**Abstract.** The liquid water path (*LWP*) adjustment due to aerosol-cloud interactions in marine stratocumulus remains a considerable source of uncertainty for climate sensitivity estimates. An unequivocal attribution of *LWP* adjustments to changes in aerosol concentration from climatology remains difficult due to the considerable covariance between meteorological conditions alongside changes in aerosol concentrations. We utilise the susceptibility framework to quantify the potential change in *LWP* adjustment with boundary layer (BL) depth in subtropical marine stratocumulus. We show that the *LWP* susceptibility, i.e. the relative change in *LWP* scaled by the relative change in cloud droplet number concentration, in marine BLs triples in magnitude from  $-0.1$  to  $-0.31$  as the BL deepens from 300 m to 1200 m.

We further find deep BLs to be underrepresented in pollution tracks, process modelling and in-situ studies of aerosol-cloud interactions in marine stratocumulus. Susceptibility estimates based on these approaches are skewed towards shallow BLs of moderate *LWP* susceptibility. Therefore, extrapolating *LWP* susceptibility estimates from shallow BLs to the entire cloud climatology, may underestimate the true *LWP* adjustment within subtropical stratocumulus, and thus overestimate the effective aerosol radiative forcing in this region.

Meanwhile, *LWP* susceptibility estimates in deep BLs remain poorly constrained. While susceptibility estimates in shallow BLs are found to be consistent with process modelling studies, they overestimate pollution track estimates.

## 1 Introduction

The aerosol radiative forcing due to changes in cloud reflectivity of low-level marine clouds remains one of the largest sources of physical uncertainty in climate sensitivity estimates. Estimates of total aerosol radiative forcing from the Fifth Assessment Report (AR5) issued by the Intergovernmental Panel on Climate Change (IPCC) range from  $-0.1 \text{ W m}^{-2}$  to  $-1.9 \text{ W m}^{-2}$  (Boucher et al., 2013; Zelinka et al., 2014). Based on these estimates, increased cloud reflectivity due to anthropogenic aerosol, may have posed a substantial offset to the greenhouse gas forcing.

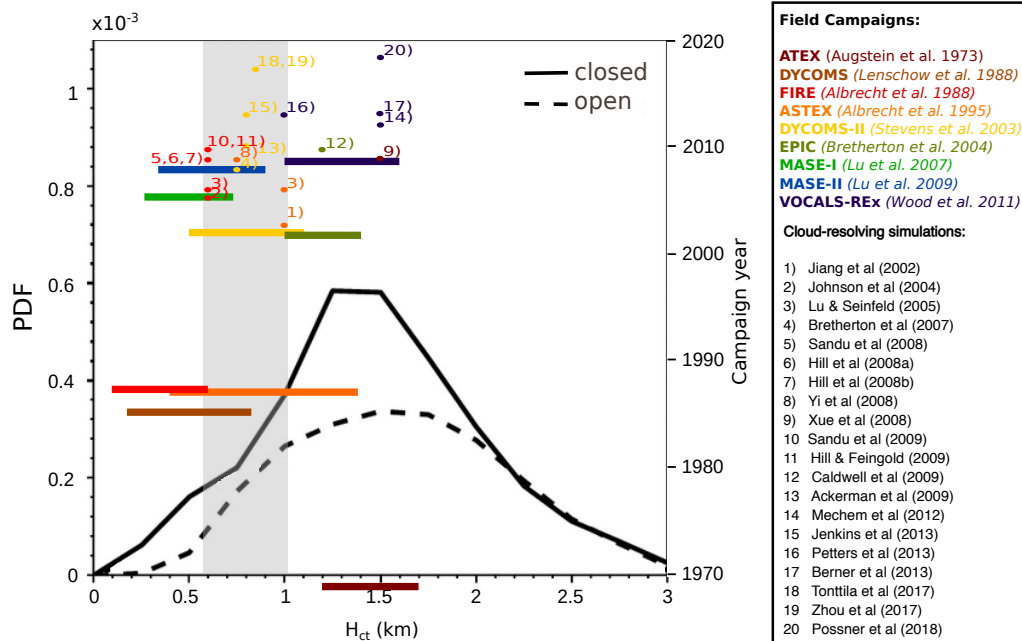

However, this cooling term is likely to reduce in coming years as anthropogenic emissions of aerosols decline (Smith and Bond, 2014). Yet, the quantification of aerosol induced changes in cloud scene albedo remains important for reducing the uncertainty in overall forcing. Subtropical marine stratocumulus are of particular relevance; the stratocumulus decks in the subtropics con-

tribute strongly to the cooling of the planet by reflecting  $\sim 40\%$  of incoming solar radiation on average, in a region of high solar intensity (Bender et al., 2011).

In particular, cloud adjustments to changes in aerosol concentration remain highly uncertain. As defined in IPCC AR5 (Boucher et al., 2013), adjustments quantify the net response in cloud-radiative properties to external forcing agents such as anthropogenic aerosols. Through microphysical or thermodynamic adjustments, such as decreased precipitation rates (Albrecht, 1989), increased mixing rates at cloud top (Ackerman et al., 2004), or the sedimentation-entrainment feedback (Bretherton et al., 2007), the thermodynamics of the cloud is impacted and the liquid water path (*LWP*) may be altered. Adjustments in cloud fraction (*CF*) by changes in aerosol concentration may also increase the overall albedo of the cloud scene (Gryspeerd et al., 2016; Andersen et al., 2017; Possner et al., 2018). However, these effects cannot be addressed within the framework of this study due to the insufficient accuracy in *CF* retrievals under polluted conditions (e.g. Twohy et al. (2009)). It is therefore mentioned here for completeness, but will not be discussed further.

