the model microphysics which allows ice supersaturation with respect to ice (100-150% in relative humidity) but not with respect to liquid water. Although microwave radiances at 183 GHz (sensitive to atmospheric scattering induced by ice particles) (Geer et al., 2017) are assimilated, clouds and precipitation are not used as control variables in the

4D-Var assimilation system and cannot be adjusted independently in the analysis (Geer et al., 2017). The microwave data have

155 sensitivity to the frozen phase hydrometeors but mainly to larger particles, such as those in the cores of deep convection (Geer

et al., 2017), but the sensitivity to cirrus clouds in ERA5 is strongly dependent on microphysical assumptions on the shape and size of the cirrus particles. Indirect feedbacks are also acting on cirrus representation in the model – e.g. changing the intensity of the convection will change the amount of outflow cirrus generated. This is why observations that affect the troposphere by changing for example the stability, the humidity, or the synoptic situation can affect the upper level ice cloud indirectly
(Geer et al., 2017). IWC<sup>ERA5</sup> is compared to the amount of ice injected in the UT and the TL as estimated by the model developed in Dion et al. (2019) and in the present study. IWC<sup>ERA5</sup> have been degraded along the vertical at 100 and 150 hPa (\langle \Delta IWC<sup>ERA5</sup> \rangle) consistently with the MLS vertical resolution of IWC<sup>MLS</sup> (5 and 4 km at 100 and 146 hPa, respectively) using a box function (see section 7.2). IWC<sup>ERA5</sup> and \langle \Delta IWC<sup>ERA5</sup> will be both considered in this study. IWC<sup>ERA5</sup>, initially provided in kg kg<sup>-1</sup>, has been converted into mg m<sup>-3</sup> using the temperature provided by ERA5 in order to be compared with

165 IWC $^{MLS}$ .

170

# 3 Methodology

This section summarizes the method developed by Dion et al. (2019) to estimate  $\Delta$ IWC, the amount of ice injected into the UT and the TL. Dion et al. (2019) have presented a model relating Prec (as proxy of deep convection) from TRMM to  $IWC^{MLS}$  over tropical convective areas during austral convective season DJF. The IWC<sup>MLS</sup> value measured by MLS during the growing phase of the convection (at x = 01:30 LT or 13:30 LT) is compared to the Prec value at the same time x in order to define the correlation coefficient (C) between Prec and IWC<sup>MLS</sup>, as follows:

$$C = \frac{IWC_x^{MLS}}{Prec_x} \tag{1}$$

The diurnal cycle of IWC estimated  $(IWC^{est}(t))$  can be calculated by using C applied to the diurnal cycle of Prec (Prec(t)), where t is the time, as follows:

175 
$$IWC^{est}(t) = Prec(t) \times C$$
 (2)

The amount of IWC injected up to the UT or the TL ( $\Delta IWC^{Prec}$ ) is defined by the difference between the maximum of IWC<sup>est</sup> (IWC<sup>est</sup><sub>max</sub>) and its minimum (IWC<sup>est</sup><sub>min</sub>).

$$\Delta IWC^{Prec} = C \times (Prec_{max} - Prec_{min}) = IWC_{max}^{est} - IWC_{min}^{est}$$
(3)

where  $Prec_{max}$  and  $Prec_{min}$  are the diurnal maximum and minimum of Prec, respectively. Figure 1 illustrates the relationship between the diurnal cycle of Prec and the two MLS measurements at 01:30 and 13:30 LT. The growing phase of the convection is defined as the period of increase in precipitation from Prec to Prec. The amplitude of the diurnal cycle is defined by

is defined as the period of increase in precipitation from  $Prec_{min}$  to  $Prec_{max}$ . The amplitude of the diurnal cycle is defined by the difference between  $Prec_{max}$  and  $Prec_{min}$ . In Fig. 1, because the growing phase of the convection illustrated is happening during the afternoon, only the MLS measurement at 13:30 LT is used in the calculation of  $\Delta$ IWC. IWC at 01:30 LT is not used in that case.

**Figure 1.** Illustration of the model developed in Dion et al. (2019) to estimate the amount of ice ( $\Delta$ IWC) injected into the UT or the TL. Diurnal cycle of a proxy of deep convection (Prec) (a), diurnal cycle of ice water content (IWC) estimated from diurnal cycle of the proxy of deep convection (b). In red line, the increasing phase of the diurnal cycle. In black dashed line, the decreasing phase of the diurnal cycle. The green diamonds are the two IWC<sup>*MLS*</sup> measurements from MLS. Grey thick cross represents the measurement of Prec during the growing phase of the convection (Prec<sub>x</sub>), used in the model. Maximum and minimum of the diurnal cycles are represented by black squares. Amplitude of the diurnal cycle is defined by the differences between the maximum and the minimum of the cycle.

# 185 4 Horizontal distribution of $\Delta$ IWC estimated from Prec over the MariCont

# 4.1 Prec from TRMM-3B42 related to IWC from MLS

**Figure 2.** Main islands and seas of the MariCont (S is for Sumatra) (a), elevation from Solar Radiation Data (SoDa) (b); daily mean of Prec obtained from TRMM analysis over the Maritime Continent, averaged over the period of DJF 2004-2017 (c), hour (local solar time (LST)) of the diurnal maxima of Prec over the MariCont (d); daily mean (01:30 LT + 13:30 LT)/2 of IWC<sup>*MLS*</sup> at 146 hPa from MLS over the MariCont averaged over the period of DJF 2004-2017 (e). Observations are presented with a horizontal resolution of  $0.25^{\circ} \times 0.25^{\circ}$  (b, c and d) and  $2^{\circ} \times 2^{\circ}$  (e).

In order to identify the main areas of injection of ice in the TL over the MariCont, Figure 2 presents different parameters associated to this area: a) the name of the main islands and seas over the MariCont, b) the elevation (http://www.sodapro.com/web-services/altitude/srtm-in-a-tile, last access: June 2019), c) the daily mean of Prec at  $0.25^{\circ} \times 0.25^{\circ}$  horizon-

West of Borneo in the China Sea and southern Sumatra in the Java Sea) (Fig. 2b and c). The times of the maxima of Prec are

- 190 tal resolution, d) the hour of the diurnal maxima of Prec at  $0.25^{\circ} \times 0.25^{\circ}$  horizontal resolution, and e) the daily mean  $(I\bar{W}C = (IWC_{01:30} + IWC_{13:30}) \times 0.5)$  of IWC<sup>MLS</sup> at 146 hPa at  $2^{\circ} \times 2^{\circ}$  horizontal resolution. Several points need to be highlighted. Daily means of Prec over land and coastal parts are higher than over oceans (Fig. 2c). Areas where the daily mean of Prec is maximum are usually surrounding the highest elevation over land (e.g. over ) and near coastal areas (North
- 195 over land during the evening (18:00-00:00 LT), over coast during the night-morning (00:00-06:00 TL) and over sea during the morning-noon and even evening depending on the sea considered (09:00-12:00 LT and 15:00-00:00 LT). These differences may be related to the impact of the land/sea breeze over the course of 24 hours. The sea breeze during the day favours the land convection at the end of the day when land surface temperature is higher than oceanic surface temperature. During the night, the coastline sea surface temperature rises above the land surface temperature, and the land breeze systematically favours the
- development of convection over coasts. These observations are consistent with results presented by Qian (2008), who explained that high precipitation is mainly concentrated over land in the MariCont because of the strong sea-breeze convergence, but also because of the combination with the mountain–valley winds and cumulus merging processes. Amplitudes of the diurnal cycles of Prec over the MariCont will be detailed as a function of island and sea in section 5. The location of the largest concentration of IWC<sup>MLS</sup> (3.5 5.0 mg m<sup>-3</sup>, Fig. 2e) is consistent with that of Prec (~ 12 16 mm day<sup>-1</sup>) over the West Sumatra Sea, and over the South of Sumatra island. However, over North Australia seas (including the Timor Sea and the Arafura Sea), we
- observed large differences between Prec low values  $(4 8 \text{ mm day}^{-1})$  and IWC<sup>MLS</sup> large concentrations  $(4 7 \text{ mg m}^{-3})$ .

