**Abstract.** This study examines the climatology of cloud phase over Southeast Asia (SEA) based on A-Train satellite observations. Using the combined CloudSat-CALIPSO (CC) data, five main cloud groups are investigated: ice-only, ice-above-liquid, liquid-only, ice-above-mixed and mixed-only clouds that have annual mean frequencies of 28.6%, 20.1%, 16.0%, 9.3% and 6.7%, respectively. Liquid-only clouds tend to occur in relatively cold, dry and stable lower troposphere. The other four cloud groups appear more frequently in relatively warm, humid and unstable conditions and their seasonal distributions move with the Asian monsoon and the Inter Tropical Convergence Zone (ITCZ). Liquid clouds are found to be highly inhomogeneous based on the heterogeneity index ( $H_\sigma$ ) from Aqua MODIS, while ice-only and mixed-only clouds are often very smooth. Ice-above-liquid clouds are more heterogeneous than ice-only clouds owing to ice clouds being optically thin. We demonstrate that the distribution of clear-sky  $H_\sigma$  has a long tail towards heterogeneous values that are caused by undetected sub-pixel cloud within both CC and MODIS datasets. The reflectance at 0.645 ( $R_{0.645}$ ) and brightness temperature at 11  $\mu\text{m}$  ( $BT_{11}$ ) of CC ice-only, liquid-only and ice-above-liquid clouds show peak frequencies near that of clear sky ( $R_{0.645} \sim 0.02$ ,  $BT_{11} \sim 294$  K), which explains why up to 30% of these CC cloud groups are classified as clear by MODIS. In contrast, mixed-only clouds are thick (average top  $\sim 13$  km), bright (average  $R_{0.645} \sim 0.6$ ) and cold (average  $BT_{11} \sim 234$  K). Cloud phase comparison between CC and MODIS reveals only modest agreement, with the best agreement (73%) occurring between CC ice-above-mixed and MODIS ice clouds. The intraseasonal and interannual behaviors of all-sky  $H_\sigma$  and spectral signatures follow that of cloud phase and vary with the Madden-Julian oscillation (MJO) and the El Niño-Southern Oscillation (ENSO) phases.

## 1. Introduction

Cloud phase and cloud vertical structure are crucial to Earth's radiation budget (Hong et al., 2016; Li et al., 2011; Liou, 1986; Matus and L'Ecuyer, 2017; Oreopoulos et al., 2017), and insufficient knowledge in these areas has contributed to large uncertainties in current climate simulations. For instance, the simulated liquid and ice cloud amount and mass from global climate models (GCMs) show large discrepancies compared with observations, differing by orders of magnitudes in regions where clouds are ubiquitous such as the Western Pacific warm pool (Dolinar et al., 2014; Jiang et al., 2012; Kay et al., 2016; Waliser et al., 2009). The biases in modeled cloud properties are able to propagate and cause biases in other fields in the model, such as shortwave (SW) and longwave (LW) radiation (Li et al., 2013), sea surface temperature and precipitation (e.g., Grose et al., 2014). By examining cloud vertical structures, Cesana and Waliser (2016) found that most of the selected GCMs overestimate the frequencies of high-level clouds over tropical ocean and consistently underestimate low-level clouds. As a result, GCMs produce insufficient heating near the surface and slightly over heating near the tropopause (Cesana et al., 2018). A recent study by Berry et al. (2019) showed that the Community Atmosphere Model, version 5 (CAM5) is in good agreement with A-Train observation in terms

of ice cloud radiative effect, though CAM5 generates more frequent ice clouds than satellite observations. These noted cloud and radiation biases ultimately point to an incomplete understanding of cloud phases, their vertical overlaps, and their interactions with large-scale circulations. Satellite observations continue to play important roles in furthering our understanding of cloud phase and vertical structure for future GCM evaluation (e.g. Cesana et al., 2019; Pincus et al., 2012).