In order to constrain the uncertainty range reflected within the wide range of AR5 forcing estimates, numerous studies have since quantified the individual contributions of the Twomey effect (Twomey, 1991) and *LWP* adjustments in global-scale and long-term satellite records (Sekiguchi et al., 2003; Quaas et al., 2008; Lebsock et al., 2008; Bellouin et al., 2013; Bender et al., 2016; Gryspeerd et al., 2017; McCoy et al., 2017; Gryspeerd et al., 2019; Rosenfeld et al., 2019), pollution track data sets (Ackerman et al., 2000; Christensen and Stephens, 2011; Christensen et al., 2014; Chen et al., 2015; Malavelle et al., 2017; Toll et al., 2017; Bender et al., 2019; Toll et al., 2019), and large-eddy simulations (LES) or cloud-resolving simulations in combination with field observations (see Fig. 1 for references). Satellite-based estimates of large data sets provide long-term and near-global constraints for the Twomey effect and the *LWP* adjustment. However, they are prone to numerous sources of uncertainties. These include, but are not limited to, uncertainties in  $N_d$  changes for a given change in aerosol metric, the distortion of the true sensitivity due to relatively coarse retrieval scales (McComiskey and Feingold, 2012), and the covariability between meteorological factors and aerosol indices. Average forcing estimates for the Twomey effect alone range between  $-0.2$  to  $-1.0 \text{ W m}^{-2}$  (Quaas et al., 2008; Lebsock et al., 2008; Bellouin et al., 2013; McCoy et al., 2017). The *LWP* adjustment may induce a partially compensating positive forcing to the Twomey effect, due to a decrease in cloud field *LWP* (Gryspeerd et al., 2019). Meanwhile, the *LWP* adjustment inside the convective cores of low clouds may be positive (Rosenfeld et al., 2019) which would locally amplify the aerosol-cloud forcing due to Twomey.

In the case of pollution tracks, the issue of covariability between confounding factors is avoided and a clear detection and attribution of the cloud response to the aerosol perturbation itself, or at least to the corresponding change in  $N_d$  is possible. Each individual track is associated with a spatially confined cloud response due to aerosol perturbations by ship or volcano plumes for a given set of meteorological conditions. However, these tracks are rare. It is estimated that merely  $0.002\%$  of all ocean-going ships generate a ship track (Campmany et al., 2009). Though a recent estimate suggests that this number might underestimate the true ship track frequency (Yuan et al., 2019). Furthermore, they are only found within a narrow window of meteorological conditions (Durkee et al., 2000). Therefore, while these estimates are prone to fewer uncertainties in detection and attribution of aerosol forcing, the representativeness of such estimates remains unclear.

**Figure 1.** Probability density function (PDF) for closed, open-cell and disorganised stratocumulus layers against cloud top height. This figure is adapted from Fig. 10 in Muhlbauer et al. (2014). Coloured bars denote range of cloud top heights sampled during each campaign listed in the legend. LES and cloud-resolving studies investigating aerosol-cloud-radiative interactions are colour-coded by the campaigns they are based on [with the exception of model study 8 which is based on an idealised profile]. Grey shading denotes narrow BL depth interval within which 75 % of all modelling studies reside. Future analyses of past campaigns summarised in Zuidema et al. (2016) will likely increase the data points sampled in deeper BLs. References: Jiang et al. (2002); Johnson et al. (2004); Lu and Seinfeld (2005); Bretherton et al. (2007); Sandu et al. (2008); Hill et al. (2008); Hill and Dobbie (2008); Yi et al. (2008); Xue et al. (2008); Caldwell and Bretherton (2009); Ackerman et al. (2009); Sandu et al. (2009); Hill and Feingold (2009); Mechem et al. (2012); Jenkins et al. (2013) Petters et al. (2013); Berner et al. (2013); Tonttila et al. (2017); Zhou et al. (2017); Possner et al. (2018); Augstein et al. (1973); Lenschow et al. (1988); Albrecht et al. (1988, 1995); Stevens et al. (2003); Bretherton et al. (2004); Lu et al. (2007, 2009); Wood et al. (2011)

The same holds true for estimates based on LES, cloud-resolving model studies, and field observations. At this resolution  
 60 insights into the interplay between microphysical, radiative and thermodynamic processes can be obtained. Yet, the estimates  
 are representative for the conditions sampled and may not be valid generally, or at larger spatial scales. The LES community re-  
 cently started to address these limitations, e.g. through extensive LES ensembles (Glassmeier et al., 2019). Here we would like  
 to draw attention to the fact that previous analyses of LES, cloud-resolving models and field campaigns have predominantly  
 focused on shallow boundary layers. Fig. 1 shows that most field campaigns and high-resolution modelling studies quantifying  
 65 aerosol-cloud-radiative interactions have been conducted in BLs below 1 km in depth.

Fig. 1 shows the global distribution of stratocumulus regimes across BL depth which was characterised by Muhlbauer et al.

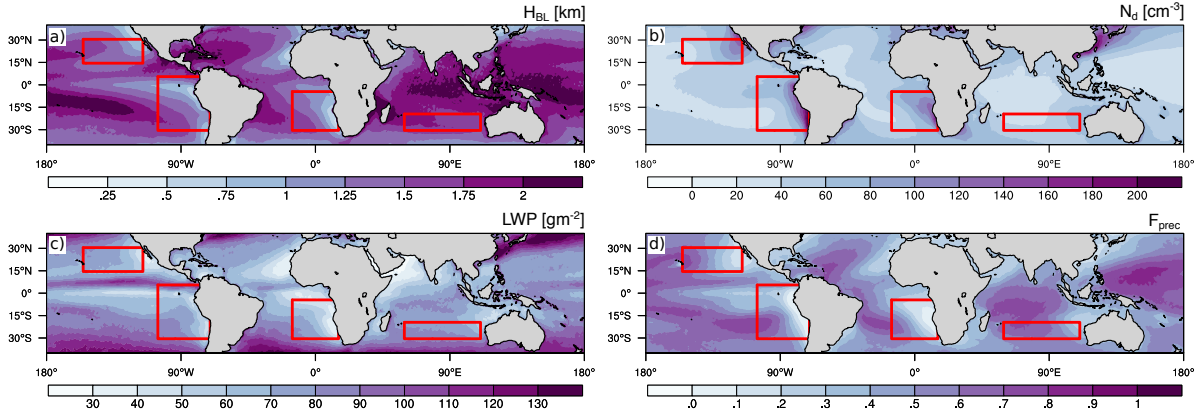

(2014) in terms of cloud-top height (Fig. 10 in Muhlbauer et al. (2014)). The Muhlbauer et al. (2014) PDF is representative of all low-clouds over the oceans (see original paper for further methodology). We find the global PDF to be comparable to the distribution of stratocumulus against BL depth in the subtropics alone (Fig. S1). The PDF for *disorganised* clouds in Fig. 10 of Muhlbauer et al. (2014) was omitted here. These scenes were governed by broken cloud decks of low  $CF$  ( $\overline{CF} = 40\%$ ) resembling shallow cumulus rather than stratocumulus.