# 4.2 Convective processes compared to IWC measurements

Although TRMM horizontal resolution is 0.25° × 0.25°, we require information at the same resolution as IWC<sup>MLS</sup>. From the diurnal cycle of Prec in TRMM analysis, the duration of the increasing phase of Prec can be known for each 2° × 2° pixel.
The duration of the growing phase of the convection can then be defined from Prec over each pixel. Figures 3a and b present the anomaly (deviation from the mean) of Prec in TRMM-3B42 over the MariCont for the pixels where convection is in the growing phase at 01:30 LT and 13:30 LT, respectively. Anomalies are calculated relative to the average computed over the entire MariCont region. Thus, red colors signify regions that are experiencing the growing phase of convection and whose Prec value is greater than the overall MariCont mean at the respective time (01:30 LT or 13:30 LT), whereas blue colors signify those
regions where there is little precipitation compared to the overall MariCont mean during the growing phase of convection. The

gray color denotes pixels for which convection is not ongoing. Pixels can be represented in the panels for both local times when: 1) the onset of the convection is before 01:30 LT and the end is after 13:30 LT, or 2) the onset of the convection is before 13:30 LT and the end is after 01:30 LT. Similar anomalies of IWC<sup>MLS</sup> over the MariCont are shown in Figs. 3c and d, over pixels when the convection is in the growing phase at 01:30 LT and 13:30 LT, respectively. Note that, within each  $2^{\circ} \times 2^{\circ}$ 

pixel, at least 60 measurements of Prec or IWC<sup>MLS</sup> at 13:30 LT or 01:30 LT over the period 2004-2017 have been selected for the average.

The Prec anomaly at 01:30 LT and 13:30 LT varies between -0.15 and +0.15 mm h<sup>-1</sup>. The IWC<sup>MLS</sup> anomaly at 13:30 LT and 01:30 LT varies between -3 and +3 mg m<sup>-3</sup>. At 13:30 LT, the growing phase of the convection is found mainly over land. At 13:30 LT, over land, the strongest Prec and IWC<sup>MLS</sup> anomalies (+0.15 mm h<sup>-1</sup> and +2.50 mg m<sup>-3</sup>, respectively) are
found over the Java island, and northern Australia for IWC<sup>MLS</sup>. At 01:30 LT, the growing phase of the convection is found mainly over sea (while the pixels of the land are mostly gray), with maxima of Prec and IWC<sup>MLS</sup> anomalies over coastlines and seas close to the coasts such as the Java Sea and the Bismarck Sea. Three types of areas can be distinguished from Fig. 3: i) area where Prec and IWC<sup>MLS</sup> anomalies have the same sign (positive or negative either at 01:30 LT or 13:30 LT) (e.g. over Java, Borneo, Sumatra, Java Sea and coast of Borneo or the China Sea); ii) area where Prec anomaly is positive and IWC<sup>MLS</sup> anomaly is negative (e.g. over West Sumatra Sea); and iii) area where Prec anomaly is negative and IWC<sup>MLS</sup> anomaly is positive (e.g. over the North Australia Sea at 01:30 LT). Convective processes associated to these three types of areas over

islands and seas of the MariCont are discussed in Sect. 6.

**Figure 3.** Anomaly (deviation from the mean) of Prec (a-b) and Ice Water Content (IWC<sup>MLS</sup>) at 146 hPa (c-d), at 01:30 LT (left) and at 13:30 LT (right) over pixels where 01:30 LT and 13:30 LT are during the growing phase of the convection, respectively, averaged over the period of DJF 2004-2017. The gray color denotes pixels for which convection is not ongoing.

# 4.3 Horizontal distribution of ice injected into the UT and TL estimated from Prec

235

From the model developed in Dion et al. (2019) based on Prec from TRMM–3B42 and IWC from MLS and synthesized in section 2.4, we can calculate the amount of IWC injected ( $\Delta$ IWC) at 146 hPa (UT, Figure 4a) and at 100 hPa (TL, Figure 4b) by deep convection over the MariCont. In the UT, the amount of IWC injected over land is on average larger (> 10 – 20 mg m<sup>-3</sup>) than over seas (< 15 mg m<sup>-3</sup>). Southern Sumatra, Sulawesi, northern New Guinea and northern Australia present the

largest amounts of  $\Delta$ IWC over land (15 – 20 mg m<sup>-3</sup>). Java Sea, China Sea and Bismarck Sea present the largest amounts of  $\Delta$ IWC over seas (7 – 15 mg m<sup>-3</sup>). West Sumatra Sea and North Australia Sea present low values of  $\Delta$ IWC (< 2 mg m<sup>-3</sup>).

- 240 We can note that the anomalies of Prec and IWC during the growing phase over North Australia Sea at 13:30 LT are positive (> 0.2 mm h<sup>-1</sup>, Fig. 3b and > 2.5 mg m<sup>-3</sup>, Fig. 3d, respectively). In the TL, the maxima (up to 3.0 mg m<sup>-3</sup>) and minima (down to 0.2 0.3 mg m<sup>-3</sup>) of  $\Delta$ IWC are located within the same pixels as in the UT, although 3 to 6 times lower than in the UT. The decrease of  $\Delta$ IWC with altitude is larger over land (by a factor 6) than over sea (by a factor 3). We can note that the similar pattern between the two layers comes from the diurnal cycle of Prec in the calculation of  $\Delta$ IWC at 146 and 100 hPa.
- 245 The differences in the magnitudes of the  $\Delta$ IWC values at 100 and 146 hPa arise from the different amounts of IWC measured by MLS at those two levels. That is, similar  $\Delta$ IWC patterns are expected between the two levels because, according to the model developed in Dion et al. (2019), deep convection is the main process transporting ice into the UT and the TL during the growing phase of the convection. Convective processes associated to land and sea are further discussed in Sect. 6.

Figure 4. Daily amount of ice injected ( $\Delta$ IWC) up to the UT (a) and up to the TL (b) estimated from Prec, averaged during DJF 2004-2017.

In order to better understand the impact of deep convection on the strongest  $\Delta$ IWC injected per pixel up to the TTL, isolated pixels selected in Fig. 4a are presented separately in Figure 5a and f. This Figure shows the diurnal cycles of Prec in four pixels selected for their large  $\Delta$ IWC in the UT ( $\geq$  15 mg m<sup>-3</sup>, Fig. 5b, c, d, e), and the diurnal cycle of Prec in four pixels selected for their low  $\Delta$ IWC in the UT (but large enough to observe the diurnal cycles of IWC between 2.0 and 5.0 mg m<sup>-3</sup>, Fig. 5g, h, i, j). Pixels with low values of  $\Delta$ IWC over land (Fig. 5g, h and i) present small amplitude of diurnal cycles of Prec (~ +0.5 mm h<sup>-1</sup>), with maxima between 15:00 LT and 20:00 LT and minima around 11:00 LT.