The  $LWP$  adjustment within shallow cumulus seems governed by lateral entrainment effects and moisture gradients (e.g. Jiang et al. (2006); Seifert et al. (2015)). This is in stark contrast to stratocumulus cloud decks ( $CF > 80\%$ ) where the  $LWP$  adjustment is predominantly governed by vertical gradients in moisture, stability and aerosol. Thus, the  $LWP$  adjustment in shallow cumulus may differ from adjustments in stratocumulus, which is the focus of this study. The distinction between detraining shallow cumulus under strong inversions and precipitating stratocumulus becomes semantic in the case of cloud scenes associated with high cloud fraction. For this reason results of the Atlantic Trade Wind Experiment (ATEX) are included in Fig. 1.

In the subtropics merely 30% of stratocumulus reside at the predominant depth range sampled in the field and studied within most high-resolution simulations. Results from merely three campaigns and few modelling studies are discussed within the literature that reside within a height range deeper than 1 km where over 70% of marine stratocumulus are found. The campaigns containing measurements of deep stratocumulus cloud decks are ATEX, EPIC (East Pacific Investigation of Climate), and VOCALS-REx (VAMOS – Variability of the American Monsoons – Ocean-Cloud-Atmosphere-Land Study Regional Experiment). Merely 25% (Fig. 1) of all high-resolution modelling studies investigating the influence of aerosol concentrations on cloud properties in marine stratocumulus decks (i.e. Xue et al. (2008); Caldwell and Bretherton (2009); Mechem et al. (2012); Berner et al. (2013); Possner et al. (2018)), are based on deep BL field campaigns.

The lack of process studies in deep boundary layers, despite their prominence, motivates the question of exploring the dependence of cloud adjustments on BL depth. This is further supported by recent findings showing an explicit dependence of the  $LWP$  adjustment on BL depth in pollution tracks (Toll et al., 2019). Here, we focus on regions dominated by marine stratocumulus, and explore these relationships within 10-year records in the subtropics. The data set is described in section 2. The change of mean cloud properties with BL depth is presented in section 3, while the impact of BL depth covariance with  $LWP$ , and  $N_d$  on the  $LWP$  adjustment estimate is presented in section 4.

## 2 Data Description

**Figure 2.** (a) Boundary layer height ( $H_{BL}$ ), (b) cloud droplet number concentration ( $N_d$ ), (c) liquid water path ( $LWP$ ) and (d) low-cloud precipitation probability ( $F_{prec}$ ) are shown. Regions of subtropical stratocumulus decks are marked in red and were defined in Eastman and Wood (2016) based on surface observations of Hahn and Warren (2007).

95 The relationship between  $LWP$  and  $N_d$  at different BL depths is analysed in the semi-permanent stratocumulus regions of the subtropics (Fig. 2). The analysis is based on a 10-year climatology of daily in-cloud and radiation retrievals between 2007 and 2016, at a spatial resolution of  $1 \times 1^\circ$ . Day-time in-cloud retrievals for  $LWP$ ,  $N_d$  and effective radius ( $R_{eff}$ ) are obtained from the level 3 Moderate Resolution Imaging Spectroradiometer (MODIS) collection 6 product (King et al., 2003; Platnick et al., 2017). As in previous collections, independent retrievals of cloud optical depth and  $R_{eff}$  are obtained using the visible and near-infrared radiances at  $2.1 \mu\text{m}$  and  $0.86 \mu\text{m}$  (Platnick et al., 2003).

The  $R_{eff}$  retrieval is further used to distinguish between precipitating ( $R_{eff} \geq 15 \mu\text{m}$ ) and non-precipitating ( $R_{eff} < 15 \mu\text{m}$ ) cloud scenes. For the year 2007 an independent retrieval of precipitation probability (Eastman et al., 2019) was available (Fig. S2). During this year, the  $R_{eff}$  criterion splits the data set into regimes where the precipitation probability remains below 50% (equivalent to non-precipitating) and above 50% (equivalent to precipitating).

105  $N_d$  is estimated based on the relationship established by Boers et al. (2006) and Bennartz (2007) for marine boundary layer clouds:

$$N_d = \sqrt{2} \frac{3}{4k\pi\rho_w} \Gamma_{eff}^{\frac{1}{2}} \frac{LWP^{\frac{1}{2}}}{R_{eff|top}^3} \quad (1)$$

where  $\rho_w$  denotes the density of water,  $\Gamma_{eff} = f_a d\Gamma_{ad}$  the effective rate of increase in adiabatic liquid water content with increasing height and  $R_{eff|top}$  denotes the effective radius at cloud top. All assumptions regarding the degree of adiabaticity and the proportionality constant  $k$  between the true and effective  $N_d$  are the same as in Eastman and Wood (2016).

The retrievals are restricted to sensor viewing angles between  $0^\circ - 65^\circ$  (Grosvenor and Wood, 2014), which does not pose

a strong constraint in the subtropics. The data is further limited to regions with high  $CF$ s exceeding 80%. This restriction permits the best possible accuracy in  $N_d$  retrievals, which assumes plane parallel clouds and restricts the analysis to large-scale stratocumulus cloud decks only, which have the largest radiative impact. All cloud properties are in-cloud mean values only, which are not weighted by areal  $CF$  within each  $1 \times 1^\circ$  grid box.

The retrieval of BL height ( $H_{BL}$ ) used in this study was first presented in Eastman and Wood (2016) and analysed in Eastman et al. (2017). The retrieval is based on a combination of MODIS and Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) cloud retrievals (Vaughan et al., 2004). The Clouds and Earth's Radiant Energy System (CERES) Single Scanner Footprint One Degree (SSF1deg) retrievals of all-sky ( $A_{toa}$ ) and clear-sky albedo ( $A_{clr}$ ) based on the top-of-atmosphere shortwave fluxes (Kato et al., 2013) were used to estimate  $A_{cld}$  from:

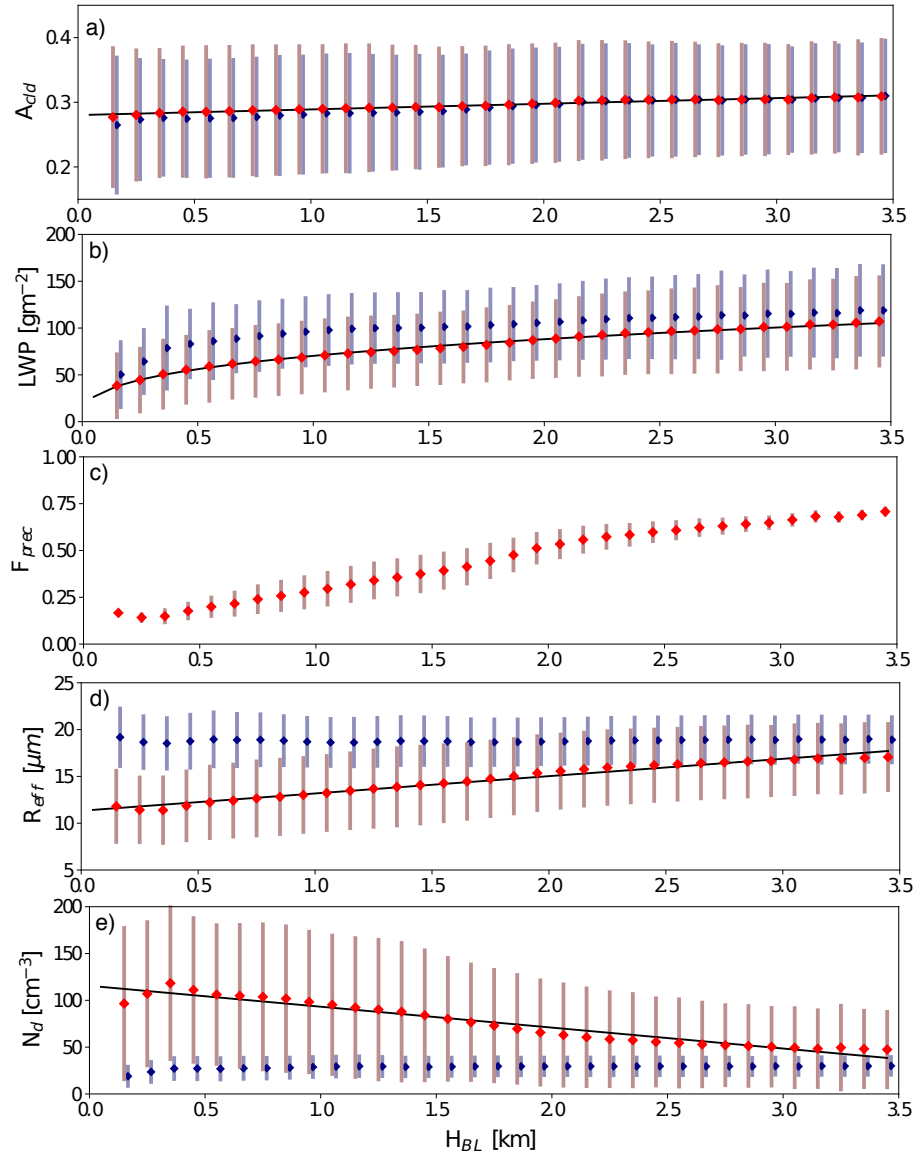

$$A_{toa} = CF * A_{cld} + (1 - CF) * A_{clr}. \quad (2)$$

It should be noted that the above equation can only provide an estimate of the cloud albedo. This definition, due to the separation of clear and cloudy skies, is highly sensitive to the definition of  $CF$ .  $CF$  retrievals are afflicted with uncertainty, due to swelling of aerosols in the high relative humidity environment near cloud edges (Twohy et al., 2009), and rather than a dichotomy, clear and cloud skies represent a continuum of albedo values (Charlson et al., 2007). Yet, Eq 3 has been shown to provide useful estimate of cloud albedo in the subtropical stratocumulus regions we focus on here.

Further environmental factors considered in this study, such as the lower tropospheric stability ( $LTS$ ), and the free troposphere relative humidity ( $RH_{FT}$ ), are obtained from the Modern-Era Retrospective Analysis for Research and Applications Version 2 (MERRA2) reanalysis (Rienecker et al., 2011; Molod et al., 2015). The  $LTS$  is defined as the change in potential temperature between 700 hPa and the surface. Conditions are considered non-stable, if the change in potential temperature between these two pressure levels remains below 15 K.  $RH_{FT}$  is diagnosed as the mean  $RH$  between the inversion and 700 hPa. Environmental conditions are considered to be dry if  $RH_{FT}$  falls below 50% and moist otherwise.

### 3 Covariance between Cloud Properties and Boundary Layer Depth

**Figure 3.** Scaling of (a)  $A_{cld}$ , (b)  $LWP$ , (c)  $F_{prec}$ , (d)  $R_{eff}$ , and (e)  $N_d$  against  $H_{BL}$ . Mean and standard deviation of the 10-year subtropical stratocumulus climatology (see Fig. 2) are shown in red within each height bin (100-m intervals). Fits across the climatology are superimposed in black (see table 1 for details on fitting parameters). The climatology of precipitating clouds is shown in blue. For completeness the climatology for non-precipitating clouds is shown in Fig. S3.

Here, we analyse the change in cloud properties of subtropical stratocumulus as a function of  $H_{BL}$ . Each cloud property is binned into 100 m  $H_{BL}$  intervals within which the 10-year mean and standard deviation are computed. The resulting relationships, which include data from all four predominant stratocumulus cloud decks, are shown in Fig. 3. All cloud properties change significantly (at the 95% level) with  $H_{BL}$ . The largest relative changes are observed for  $LWP$  (Fig. 3b) and  $N_d$  (Fig. 3e), while merely moderate and small changes are observed in  $R_{eff}$  (Fig. 3d) and  $A_{cld}$  (Fig. 3a) respectively.