255 The pixel with low value of  $\Delta$ IWC over sea (Fig. 5j) presents an almost null amplitude of the diurnal cycle of Prec, with low values of Prec all day long (~ 0.25 mm h<sup>-1</sup>). Pixels with large values of  $\Delta$ IWC over land (Fig. 5b, c, d, e) present longer duration of the increasing phase of the diurnal cycle (from ~ 09:00 LT to 20:00 – 00:00 LT) than the increasing phase of Prec

**Figure 5.** a) and f) Location of  $2^{\circ} \times 2^{\circ}$  pixels where  $\Delta$ IWC have been found higher than 15 mg m<sup>-3</sup> (in Fig. 4) and where  $\Delta$ IWC have been found between 2 and 5 mg m<sup>-3</sup> (in Fig. 4), respectively. Diurnal cycle of Prec (solid line): (b, c, d, e) over 4 pixels where  $\Delta$ IWC have been found higher than 15 mg m<sup>-3</sup> (in Fig. 4), (g, h, i, j) over 4 pixels where  $\Delta$ IWC have been found between 2 and 5 mg m<sup>-3</sup> (in Fig. 4), (g, h, i, j) over 4 pixels where  $\Delta$ IWC have been found between 2 and 5 mg m<sup>-3</sup> (in Fig. 4), during DJF 2004-2017. The diamond represents IWC<sup>MLS</sup> during the increasing phase of the convection. The dashed line is the diurnal cycle of IWC estimated from the diurnal cycle of Prec and from IWC<sup>MLS</sup>.

diurnal cycle over pixels with low values of  $\Delta$ IWC (from 10:00 LT to 15:00 – 19:00 LT). More precisely, pixels labeled 1 and 2 over New Guinea (Fig. 5d and e) and the pixel over southern Sumatra (Fig. 5c) show amplitude of diurnal cycle of Prec reaching 1.0 mm h<sup>-1</sup>, while the pixel over North Australia (Fig. 5b) presents lower amplitude of diurnal cycle of Prec (0.5 mm

260 1

 $h^{-1}$ ).

IWC<sup>*MLS*</sup> during the growing phase of deep convection and the diurnal cycle of IWC estimated from Prec are also shown on Fig. 5. For pixels with large values of  $\Delta$ IWC, IWC<sup>*MLS*</sup> is between 4.5 and 5.7 mg m<sup>-3</sup> over North Australia, South Sumatra and New Guinea 1. For pixels with low values of  $\Delta$ IWC, IWC<sup>*MLS*</sup> is found between 1.9 and 4.7 mg m<sup>-3</sup>. To summarize, large values of  $\Delta$ IWC are observed over land in combination to i) longer growing phase of deep convection (> 9 hours) and/or

265

ii) large diurnal amplitude of Prec (> 0.5 mm h<sup>-1</sup>). However, as IWC<sup>*MLS*</sup> ranges overlap for the high and low  $\Delta$ IWC, no definitive conclusion about the relationship between IWC<sup>*MLS*</sup> and  $\Delta$ IWC can be drawn.

In the next section, we estimate  $\Delta$ IWC using another proxy of deep convection, namely Flash measurements from LIS.

# 5 Relationship between diurnal cycle of Prec and Flash over MariCont land and sea

270 Lightning is created in cumulonimbus clouds when the electric potential energy difference is large between the base and the top of the cloud. Lightning can appear at the advanced stage of the growing phase of the convection and during the mature phase of the convection. For these reasons, in this section, we use Flash measured from LIS during DJF 2004-2015 as another proxy of deep convection in order to estimate  $\Delta$ IWC ( $\Delta$ IWC<sup>*Flash*</sup>) and check the consistency with  $\Delta$ IWC obtained with Prec ( $\Delta$ IWC<sup>*Prec*</sup>).

# 275 5.1 Flash distribution over the MariCont

Figure 6a presents the daily mean of Flash in DJF 2004-2015 at 0.25° × 0.25° horizontal resolution. Over land, Flash can reach a maximum of 10<sup>-1</sup> flashes day<sup>-1</sup> per pixel while, over seas, Flash are less frequent (~ 10<sup>-3</sup> flashes day<sup>-1</sup> per pixel). When compared to the distribution of Prec (Fig. 2c), maxima of Flash are found over similar areas as maxima of Prec (Java, East of Sulawesi coast, Sumatra and northern Australia). Over Borneo and New Guinea, coastlines present more Flash (~10<sup>-2</sup> flashes day<sup>-1</sup>) than inland (~10<sup>-3</sup> flashes day<sup>-1</sup>). Differences between Flash and Prec distributions are found over North Australia Sea, with relatively large number of Flash (>10<sup>-2</sup> flashes day<sup>-1</sup>) compared to low Prec (4 – 10 mm day<sup>-1</sup>) (Fig. 2c), and over several inland areas of New Guinea where the number of Flash is relatively low (~10<sup>-2</sup> – 10<sup>-3</sup> flashes day<sup>-1</sup>) while Prec is high (~14 – 20 mm day<sup>-1</sup>). Figure 6b shows the hour of the Flash maxima. Over land, the maximum of Flash is between 15:00 LT and 24:00 LT. Coastal areas

285 present similar hours of maximum of Prec and Flash, i.e between 00:00 LT and 04:00 LT although, over the West Sumatra Coast, diurnal maxima of both Prec and Flash happen 1–4 hours earlier (from 23:00-24:00 LT) than those of other coasts.

Figure 6. Daily mean of Flash measured by LIS averaged over the period DJF 2004-2015 (a); Hour (local solar time (LST)) of the diurnal maximum of Flash (b).

# 5.2 Prec and Flash diurnal cycles over the MariCont

290

This section compares the diurnal cycle of Flash with the diurnal cycle of Prec in order to assess the potential for Flash to be used as a proxy of deep convection over land and sea of the MariCont. Diurnal cycles of Prec and Flash over the MariCont land, coastline and offshore (MariCont\_L, MariCont\_C, MariCont\_O, respectively) are shown in Figs. 7a–c, respectively. Within each  $0.25^{\circ} \times 0.25^{\circ}$  bin, land/coast/ocean filters were applied from the Solar Radiation Data (SoDa, http://www.soda-pro. com/web-services/altitude/srtm-in-a-tile). MariCont\_C is the average of all coastlines defined as 5 pixels extending into the sea from the land limit. This choice of 5 pixels was made after consideration of some sensitivity tests in order to have the best compromise between a high signal-to-noise ratio and a good representation of the coastal region. The MariCont\_O is the average of all offshore pixels defined as sea pixels excluding 10 pixels (2000 km) over the sea from the land, thus coastline

average of all offshore pixels defined as sea pixels excluding 10 pixels (2000 km) over the sea from the land, thus coastline pixels are excluded as well as all the coastal influences. MariCont\_L is the area of all land pixels. At the border between the land and the coast areas, a given  $0.25^{\circ} \times 0.25^{\circ}$  pixel can contain information from both land and coastlines. In that case, we can easily discriminate between land and coastlines by applying the land/coastlines filters. Consequently, this particular pixel will be flagged both as land and coastlines.

**Figure 7.** Diurnal cycle of Prec (solid line) and diurnal cycle of Flash (dashed line) over MariCont\_L (a), MariCont\_C (b) and MariCont\_O (c).

- Over land, during the growing phase of the convection, Prec and Flash start to increase at the same time (10:00 LT 12:00 LT) but Flash reaches a maximum earlier (15:00 LT 16:00 LT) than Prec (17:00 LT 18:00 LT). This is consistent with the finding of Liu and Zipser (2008) over the whole tropics. Different maximum times could come from the fact that, while the deep convective activity intensity starts to decrease with the number of flashes, Prec is still high during the dissipating stage of the convection and takes longer to decrease than Flash. Consequently, combining our results with the ones presented in Dion
- 305 et al. (2019), Flash and Prec can be considered as good proxies of deep convection during the growing phase of the convection over the MariCont\_L.