The adiabatic  $LWP$  ( $LWP_{ad}$ ) scales with cloud depth ( $H_c$ ) as  $LWP_{ad} \propto H_c^2$ , where  $H_c = H_{BL} - H_b$  and  $H_b$  denotes cloud base. Based on this relationship we regress  $\ln LWP$  against  $\ln H_{BL}$  to identify the exponent of the  $LWP-H_{BL}$  relationship (Fig. 3b). Meanwhile, a simple linear regression is obtained for all other cloud climatologies (Fig. 3a,d,e). To understand the relative sensitivity amongst cloud properties to changes in  $H_{BL}$ , the slopes obtained by linear regression in the physical, as opposed to logarithmic space, are scaled by the climatological mean (Table 1).

As expected, larger  $LWPs$  are associated with deeper BLs (Fig. 3b). In particular we find  $LWP$  to scale as  $LWP \propto H_{BL}^{0.33}$  (Table 1). Therefore  $LWP$  scales considerably weaker with  $H_{BL}$  than  $H_c$ . Combining these two relationships, it follows that in adiabatic clouds  $H_c \propto H_{BL}^{0.17}$ . That is,  $H_c$  increases on average by merely 2 m for every 100 m increase in  $H_{BL}$ . Thus  $H_c$  seems largely independent of  $H_{BL}$  variations.

Adiabaticity is known to change with cloud depth in marine stratocumulus (Merk et al., 2016; Braun et al., 2018). Furthermore, we find that clouds in deep BLs are more likely to precipitate than clouds in shallow BLs (Fig. 3c). Consequently, one might expect cloud adiabaticity to change as a function of  $H_{BL}$  due to the change in likelihood of precipitation ( $F_{prec}$ ). However, we find the  $LWP-H_{BL}$  relationship is hardly impacted by precipitation (Table 1: columns 6 and 7). It also seems unlikely that the functional relationship between adiabaticity and  $H_c$  would be sufficient to reduce the quadratic exponent of the  $LWP-H_c$  relationship to that of the sub-linear exponent in the  $LWP-H_{BL}$  relationship. It therefore follows that  $LWP$  scales very differently and seemingly independently with  $H_{BL}$  and  $H_c$  in marine subtropical stratocumulus.

Thermodynamic adjustments in  $LWP$  and  $H_c$  occur rapidly (hourly timescale) while adjustments in BL depth and thus  $LWP$  occur on longer time scales (multi-day timescale).  $H_c$  is predominantly constrained by the vertical displacement of  $H_b$ , as has been quantified by  $LWP$  budgets (Wood, 2007; van der Dussen et al., 2014; Ghonima et al., 2015; Hoffmann et al., submitted).  $H_b$  in turn is governed by Clausius Clapeyron in response to variability in BL humidity and temperature. Meanwhile, the multi-day evolution of  $H_{BL}$  and thus  $LWP$ , characterises their evolution as a function of external drivers such as gradients in sea surface temperature ( $SST$ ),  $FT$  conditions, and large-scale advection. This is consistent with the weak relationship between  $H_c$  and  $H_{BL}$  inferred here from climatology.

$LWP$  increases more rapidly with  $H_{BL}$  under dry  $FT$  and non-stable lower tropospheric conditions (Table 1 columns 2–4). This behaviour is consistent with cloud-scale observations (Eastman and Wood, 2018), simulations (Bretherton et al., 2013) and mixed-layer theory (Dal Gesso et al., 2014). Under low  $RH_{FT}$  cloud-top cooling and cloud-top generated mixing are more effective. Therefore, a deeper and moister mixed layer associated with larger  $LWP$  can be maintained. Thus, the reinforcement of the cloud through stronger radiative cooling has a larger impact on  $LWP$ , than the increased drying through entrainment under low  $RH_{FT}$  conditions. Similarly, the weaker buoyancy jump across the inversion under non-stable lower troposphere conditions, likely induces less warming in the sub-cloud layer as the BL deepens, which corresponds to a weaker upward shift

of the cloud base.

175 Meanwhile, deeper BLs are characterised by lower  $N_d$  (Fig. 3e). As the BL deepens,  $F_{prec}$  (Fig. 3c), and thus the  $N_d$  sink through collision-coalescence processes, increases. Yet,  $N_d$  primarily decreases with  $H_{BL}$  in non-precipitating BLs. This suggests that precipitation scavenging is not the only constraint on  $N_d$ . In the absence of precipitation we attribute the negative correlation between  $N_d$  and  $H_{BL}$  to (i) the climatological deepening of the BL away from the cold upwelling zones near the coasts (Fig. 2a), and (ii) the increasing distance to continental sources of anthropogenic pollution, which manifest in a pronounced negative gradient in  $N_d$  (Fig. 2b). This is also explicitly illustrated in Fig. S4.

180 The negative correlation vanishes in a deregionalised and deseasonalised version of this data set (Fig. S5). Following Bender et al. (2016) we remove geographical and seasonal trends. In doing so, the significant negative correlation between  $N_d$  and  $H_{BL}$  in non-precipitating clouds disappears. This further confirms, that the observed negative correlation between  $N_d$  and  $H_{BL}$  in non-precipitating clouds is intrinsic to the data, but not a manifestation of a given physical process.

The observed negative correlation disappears in the presence of precipitation (Fig. 3e and Table 1). Our two process hypotheses governing the negative correlation between  $N_d$  and  $H_{BL}$  are not impacted directly by precipitation. Yet the negative correlation 185 vanishes. This also holds for the deseasonalised and deregionalised  $N_d$  climatology (Fig. S5). It follows that precipitation is the predominant constraint on climatological  $N_d$  in subtropical marine stratocumulus at this scale. In addition  $F_{prec}$  changes with  $H_{BL}$ . Thus, a significant negative slope manifests within the whole  $N_d$  climatology ( $\overline{c_{N_d}} = -0.3$ ), as the fraction of precipitating to non-precipitating clouds changes. Therefore, the  $N_d$  climatology of all subtropical stratocumulus is constrained to first order by precipitation and to second order by the proximity to sources of cloud condensation nuclei.

190 The weakly positive scaling in  $R_{eff}$  against  $H_{BL}$  is consistent with the relationship between  $LWP$  and  $N_d$ , and  $H_{BL}$ . The decrease in  $N_d$  with  $H_{BL}$  is insufficient to offset the increase in  $LWP$ . The combined increase in  $LWP$  and  $R_{eff}$  with BL deepening results in a significant, but inconsequential increase in  $A_{cld}$  with  $H_{BL}$  (Table 1). Stratocumulus with cloud tops above 1 km are associated with larger  $LWP$ , lower  $N_d$ , larger  $R_{eff}$ , and an elevated  $A_{cld}$  of 0.01 as compared to stratocumulus with cloud tops below 1 km.

195

#### 4 Liquid Water Path Adjustment

The climatological fields of  $LWP$  and  $N_d$  display a significant correlation and anticorrelation with  $H_{BL}$ . The largest climatological values of  $LWP$  are found in deep BLs with low  $N_d$  (Fig. 4a). The increase in  $LWP$  with  $H_{BL}$  is consistent with Fig. 3b). The displayed sensitivity of  $LWP$  to  $N_d$  is potentially attributable to a multitude of competing factors; not all representative of cloud adjustments. The decrease in  $LWP$  with increased levels of pollution has been noted multiple times in 200 observations and various process hypotheses have been put forward.

Less polluted clouds could potentially be associated with weaker entrainment drying through the entrainment-sedimentation feedback (Bretherton et al., 2007). Alternatively, increased rates of precipitation in cleaner environments could stabilise the cloud (Wood, 2012), which results in weaker overall cloud-top entrainment of dry sub-saturated air (Ackerman et al., 2004).

Quantity	stability		above cloud RH		cloud-base precipitation		all	
	stable	non-stable	dry	moist	no-rain	rain		
$c_{\ln LWP}$	0.4	0.6	0.5	0.2	0.3	0.3	0.42	
$\overline{c_{R_{eff}}}$	0.10	0.08	0.13	0.13	0.07	x	0.13	
$\overline{c_{N_d}}$	-0.2	x	-0.3	-0.28	-0.13	x	-0.3	
$\overline{c_{A_{cld}}}$	0.03	0.04	0.04	x	0.03	0.04	0.03	
						fully	intermittently	
$s_{lwp}$ (bivariate)	-0.29	-0.18	-0.29	-0.15	-0.28	0.14	-0.23	-0.28
$s_{lwp}$ ( $N_d$ -only)	-0.31	-0.2	-0.32	-0.16	-0.28	0.28	-0.26	-0.33

**Table 1.** This table summarises the regime dependence of each slope. The relationship between cloud properties and  $H_{BL}$  is determined logarithmically ( $\ln \Psi \sim c_{\ln \Psi} \times \ln H_{BL}$  for  $\Psi = LWP$ ), or as normalised linear slopes ( $\overline{c_{\Psi}} = c_{\Psi} / \overline{\Psi}$  where  $\Psi \sim c_{\Psi} \times H_{BL}$  for  $\Psi \in \{R_{eff}, N_d, A_{cld}\}$  and  $\overline{\Psi}$  denotes the average). Slopes were determined by linear regression if and only if: (i) a significant fit was obtained at the 95-% confidence level and (ii) the fit explained at least 80% of the variance of the climatological relationship shown in Fig. 3. If no such fit is obtained, "x" is given. The regime dependence of  $s_{lwp}$ , which is defined and discussed in section 4, is summarised in the last two rows. Estimates for  $s_{lwp}$  were either obtained by simple linear regression or by a bivariate fit taking the covariability between  $LWP$ ,  $N_d$  and  $H_{BL}$  into account. All slopes are given to the significant digit which is determined based on the error of the respective fit. Error statistics and sample sizes for each category are provided in Table S1.

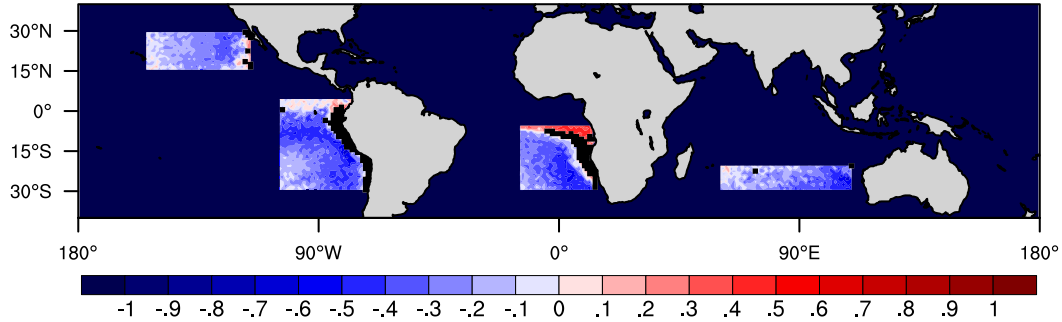

205 Furthermore, recent results show that the strengthening of convective overturning in the sub-cloud layer through precipitation can also have a net positive impact on  $LWP$  (Goren et al., 2018). All these, are examples of adjustments to the initial cloud microphysical response caused by an increase in droplet number. However, other factors not representative of cloud adjustments, such as the climatological covariance between  $H_{BL}$  and  $N_d$  noted in Section 3, may impact  $s_{lwp}$  estimates.

Here, we estimate  $s_{lwp}$  by either fitting  $\ln LWP$  against  $\ln N_d$  as in (Gryspeerd et al., 2019), or by fitting the two-dimensional  
210 surface of  $\ln LWP$  against  $\ln H_{BL}$  and  $\ln N_d$ . Both fits are simple linear, single- or bivariate regressions across the phase space containing 80 % of all data (Fig. 4a). Both fitting approaches yield similar and negative  $s_{lwp}$  estimates. Taking the covariance with  $H_{BL}$  into account merely reduces the magnitude of  $s_{lwp}$  from  $-0.33$ , which is consistent with previous global estimates of marine low-level clouds (Gryspeerd et al., 2019), to  $-0.28$  (Table 1). Therefore the bivariate fit of the entire climatology is likely subject to the same confounding factors impacting  $LWP$  adjustments as in Gryspeerd et al. (2019). Furthermore, the  
215 two predictor variables  $H_{BL}$  and  $N_d$  of the bivariate fit are not independent (Fig. 3e), which may bias the  $s_{lwp}$  estimate.