Over coastlines (Fig. 7b), the Prec diurnal cycle is delayed by about +2 to 7 h with respect to the Flash diurnal cycle. Prec minimum is around 18:00 LT while Flash minimum is around 11:30 LT. Maxima of Prec and Flash are found around

04:00 LT and 02:00 LT, respectively. This means that the increasing phase of Flash is 2-3 h longer than that of Prec. These

- results are consistent with the work of Mori et al. (2004) showing a diurnal maximum of precipitation in the early morning 310 between 02:00 LT and 03:00 LT and a diurnal minimum of precipitation between 11:00 LT and 21:00 LT, over coastal zones of Sumatra. According to Petersen and Rutlegde (2001) and Mori et al. (2004), coastal zones are areas where precipitation results more from convective activity than from stratiform activity and the amplitude of diurnal maximum of Prec decreases with the distance from the coastline.
- 315 Over offshore areas (Fig. 7c), minima of diurnal cycle of Prec and diurnal cycle of Flash are in the late afternoon, between 16:00 LT and 17:00 LT (Flash) and 17:00 LT and 18:00 LT (Prec), whilst maxima of diurnal cycle of Prec and Flash are reached in the early morning, between 06:00 LT and 07:00 LT (Flash) and around 08:00 LT – 09:00 LT (Prec). Results over offshore areas are consistent with diurnal cycle of Flash and Prec calculated by Liu and Zipser (2008) over the whole tropical ocean, showing the increasing phase of the diurnal cycle of Flash starting 1-2 hours before the increasing phase of the diurnal cycle 320 of Prec.

The time of transition from maximum to minimum of Prec is always longer than that of Flash. The period after the maximum of Prec is likely more representative of stratiform rainfall than deep convective rainfall. Consistent with that picture, model results from Love et al. (2011) have shown the suppression of deep convection over the offshore area west of Sumatra from the early afternoon due to a downwelling wavefront characterized by deep warm anomalies around noon. According to the

325 authors, later in the afternoon, gravity waves are forced by the stratiform heating profile and propagate slowly offshore. They also highlighted that the diurnal cycle of the offshore convection responds strongly to the gravity wave forcing at the horizontal scale of 4 km. To summarize, diurnal cycles of Prec and Flash show that:

i) over land, Flash increases proportionally with Prec during the growing phase of the convection,

ii) over coastlines, Flash increasing phase is more than 6–7 hours ahead of Prec increasing phase,

iii) over offshore areas, Flash increasing phase is about 1-2 hours ahead of Prec increasing phase. 330

In section 7, we investigate whether this time difference impacts the estimation of  $\Delta$ IWC over land, coasts, and offshore areas.

#### 5.3 Prec and Flash diurnal cycles and small-scale processes

- 335
- In this subsection, we study the diurnal cycle of Prec and Flash at  $0.25^{\circ} \times 0.25^{\circ}$  resolution over areas of deep convective activity over the MariCont. In line with the distribution of large value of Prec (Fig. 2), IWC<sup>MLS</sup> (Fig. 3) and  $\Delta$ IWC (Fig. 4), we have selected five islands and five seas over the MariCont. Diurnal cycles of Prec and Flash are presented over land for a) Java, b) Borneo, c) New Guinea, d) Sulawesi and e) Sumatra as shown in Figure 8 and over sea for the a) Java Sea, b) North Australia Sea (NAusSea), c) Bismarck Sea, d) West Sumatra Sea (WSumSea) and e) China Sea as shown in Figure 9. Diurnal cycles of IWC from ERA5 (IWC<sup>ERA5</sup>) are also presented in Figs. 8 and 9 and will be discussed in Section 6.
- Over land, the amplitude of the diurnal cycle of Prec is the largest over Java (Fig. 8a), consistent with Oian (2008), with a 340 maximum reaching 1 mm  $h^{-1}$ , while, over the other areas, maxima are between 0.4 and 0.6 mm  $h^{-1}$ . Furthermore, over Java, the duration of the increasing phase in the diurnal cycle of Prec is 6 h, consistent with that of Flash, whereas elsewhere the

**Figure 8.** Diurnal cycles of Prec (solid line), Flash (dashed line) and IWC<sup>*ERA5*</sup> from ERA5 at 150 hPa (dotted line) over MariCont islands: Java (a), Borneo (b), New Guinea (c), Sulawesi (d) and Sumatra (e) and map of the study zones over land (f).

duration of the increasing phase is longer in Prec than in Flash by 1–2 h. The particularity of Java is related to the increasing phase of the diurnal cycle of Prec (6 h), which is faster than over all the other land areas considered in our study (7 – 8 h). The
strong and rapid convective growing phase measured over Java might be explained by the fact that the island is narrow with high mountains (up to ~ 2000 m of altitude, as shown in Fig. 2b) reaching the coast. The topography promotes the growth of intense and rapid convective activity. The convection starts around 09:00 LT, rapidly elevating warm air up to the top of the mountains. Around 15:00 LT, air masses cooled in altitude are transported to the sea favoring the dissipating stage of the convection. Sulawesi is also a small island with high topography as Java. However, the amplitude of the diurnal cycle of Prec
and Flash is not as strong as over Java. Other islands, such as Borneo, New Guinea and Sumatra, have high mountains but also large lowland areas. Mountains promote deep convection at the beginning of the afternoon while lowlands help maintain the convective activity through shallow convection and stratiform rainfall (Nesbitt and Zipser, 2003; Qian, 2008). Deep and shallow convection are then mixed during the slow dissipating phase of the convection (from ~ 16:00 LT to 08:00 LT). However, because Flash are observed only in deep convective clouds, the decreasing phase of Flash diurnal cycles decreases

more rapidly than the decreasing phase of Prec. The diurnal maxima of Prec found separately over the 5 islands of the MariCont (at  $0.25^{\circ} \times 0.25^{\circ}$  resolution) are much higher than the diurnal maxima of Prec found over tropical land (South America, South Africa and MariCont\_L, at  $2^{\circ} \times 2^{\circ}$  resolution) from Dion et al. (2019):  $\sim 0.6 - 1.0$  mm h<sup>-1</sup> and  $\sim 0.4$  mm h<sup>-1</sup>, respectively. However, the duration of the increasing phase of the diurnal cycle of Prec is consistent with the one calculated over tropical land by Dion et al. (2019).

**Figure 9.** Diurnal cycles of Prec (solid line), Flash (dashed line) and  $IWC^{ERA5}$  from ERA5 at 150 hPa (dotted line) over MariCont seas: Java Sea (a), North Australia Sea (NAusSea) (b), Bismarck Sea (c), West Sumatra Sea (WSumSea) (d), China Sea (e) and map of the study zones over sea (f).

Over sea, the five selected areas (Fig. 9a–e) show a diurnal cycle of Prec and Flash similar to that of either coastline or offshore areas depending on the region considered. The diurnal cycle of Prec and Flash over Java Sea is similar to the one over coastlines (Fig. 7b). Java Sea (Fig. 9a), an area mainly surrounded by coasts, shows the largest diurnal maximum of Prec ( $\sim 0.7 \text{ mm h}^{-1}$ ) and Flash ( $\sim 1.1 \ 10^{-3}$  flashes h<sup>-1</sup>) with the longest growing phase. In this area, land and sea breezes observed in coastal areas impact the diurnal cycle of the convection (Qian, 2008). During the night, land breeze develops from

- 365 a temperature gradient between warm sea surface temperature and cold land surface temperature and conversely during the day. Over Java Sea, Prec is strongly impacted by land breezes from Borneo and Java islands (Qian, 2008), explaining why Prec and Flash reach largest values during the early morning. By contrast, NAusSea, Sea and WSumSea (Figs. 9b, c and d, respectively) present small amplitude of diurnal cycle. In our analysis, these three study zones are the areas including the most offshore pixels. Java Sea and WSumSea present a similar diurnal cycle of Prec and Flash, with Flash growing phase starting
- about 4 h earlier than that of Prec. China Sea also shows a diurnal maximum of Flash shifted by about 4 hours before the diurnal maximum of Prec, but the time of the diurnal minimum of Prec and Flash is similar. Over China Sea and Bismarck Sea, the diurnal cycle of Flash shows a weak amplitude with maxima reaching only 0.1 0.2 10<sup>-3</sup> flashes h<sup>-1</sup>. Furthermore, over the Sea, while the diurnal minimum in Prec is around 18:00 LT, there are several local minima in Flash (08:00, 14:00 and 18:00 LT). Over NAusSea, the diurnal minimum of Prec is delayed by more than 7 hours compared to the diurnal minimum of Prec Elech

375 Flash.

To summarize, over islands, Flash and Prec convective increasing phases start at the same time and increase similarly but the diurnal maximum of Flash is reached 1–2 hours before the diurnal maximum of Prec. Over seas, the duration of the convective increasing phase and the amplitude of the diurnal cycles are not always similar depending on the area considered. The diurnal cycle of Flash over Java Sea and West Sumatra Sea is 4 hours ahead of the diurnal cycle of Prec, and over North Australia Sea, it is more than 7 hours ahead. China Sea and Bismarck Sea present the same time of the onset of the Flash and Prec

380 Sea, it is more than 7 hours ahead. China Sea and Bismarck Sea present the same time of the onset of the Flash and Prec increasing phase. In Section 7, we estimate  $\Delta$ IWC over the 5 selected island and sea areas from Prec and Flash as a proxy of

deep convection.

### 6 Horizontal distribution of IWC from ERA5 reanalyses

The ERA5 reanalysis provides hourly IWC at 150 and 100 hPa (IWC<sup>ERA5</sup>). The diurnal cycle of IWC<sup>ERA5</sup> over the MariCont will be used to calculate  $\Delta IWC^{ERA5}$  in order to support the horizontal distribution and the amount of ice injected in the UT 385 and the TL deduced from our model combining IWC<sup>MLS</sup> and TRMM-3B42 Prec or IWC<sup>MLS</sup> and LIS flash. Since IWC<sup>ERA5</sup> data quality has not yet been fully evaluated, this may impact on the consistency or lack of thereof found in the comparisons between  $\Delta IWC^{ERA5}$  and both  $\Delta IWC^{Prec}$  and  $\Delta IWC^{Flash}$ . Figures 10a, b, c and d present the daily mean and the hour of the diurnal maxima of IWC<sup>ERA5</sup> at 150 and 100 hPa. In the UT, the daily mean of IWC<sup>ERA5</sup> shows a horizontal distribution over the MariCont consistent with that of IWC<sup>MLS</sup> (Fig. 2e), except over New Guinea where IWC<sup>ERA5</sup> (exceeding 6.4 mg m<sup>-3</sup>) 390 is much stronger than IWC<sup>MLS</sup> ( $\sim 4.0 \text{ mg m}^{-3}$ ). The highest amount of IWC<sup>ERA5</sup> is located over New Guinea mountain chain and in the West coast of North Australia (exceeding 6.4 mg m<sup>-3</sup> in the UT and 1.0 mg m<sup>-3</sup> in the TL). Over islands in the UT and the TL, the hour of the IWC<sup>ERA5</sup> diurnal maximum is found between 12:00 LT and 15:00 LT over Sulawesi and New Guinea and between 15:00 LT and 21:00 LT over Sumatra, Borneo and Java, which is close to the hour of the diurnal maximum of Flash over islands (Fig. 6). Over sea, in the UT and the TL, the hour of the IWC<sup>ERA5</sup> diurnal maximum is found 395 between 06:00 LT and 09:00 LT over West Sumatra Sea, Java Sea, North Australia Sea, between 06:00 LT and 12:00 LT over China Sea and between 00:00 LT and 03:00 LT over Bismarck Sea. There are no significant differences between the hour of the maximum of  $IWC^{ERA5}$  in the UT and in the TL.

- The diurnal cycles of IWC<sup>ERA5</sup> at 150 hPa are presented in Figs. 8 and 9 over the selection of islands and seas of the MariCont together with the diurnal cycles of Prec and Flash. Over islands (Fig. 8), the maximum of the diurnal cycle of 400  $IWC^{ERA5}$  is found between 16:00 LT and 17:00 LT, consistent with the diurnal cycle of Prec and Flash. The durations of the increasing phase of the diurnal cycles of Prec, Flash and IWC<sup>ERA5</sup> are all consistent to each other (6 - 8 h). Over sea (Fig. 9), the maximum of the diurnal cycle of IWC<sup>ERA5</sup> is mainly found between 07:00 LT and 10:00 LT over Java Sea and North Australia Sea, consistent with the diurnal cycle of Prec, and a second peak is found around 16:00 LT. Thus, the duration
- of the increasing phase of the diurnal cycles of IWC<sup>ERA5</sup> is consistent with the one of Prec over these two sea study zones 405 ( $\sim$ 10 hours), but not with the one of Flash. Over Bismarck Sea, the diurnal maxima of IWC<sup>ERA5</sup> are found at 04:00 LT with a second peak later at noon. Over West Sumatra Sea, two diurnal maxima are found at 08:00 LT and 17:00 LT. Over China Sea, the diurnal maximum of IWC $^{ERA5}$  is found at 16:00 LT with a second peak at 08:00 LT. These differences in the timing of the maximum of the diurnal cycle of Prec, Flash and IWC<sup>ERA5</sup> observed at small-scale over sea of the MariCont are not
- well understood. However, these differences do not impact on the calculation of the  $\Delta IWC^{Prec}$ .  $\Delta IWC^{Flash}$  or  $\Delta IWC^{ERA5}$ . 410 because only the magnitude of the diurnal cycle (max-min) matters for the calculation of  $\Delta$ IWC.

#### 7 Ice injected over a selection of island and sea areas

Figure 11 synthesizes  $\Delta$ IWC deduced from observations and reanalysis in the UT and the TL over the 5 islands and 5 seas of the MariCont studied in the previous section.