The entire phase space can be further characterised by  $F_{prec}$  (Fig. 4e): 14% (Table S1) of the climatological phase space is characterised by precipitating cloud scenes (Fig. 4b), 37% by intermittently precipitating cloud scenes (Fig. 4c), and 48% by non-precipitating clouds (Fig. 4d). The analysis shows that  $\ln LWP$  increases with  $\ln N_d$  in the precipitating fraction of the cloud climatology ( $s_{lwp} = 0.14$ ) and decreases in the intermittently ( $s_{lwp} = -0.23$ ) and non-precipitating climatologies  
220 ( $s_{lwp} = -0.28$ ). Thus  $s_{lwp}$  inferred from the entire climatology is dominated by the  $LWP$ - $N_d$  relationship in non-precipitating clouds.

**Figure 4.** Climatology of  $\ln LWP$  against  $\ln N_d$  and  $\ln H_{BL}$  for (a) all subtropical stratocumulus (see Fig. 2), (b) fully precipitating, (c) intermittently precipitating and (d) non-precipitating stratocumulus. Points are classified as fully precipitating (non-precipitating) if the fraction of precipitating cloud scenes shown in panel (e) exceeds 0.98 (remains below 0.02). All other cloud scenes are classified as intermittently precipitating. At the top of each panel (a)–(d)  $\ln LWP$  binned in  $\ln N_d$  is shown as in Gryspeerdt et al. (2019). A minimum number of 100 points within each  $\ln N_d - \ln H_{BL}$  bin was required to be included in the climatology shown in opaque contours (a–e). The bivariate (simple linear) regression across the 2-dimensional (one-dimensional) climatology is shown in transparent contours (as black line) in panels (a)–(d). White and grey lines in panel (a) denote the region of the phase space containing 80 % and 90 % of all data respectively. The slopes of all fits are summarised in Table 1.

**Figure 5.** Map  $s_{lwp}$  which was obtained from bivariate linear regression of daily  $\ln LWP$ ,  $\ln N_d$  and  $\ln H_{BL}$  retrievals at a spatial scale of  $1^\circ \times 1^\circ$ . Regions where  $s_{lwp}$  is not statistically significant are masked in black.

The opposing response in precipitating and non-precipitating regions is consistent with numerous previous studies (Albrecht, 1989; Ackerman et al., 2004; Bretherton et al., 2007; Wood, 2007; Wang et al., 2012; Suzuki et al., 2013; Gryspeerdt et al., 2019). While the largest fraction of  $H_{BL}$ - $N_d$  phase space is characterised by non-precipitating clouds (Table S2), only a narrow  
 225 band in close proximity to the coast lines of the Americas and the African continent is characterised by little to no precipitation ( $F_{prec} < 0.1$ , Fig.2d). Most regions are characterised by intermittent rain occurrence ( $0.2 < F_{prec} < 0.8$ ) and are associated with more moderate susceptibilities of -0.23 or less (Fig. 5). Thus the results of Fig. 4c) are representative for most stratocumulus regions in the subtropics. Overall, few stratocumulus regions are associated with an average positive susceptibility.

Non-precipitating and intermittently precipitating cloud climatologies are not sensitive to the fitting technique applied (Ta-  
 230 ble 1). Yet,  $s_{lwp}$  halved when the covariance of  $LWP$  with  $H_{BL}$  is taken into account in consistently precipitating clouds. In order to gain further insight into the potential variance of  $s_{lwp}$  with  $H_{BL}$ , we calculated  $s_{lwp}$  within constrained BL-depth ranges for the three precipitation regimes characterised in Fig. 4.

**Figure 6.** (a)  $s_{lwp}$  determined within 100-m height intervals for subtropical stratocumulus, (b) precipitating clouds only, (c) intermittently precipitating clouds, and (d) non-precipitating clouds.  $s_{lwp}$  was obtained from bivariate linear regression of the  $\ln LWP$  surfaces shown in Fig. 4(a)–(d) within each height interval respectively. Only statistically significant results at the 95% confidence level are shown. The probability density function (PDF) of the subtropical cloud climatology across the height bins is superimposed.

Analyses of ship tracks (Christensen and Stephens, 2011) and Lagrangian studies of cloud evolution (Eastman et al., 2017) have shown that  $H_{BL}$  may increase under more polluted conditions. This, however, is not manifested within the  $H_{BL}$ - $N_d$  climatology (Fig. 3e). Therefore, by constraining  $s_{lwp}$  estimates in this manner, we attempt to remove some of the covariance between  $LWP$ ,  $N_d$  and  $H_{BL}$  which may impact the estimated strength of the  $LWP$  adjustment.

$s_{lwp}$  in precipitating subtropical stratocumulus is considerably larger in BLs below 1.5 km in depth than in deeper BLs (Fig. 6b). While  $s_{lwp}$  may be as large as 0.48, which constitutes a tremendous cloud adjustment in shallow BLs, it does not exceed 0.08 in deep BL clouds. It should be noted that the large negative adjustment of  $s_{lwp} = -1.0$  within the first height bin in Fig. 6b) is statistically significant, but characterises a very small sub-sample of the total climatology.

Meanwhile,  $s_{lwp}$  increases in magnitude from  $-0.1$  in BLs below 500 m in altitude to  $-0.31$  in BLs exceeding 1 km in depth (Fig. 6d). A weaker height dependence is observed for intermittently precipitating cloud scenes (Fig. 6c). Both results of Fig. 6c) and Fig. 6d) are consistent with the increase in  $LWP$  susceptibility noted within pollution tracks around the globe (Toll et al., 2019). Moreover, the change in  $s_{lwp}$  with  $H_{BL}$  shown in Fig. 6c), which characterises the behaviour in most stratocumulus regions, is within a  $1\sigma$  uncertainty range of  $s_{lwp}$  estimates based on pollution tracks. Within pollution tracks  $s_{lwp}$  increased in magnitude from less than  $-0.01 \pm 0.13$  in shallow BL clouds to  $-0.1 \pm 0.13$  for a cloud top height of 2 km (Toll et al., 2019).