#### 7.1 $\Delta$ IWC deduced from observations 415

Eqs. (1-3) are used to calculate  $\Delta IWC$  from Prec ( $\Delta IWC^{Prec}$ ) and from Flash ( $\Delta IWC^{Flash}$ ). As presented in the previous section, Prec and Flash can be used as two proxies of deep convection, although differences in their diurnal cycles may be present as a function of the region considered. Thus, the observational  $\Delta IWC$  range calculated between  $\Delta IWC^{Prec}$  and  $\Delta IWC^{Flash}$  provides an upper and lower bound of  $\Delta IWC$  calculated from observational datasets. In the following, we will consider the relative difference between  $\Delta IWC^{Prec}$  and  $\Delta IWC^{Flash}$  as:

$$r^{Prec-Flash} = 100 \times \frac{\Delta IWC^{Prec} - \Delta IWC^{Flash}}{(\Delta IWC^{Prec} + \Delta IWC^{Flash}) \times 0.5} \tag{4}$$

In the UT (Fig. 11a), over islands,  $\Delta$ IWC calculated over Sumatra, Borneo, Sulawesi and New Guinea varies from 4.9 to 6.9 mg m<sup>-3</sup> whereas, over Java,  $\Delta$ IWC reaches 7.9–8.7 mg m<sup>-3</sup>.  $\Delta$ IWC<sup>*Flash*</sup> is generally greater than  $\Delta$ IWC<sup>*Prec*</sup> by 0.8 mg m<sup>-3</sup> (with  $r^{Prec-Flash}$  ranges from - 6 to - 22% over the study zone) for all the islands, except for Java where  $\Delta IWC^{Prec}$  is larger than  $\Delta IWC^{Flash}$  by 0.8 mg m<sup>-3</sup> ( $r^{Prec-Flash} = 7.1\%$ ). Over sea,  $\Delta IWC$  varies from 1.2 to 4.4 mg m<sup>-3</sup>.  $\Delta IWC^{Flash}$ is greater than  $\Delta IWC^{Prec}$  by 0.6 to 2.1 mg m<sup>-3</sup> ( $r^{Prec-Flash} = -35$  to -71%), except for Java Sea, where  $\Delta IWC^{Prec}$  is

420

**Figure 10.** Daily mean of IWC<sup>ERA5</sup> averaged over the period DJF 2005-2016 at 150 hPa (a) and at 100 hPa (c); Time (hour, local time (LT)) of the diurnal maximum of IWC<sup>ERA5</sup> at 150 hPa (b) and at 100 hPa (d).

150°E

120°E

90°E

greater than  $\Delta IWC^{Flash}$  by 0.2 mg m<sup>-3</sup> ( $r^{Prec-Flash} = 6\%$ ). Over North Australia Sea and West Sumatra Sea,  $\Delta IWC^{Flash}$  are more than twice as large as  $\Delta IWC^{Prec}$  ( $r^{Prec-Flash} = -63\%$  and -71%, respectively).

In the TL (Fig. 11b), the observational  $\Delta$ IWC range is found between 0.7 and 1.3 mg m<sup>-3</sup> over islands and between 0.2 430 and 0.7 mg m<sup>-3</sup> over seas. The same conclusions apply to the observational  $\Delta$ IWC range calculated between  $\Delta$ IWC<sup>*Prec*</sup> and  $\Delta$ IWC<sup>*Flash*</sup> in the TL as in the UT with differences less than 0.4 mg m<sup>-3</sup>.

To summarize, independently of the proxies used for the calculation of  $\Delta$ IWC, and at both altitudes, Java island shows the largest injection of ice over the MariCont. Observational  $\Delta$ IWC over Java island is larger by about 1.0 mg m<sup>-3</sup> in the UT and about 0.3 mg m<sup>-3</sup> in the TL than other land study zones. Furthermore, it has been shown that both proxies can be used in our model, with more confidence over land:  $\Delta$ IWC<sup>*Prec*</sup> and  $\Delta$ IWC<sup>*Flash*</sup> are consistent to each other to within  $r^{Prec-Flash}$  = - 6 to -22% over islands and  $r^{Prec-Flash}$  = +6 to -71% over seas in the UT and the TL. The largest difference over seas is probably due to the larger contamination by stratiform precipitation included in Prec over sea.

### 7.2 $\Delta$ IWC deduced from reanalysis

435

ΔIWC from ERA5 (ΔIWC<sup>ERA5</sup><sub>z0</sub>) is calculated in the UT and the TL (z<sub>0</sub> = 150 and 100 hPa, respectively) as the max-min difference in the amplitude of the diurnal cycle. We can use the IWC<sup>ERA5</sup> to assess the impact of the vertical resolution of the MLS measurements on the observationally-derived ΔIWC estimates. According to Wu et al. (2008), estimates of IWC derived from MLS represent spatially-averaged quantities within a volume that can be approximated by a box of ~ 300×7×4 km<sup>3</sup> near the pointing tangent height. In order to compare IWC<sup>MLS</sup> and IWC<sup>ERA5</sup>, two steps were taken: 1) the horizontal resolution of ERA5 was degraded from 0.25°×0.25° to 2°×2° (~ 200 km×200 km), and 2) the vertical resolution of ERA5
445 was degraded by convolving the vertical profiles of IWC<sup>ERA5</sup> with a box function whose width is 5 and 4 km at 100 and 146 hPa, respectively. The ice injected from ERA5 at z<sub>0</sub> = 146 and 100 hPa with degraded vertical resolution (\(\lambda IWC<sup>ERA5</sup>\)) is thus calculated from \(\lambda IWC<sup>ERA5</sup>\). In the following we can consider the difference r<sup>ERA5-(ERA5)</sup> between \(\Delta IWC<sup>ERA5</sup>\) as:

$$r^{ERA5-\langle ERA5\rangle} = 100 \times \frac{\Delta IWC^{ERA5} - \left\langle \Delta IWC^{ERA5} \right\rangle}{\left(\Delta IWC^{ERA5} + \left\langle \Delta IWC^{ERA5} \right\rangle\right) \times 0.5} \tag{5}$$

Figure 11 shows ΔIWC<sup>ERA5</sup><sub>z0</sub> and (ΔIWC<sup>ERA5</sup><sub>z0</sub>) at z<sub>0</sub> = 150 and 100 hPa, over the island and the sea study zones. In the UT (Fig. 11a), over islands, ΔIWC<sup>ERA5</sup><sub>150</sub> and (ΔIWC<sup>ERA5</sup><sub>150</sub>) calculated over Sumatra and Borneo vary from 4.9 to 7.0 mg m<sup>-3</sup> (r<sup>ERA5-(ERA5)</sup> ranges from 20 to 22 %) whilst ΔIWC<sup>ERA5</sup><sub>150</sub> and (ΔIWC<sup>ERA5</sup><sub>150</sub>) over Java, Sulawesi and New Guinea reach 7.5–10.0 mg m<sup>-3</sup> (r<sup>ERA5-(ERA5)</sup> = 21 to 24 %). Over sea, ΔIWC<sup>ERA5</sup><sub>150</sub> and (ΔIWC<sup>ERA5</sup><sub>150</sub>) vary from 0.35 to 1.1 mg m<sup>-3</sup> (r<sup>ERA5-(ERA5)</sup> = 9 to 33 %). Over island and sea, ΔIWC<sup>ERA5</sup><sub>150</sub> is greater than (ΔIWC<sup>ERA5</sup><sub>150</sub>). The small differences between ΔIWC<sup>ERA5</sup><sub>150</sub> and (ΔIWC<sup>ERA5</sup><sub>150</sub>) over island and sea in the UT support the fact that the vertical resolution at 150 hPa has a low impact on the estimated ΔIWC.

In the TL, over land,  $\Delta IWC_{100}^{ERA5}$  and  $\langle \Delta IWC_{100}^{ERA5} \rangle$  vary from 0.5 to 3.9 mg m<sup>-3</sup> ( $r^{ERA5-\langle ERA5 \rangle} = -32$  to -138%) with  $\langle \Delta IWC_{100}^{ERA5} \rangle$  being larger than  $\Delta IWC_{100}^{ERA5}$  by less than 2.5 mg m<sup>-3</sup>. Over sea,  $\Delta IWC_{100}^{ERA5}$  and  $\langle \Delta IWC_{100}^{ERA5} \rangle$  vary

**Figure 11.** Top:  $\Delta$ IWC (mg m<sup>-3</sup>) estimated from Prec (red) and Flash (orange) at 146 hPa and  $\Delta$ IWC estimated from ERA5 at the level 150 hPa and at the level 150 hPa degraded in the vertical, over islands and seas of the MariCont: MariCont\_L (MCL) and MariCont\_O (MCO); from West (W) to East (E) over land, Sumatra (Sum), Borneo (Bor), Java, Sulawesi (Sul) and New Guinea (NG); and over seas, West Sumatra Sea (WSS), China Sea (ChinS), Java Sea (JS), North Australia Sea (NAS) and Sea (BS). Bottom: Same as in top but for 100 hPa.

from 0.05 to 0.4 mg m<sup>-3</sup> ( $r^{ERA5-\langle ERA5 \rangle}$  = -85 to -139%) with  $\Delta IWC_{100}^{ERA5}$  lower than  $\langle \Delta IWC_{100}^{ERA5} \rangle$  by as much as 0.2 460 mg m<sup>-3</sup>. The large differences between  $\Delta IWC_{100}^{ERA5}$  and  $\langle \Delta IWC_{100}^{ERA5} \rangle$  over island and sea in the TL support the fact that the vertical resolution at 100 hPa has a high impact on the estimation of  $\Delta IWC$ .

# 7.3 Synthesis

The comparison between the observational  $\Delta IWC$  range and the reanalysis  $\Delta IWC$  range is presented in Fig. 11. In the UT, over land, observation and reanalysis  $\Delta$ IWC ranges agree to within 0.1 to 1.0 mg m<sup>-3</sup>, which highlights the robustness of our 465 model over land, except over Sulawesi and New Guinea, where the observational and the reanalysis  $\Delta$ IWC range differ by at least 1.7 and 0.7 mg m<sup>-3</sup>, respectively. Over sea, the observational  $\Delta$ IWC range is systematically greater than the reanalysis by  $\sim 1.0 - 2.2 \text{ mg m}^{-3}$ , showing a systematic larger estimate derived from observation than derived from reanalysis. The consistency between observational and reanalysis  $\Delta$ IWC range is calculated as the difference between the minimal value of the largest range minus the maximum value of the lowest range divided by the mean of these two values. In the UT, over land, 470 observational and reanalysis  $\Delta$ IWC are found consistent to within 0 to 25% while over sea they are inconsistent (to within 62 to 96%) in the UT. In the TL, observational and reanalysis  $\Delta$ IWC ranges are consistent to within 0 to 49% over land and to within 0 to 28% over sea. In the following we will consider  $r^{Total}$  as the relative differences between the minimal value of the lower range minus the maximum value of the largest range divided by the mean of these two values. The range between observational and reanalysis ranges is named the total IWC range, and is estimated in the UT between 4.2 and 10.0 mg m<sup>-3</sup>  $(r^{Total} \text{ from 8 to 59\%})$  over land and between 0.3 and 4.4 mg m<sup>-3</sup>  $(r^{Total} \text{ from 104 to 149\%})$  over sea and, in the TL, between 475

0.5 and 3.7 mg m<sup>-3</sup> ( $r^{Total}$  = 85 to 127%) over land, and between 0.1 and 0.7 mg m<sup>-3</sup> ( $r^{Total}$  = 142 to 160%) over sea. Amounts of ice injected deduced from observations and reanalysis are consistent to each other over land in the UT and over land and sea in the TL (to within 0 to 49%) but inconsistent over sea in the UT (up to 96%). However, the impact of the vertical resolution on the estimation of  $\Delta$ IWC is much larger in the UT than in the TL ( $r^{Total}$  is larger in the TL than in the UT). At

480 both levels, observational and reanalyses  $\Delta$ IWC estimated over land is more than twice as large as  $\Delta$ IWC estimated over sea. Java island presents the highest observational and reanalysis  $\Delta$ IWC range in the UT (between 7.7 and 9.5 mg m<sup>-3</sup> daily mean,  $r^{Total} = 21\%$ ). However, whatever the level considered, although Java has shown particularly high values in the observational  $\Delta$ IWC range compared to other study zones, the reanalysis  $\Delta$ IWC range shows that Sulawesi and New Guinea would also be able to reach similar high values of  $\Delta$ IWC as Java (assuming that ERA5 IWC data have not yet been evaluated).

### 485 8 Discussion on small-scale convective processes impacting $\Delta$ IWC over a selection of areas

Our results have shown that, in all the datasets used, Java island and Java Sea are the two areas with the largest amount of ice injected up to the UT and the TL over the MariCont land and sea, respectively. In this section, processes impacting  $\Delta$ IWC in the different study zones are discussed.

# 8.1 Java island, Sulawesi and New Guinea

- 490 Sulawesi, New Guinea and particularly Java island have been shown as the areas of the largest ΔIWC in the UT and TL. Qian (2008) have used high resolution observations and regional climate model simulations to show the three main processes impacting the diurnal cycle of rainfall over the Java island. The main process explaining the rapid and strong peak of Prec during the afternoon over Java (Fig. 8a) is the sea-breeze convergence around midnight. This convergence caused by sea-breeze phenomenon increases the deep convective activity and impacts on the diurnal cycle of Prec and on the IWC injected up to the
- 495 TL by amplifying their quantities. The second process is the mountain-valley wind converging toward the mountain peaks, and reinforcing the convergence and the precipitation. The land breeze becomes minor compared to the mountain-valley breeze and this process is amplified with the mountain altitude. As shown in Fig. 2b, New Guinea has the highest mountain chain of the MariCont. The third process shown by Qian (2008) is precipitation that is amplified by the cumulus merging processes which are processes more important over small islands such as Java (or Sulawesi) than over large islands such as Borneo
- 500 or Sumatra. Another process is the interaction between sea-breeze and precipitation-driven cold pools that generates lines of strong horizontal moisture convergence (Dauhut et al., 2016). Thus, IWC is increasing proportionally with Prec consistent with the results from Dion et al. (2019) and rapid convergence combined with deep convection transports elevated amounts of IWC at 13:30 LT (Fig. 3) producing high ΔIWC during the growing phase of the convection (Fig. 4 and Fig. 11) over Java Island.

### 8.2 West Sumatra Sea

- 505 In section 4.2, it has been shown that the West Sumatra Sea is an area with positive anomaly of Prec during the growing phase of the convection but negative anomaly of IWC, which differs from other places. These results suggest that Prec is representative not only of convective precipitation but also of stratiform precipitation. The diurnal cycle of stratiform and convective precipitations over West Sumatra Sea has been studied by Mori et al. (2004) using 3 years of TRMM precipitation radar (PR) datasets, following the 2A23 Algorithm (Awaka, 1998). Mori et al. (2004) have shown that rainfall over Sumatra is
- 510 characterized by convective activity with a diurnal maximum between 15:00 LT and 22:00 LT while, over the West Sumatra Sea, the rainfall type is convective and stratiform, with a diurnal maximum during the early morning (as observed in Fig. 9). Furthermore, their analyses have shown a strong diurnal cycle of 200-hPa wind, humidity and stability, consistent with the PR over West Sumatra Sea and Sumatra Island. Stratiform and convective clouds are both at the origin of heavy rainfall in the tropics (Houze and Betts, 1981; Nesbitt and Zipser, 2003) and in the West Sumatra Sea, but stratiform clouds are mid-altitude
- 515 clouds in the troposphere and do not transport ice up to the tropopause. Thus, over the West Sumatra Sea, the calculation of  $\Delta$ IWC estimated from Prec is possibly overestimated because Prec include a non-negligible amount of stratiform precipitation over this area.