## 5 Conclusions

Isolating the  $LWP$  adjustment due to changes in  $N_d$  from potentially covarying meteorological factors has remained a significant hindrance in quantifying the radiative forcing of aerosol-cloud interactions. It also is a likely cause between diverging estimates from low-cloud climatology, process-scale models, and pollution track estimates.

Here, we address whether  $LWP$  adjustments vary with BL depth, and whether climatological susceptibility estimates are

impacted by the covariance of cloud properties with  $H_{BL}$ . Like previous studies we find evidence for a positive relationship  
255 between  $LWP$  and  $N_d$  climatologies in precipitating marine stratocumulus (Albrecht, 1989; Christensen and Stephens, 2011;  
Wang et al., 2012; Suzuki et al., 2013; Rosenfeld et al., 2019) which is consistent with the suppression of precipitation. Par-  
ticularly in shallow precipitating BLs ( $H_{BL} < 1$  km) the estimated susceptibility can become very large ( $s_{lwp} > 0.4$ , Fig. 6).  
Such adjustments would correspond to a considerable enhancement of the negative cloud-radiative forcing. However, these  
shallow precipitating BLs are rare (10–25 % of all cloud scenes analysed within the 10–year climatology). Therefore, such  
260 cloud scenes are unlikely to govern the radiative forcing of aerosol-cloud interactions.

The  $LWP$  adjustment inferred from the entire climatology of marine subtropical stratocumulus ( $s_{lwp} = -0.33$ ) is driven by  
non-precipitating cloud climatologies which govern the climatological statistics, but are only representative for a small subset  
stratocumulus regions in the subtropics. Susceptibility estimates restricted to the phase space of intermittently precipitating  
climatologies which represent most stratocumulus regions in the subtropics are lower ( $s_{lwp} = -0.23$ ) and are representative  
265 for most stratocumulus regions in the subtropics (Fig. 2d). Performing a bivariate fit of the  $\ln LWP$  phase space, which re-  
moves any potential impact of the  $LWP$ - $H_{BL}$  covariance on estimates of  $s_{lwp}$ , does not provide substantially different results  
(Table 1) to previous global estimates of  $s_{lwp}$  in marine low clouds (Michibata et al., 2016; Gryspeerdt et al., 2019).

A further division of the entire phase space into BL-depth regimes showed that overall, cloud adjustments are less effective in  
shallow BLs. The potential increase in  $LWP$  adjustment with BL depth has very recently been noted in pollution tracks (Toll  
270 et al., 2019). Here, we show that this behaviour may generalise to the whole climatology. The simulated change in  $s_{lwp}$  with  
 $H_{BL}$  within clouds of intermittent precipitation is consistent with the lower end of  $s_{lwp}$  estimates within the  $1\sigma$  range inferred  
from pollution tracks. Stratifying the  $\ln LWP - \ln N_d$  surface by BL depth, further closes the gap between  $s_{lwp}$  estimates in-  
ferred from climatology and cloud-scale modelling. Shallow BLs, such as the ones sampled during ASTEX and DYCOMS-II  
(Fig. 1) are associated with  $-0.22 < s_{lwp} < -0.1$  (Fig. 6c–d). This is consistent with estimates of  $s_{lwp}$  obtained in LES ex-  
275 periments of these campaigns (Ackerman et al., 2004; Bretherton et al., 2007).

Different remote-sensing-based estimates for  $s_{lwp}$  have been proposed. Their spatial distribution not only differs in magnitude,  
but also in sign among one another (e.g. Michibata et al. (2016) and Gryspeerdt et al. (2019)), as well as compared to Fig. 5  
of this study. This is likely a result of different methodologies of categorising and processing different retrievals. Different  
methodologies to distinguish between precipitating and non-precipitating clouds, as well as different methods to retrieve and  
280 process  $N_d$  may impact  $s_{lwp}$  estimates. In particular,  $N_d$  remains a highly uncertain retrieval from space-borne observations.  
For this study, we chose to limit the uncertainty of the physical retrieval of  $N_d$  while capturing as much of the variability in the  
subtropics as possible. Stricter filtering approaches may yield less retrieval uncertainty, but may imply a loss of some of the  
variability characteristic to the system. Either approach could influence  $s_{lwp}$  estimates. Thus our results, like previous studies,  
are subject to this uncertainty and remain to be verified in independent data sets.

285 In summary, our results show that aerosol-cloud interactions may manifest differently in deep precipitating, and non-precipitating,  
marine BLs as compared to shallow BLs. Furthermore, this work highlights the importance of understanding aerosol-cloud in-  
teractions in deep marine stratocumulus, which are underrepresented in currently analysed field data, numerical process models,

and pollution tracks.

290 *Data availability.* MODIS cloud retrievals were obtained from: [https://ladsweb.modaps.eosdis.nasa.gov/archive/allData/61/MYD08\\_D3](https://ladsweb.modaps.eosdis.nasa.gov/archive/allData/61/MYD08_D3) (last accessed January 2019). MERRA-2 data were downloaded from <https://disc.gsfc.nasa.gov/datasets> (last accessed March 2019). Albedo fields from CERES were downloaded from [https://ceres.larc.nasa.gov/compare\\_products.php](https://ceres.larc.nasa.gov/compare_products.php) (last accessed November 2018)

*Author contributions.* AP conceived this study and wrote the manuscript. RE compiled the remote sensing retrievals for the study. AP and RE performed the analyses with input from FB and FG. All authors contributed to the discussion of the results, and editing of the manuscript.

295 *Competing interests.* The authors declare to have no competing interests.

*Acknowledgements.* We would like to thank D. McCoy for initial discussions of the project idea in the context of remote sensing products, L. Josipovic for his technical support in figure optimisation and F. Hoffmann for Mixed-layer theory discussions. We also thank the anonymous reviewers for their constructive criticisms which greatly improved the quality of this manuscript. A. Possner was funded by the Federal Ministry of Education and Research (BMBF) under the "Make our Planet Great Again – German Research Initiative", grant number 57 429 624, implemented by the German Academic Exchange Service (DAAD).