### 8.3 North Australia Sea and seas with nearby islands

The comparisons between Figs. 2c and 6a have shown strong daily mean of Flash  $(10^{-2} - 10^{-1} \text{ flashes day}^{-1})$  but low daily 520 mean of Prec  $(2.0 - 8.0 \text{ mm day}^{-1})$  over the North Australia Sea. Additionally, Fig. 11 shows that the strongest differences between  $\Delta IWC^{Prec}$  and  $\Delta IWC^{Flash}$  are found over the North Australia Sea, with  $\Delta IWC^{Flash}$  greater than  $\Delta IWC^{Prec}$  by 2.3 mg m<sup>-3</sup> in the UT ( $r^{Prec-Flash} = \sim 71\%$ ) and by 0.4 mg m<sup>-3</sup> in the TL ( $r^{Prec-Flash} = -75\%$ ). These results imply that the variability range in our model is too large highlighting the difficulty to estimate  $\Delta IWC$  over this study zone. Furthermore, as for Java Sea or Bismarck Sea, North Australia Sea is surrounded by several islands. According to the study from Pope et al.

525

(2008), the cloud size is the largest during the afternoon over the North Australia land, during the night over North Australia coastline and during the early morning over the North Australia sea. These results suggest that deep convective activity moves from the land to the sea during the night. Over the North Australia Sea, it seems that the deep convective clouds are mainly composed of storms with lightning but precipitation is weak or does not reach the surface before evaporating.

#### 9 Conclusions

- The present study has combined observations of ice water content (IWC) measured by the Microwave Limb Sounder (MLS), 530 precipitation (Prec) from the algorithm 3B42 of the Tropical Rainfall Measurement Mission (TRMM), the number of flashes (Flash) from the Lightning Imaging Sensor (LIS) on board of TRMM with IWC provided by the ERA5 reanalyses in order to estimate the amount of ice injected ( $\Delta$ IWC) in the upper troposphere (UT) and the tropopause level (TL) over the MariCont, from the method proposed in a companion paper (Dion et al., 2019). The study is focused on the austral convective season 535 of DJF from 2004 to 2017. In the model used (Dion et al., 2019), Prec is considered as a proxy of deep convection injecting ice  $(\Delta IWC^{Prec})$  in the UT and the TL.  $\Delta IWC^{Prec}$  is firstly calculated by the correlation between the growing phase of the diurnal cycle of Prec from TRMM-3B42 (binned at a 1-hour diurnal cycle) and the value of IWC measured by MLS (IWC<sup>MLS</sup>, provided at the temporal resolution of 2 observations in local time per day) selected among the growing phase of the diurnal cycle of Prec. While Dion et al. (2019) have calculated  $\Delta IWC^{Prec}$  over large convective study zones in the tropics, we show the spatial distribution of  $\Delta IWC^{Prec}$  in the UT and the TL at  $2^{\circ} \times 2^{\circ}$  horizontal resolution over the MariCont, highlighting 540 local areas of strong injection of ice up to 20 mg m<sup>-3</sup> in the UT and up to 3 mg m<sup>-3</sup> in the TL.  $\Delta$ IWC injected in the UT and the TL has also been evaluated by using another proxy of deep convection: Flash measured by TRMM-LIS. Diurnal cycle of Flash has been compared to diurnal cycle of Prec, showing consistencies in 1) the spatial distribution of Flash and Prec over the MariCont (maxima of Prec and Flash located over land and coastline), and 2) their diurnal cycles over land (similar onset and duration of the diurnal cycle increasing phase). Differences have been mainly observed over sea and coastline areas, with the 545 onset of the diurnal cycle increasing phase of Prec delayed by several hours depending on the considered area (from 2 to 7 h) compared to Flash.  $\Delta$ IWC calculated by using Flash as a proxy of deep convection ( $\Delta$ IWC<sup>*Flash*</sup>) is compared to  $\Delta$ IWC<sup>*Prec*</sup> over five islands and five seas of the MariCont to establish an observational  $\Delta$ IWC range over each study zone.  $\Delta$ IWC is also estimated from IWC provided by the ERA5 reanalyses ( $\Delta$ IWC<sup>ERA5</sup> and IWC<sup>ERA5</sup>, respectively) at 150 and 100 hPa over the study zones. We have also degraded the vertical resolution of  $IWC^{ERA5}$  to be consistent with that of  $IWC^{MLS}$  observations: 550
- 4 km at 146 hPa and 5 km at 100 hPa. The  $\Delta$ IWC ranges calculated from observations and reanalyses were evaluated over the selected study zones (island and sea).

With the study of  $\Delta IWC^{Prec}$ , results show that the largest amounts of ice injected in the UT and TL per 2° × 2° pixels are related to i) an amplitude of Prec diurnal cycle larger than 0.5 mm h<sup>-1</sup> and ii) a duration of the growing phase of the convection

- 555 longer than 9 hours. The largest  $\Delta IWC^{Prec}$  has been found over areas where the convective activity is the deepest.  $\Delta IWC^{Prec}$ and  $\Delta IWC^{Flash}$  depart from -6 to -22 % over land and to -6 to -71 % over sea. The largest differences between  $\Delta IWC^{Prec}$ and  $\Delta IWC^{Flash}$  over sea might be due to the combination of the presence of stratiform precipitation included in Prec and the very low values of Flash over seas (<10<sup>-2</sup> flashes day<sup>-1</sup>). The diurnal cycle of IWC<sup>ERA5</sup> at 150 hPa is more consistent with that of Prec and Flash over land than over ocean. Finally,  $\Delta IWC$  estimated from observations has been shown to be consistent
- 560 with  $\Delta$ IWC estimated from reanalysis to within 25% over land in the UT, to within 49% over land in the TL and to within 28 % over sea in the TL, but inconsistent to within 96% over sea in the UT. Thus, thanks to the combination of the observational and reanalysis  $\Delta$ IWC ranges, the total  $\Delta$ IWC range has been found in the UT to be between 4.2 and 10.0 mg m<sup>-3</sup> over land and between 0.3 and 4.4 mg m<sup>-3</sup> over sea and, in the TL, between 0.5 and 3.7 mg m<sup>-3</sup> over land and between 0.1 and 0.7 mg m<sup>-3</sup> over sea. The impact of the vertical resolution on the estimation of  $\Delta$ IWC has been found higher in the TL than in the 565 UT.

The study at small scale over islands and seas of the MariCont has shown that  $\Delta$ IWC from ERA5, Prec and Flash in the UT agree to within 0.1 – 1.0 mg m<sup>-3</sup> over MariCont\_L, Sumatra, Borneo and Java with the largest values obtained over Java Island. Based on observations, the Java Island presents the largest amount of ice in the UT and the TL (larger by about 1.0 mg m<sup>-3</sup> in the UT and about 0.3 mg m<sup>-3</sup> in the TL than other land study zones). Based on the reanalysis, New Guinea and Sulawesi reach similar ranges of ice injection in the UT and even larger ranges of values in the TL than the Java Island keeping in mind that ERA5 IWC data have not yet been evaluated. Processes related to the strongest amount of  $\Delta$ IWC injected into the UT and the TL have been identified as the combination of sea-breeze, mountain-valley breeze and merged cumulus, accentuated over small islands with high topography such as Java or Sulawesi.

Author contributions. IAD analysed the data, formulated the model and the method combining MLS, TRMM and LIS data and took primary
 responsibility for writing the paper. CD has treated the LIS data, provided the Figures with Flash datasets, gave advices on data processing and contributed to the Prec and Flash comparative analysis. PR strongly contributed to the design of the study, the interpretation of the results and the writing of the paper. PR, FC, PH and TD provided comments on the paper and contributed to its writing.