The radar on CloudSat and the lidar on Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) have offered unprecedented opportunities to explore cloud vertical details globally (Stephens et al., 2002; Winker et al., 2003). Using the combined CloudSat-CALIPSO (CC) observations, the vertical and horizontal structures of global hydrometeor have been examined in Mace et al. (2009). More details of cloud phase characteristics including their macrophysical properties such as cloud amount, heights and water mass, and microphysical properties such as effective radius ( $R_e$ ), and ice and liquid water content (IWC, LWC), have also been examined in many studies (Eliasson et al., 2011; Hong and Liu, 2015; Hu et al., 2010; Yoshida et al., 2010). With the enhancement of our understanding of different cloud phase properties, these studies have assisted to improve GCM simulations (Kay et al., 2016; Zhao et al., 2018). The CC data has also helped characterize cloud vertical overlaps, showing that multi-layer cloud occurrence frequency is greater than 50% in large-scale ascending regions such as the Western Pacific warm pool (Li et al., 2011; Matus and L'Ecuyer, 2017). Furthermore, Li et al. (2015) showed that cirrus, cumulus, altostratus and altocumulus tend to overlap with other cloud types. Oreopoulos et al. (2017) focused more on cloud altitudes by interpreting the overlap feature of high, middle and low clouds, revealing that the two most prevalent cloud classes globally are single-layer low and high clouds (26% and 13.3%), respectively, followed by high over low clouds. Both Li et al. (2015) and Oreopoulos et al. (2017) showed distinct radiative effects between various cloud overlaps. Particularly, the radiative effects at the TOA in the LW of high over low clouds are weaker than high clouds but much stronger than single-layer low clouds. These studies nicely demonstrate the importance of accurately representing cloud vertical structures in GCMs. Although vertical structures for clouds have been examined in traditional designations (i.e. cloud types or cloud altitudes), cloud phase itself has not been used. Since cloud phase has been demonstrated to be a sensitive parameter in GCMs that needs to be constrained (Cesana, 2016; Cesana et al., 2015; Cesana and Storelvmo, 2017), improved knowledge of cloud phases and their overlaps will be beneficial to improve climate simulations.

While cloud overlap or vertical heterogeneity is important in the radiative transfer, so is cloud horizontal heterogeneity (Marshak and Davis, 2005). It has long been demonstrated that the neglect of cloud horizontal heterogeneity with the plane-parallel assumption in radiative transfer can cause significant biases in computing irradiances and atmospheric heating rates (e.g., O'Hirok and Gautier, 2005), photolysis rates (e.g., Bouet et al., 2006), the emerging spectral and angular distribution of outgoing radiation field (Loeb and Davies, 1997; Song et al., 2016) and in retrieving cloud microphysical properties from passive sensors (Loeb and Davies, 1996; Marshak et al., 2006). Many studies have since examined, at least in part, the global nature of these biases by successfully associating them with measured local spatial heterogeneity in SW radiance (Di Girolamo et al., 2010; Ham et al., 2015; Liang et al., 2015). Zhang and Platnick (2011), for instance, found that the differences of the Moderate Resolution Imaging Spectroradiometer (MODIS) liquid cloud  $R_e$  retrieved at 3.7 and 2.1  $\mu\text{m}$  increase with heterogeneity for

inhomogeneous clouds. To avoid the difficulty in interpreting satellite products whose biases co-vary with scene heterogeneity, focus on examining the spatial-temporal variability of the measured radiances in terms of their spatial heterogeneity and spectral signatures is a logical first step to understand Earth's climate systems – an approach that has successfully been carried out over the Terra satellite record over the globe (Zhao et al., 2016). However, the association of spectral and spatial heterogeneity signatures between different cloud phases and their overlap has not yet been examined, which may be possible if cloud phase can be accurately characterized from active space-based observations.

This study concentrates on cloud phase with an overall objective to investigate the characteristics of their climatology using the CC data with an emphasis on cloud phase overlap and the association with the spectral and spatial heterogeneity features from MODIS. We focus on South East Asia (SEA) because this region is strongly influenced by the Asian monsoon, the intertropical convergence zone (ITCZ) (As-Syakur et al., 2016; Hong and Liu, 2015), the Madden-Julian oscillation (MJO) and the El Niño-Southern Oscillation (ENSO). All of them influence cloud systems and modulate cloud overlap structures. Also, current satellite products show wide ranging retrieval skills over SEA, in both aerosol and cloud properties, that are difficult to interpret (e.g., Reid et al., 2013). This has motivated several field campaigns in the SEA environment to better characterize aerosol, cloud properties and their interactions, including 7-SEAS (7-Southeast Asian Studies) in 2010 and 2013 (Lin et al., 2013; Reid et al., 2013) and CAMP2Ex (Cloud and Aerosol Monsoonal Processes Philippines Experiment) in 2019 (Di Girolamo et al., 2018). Enhancing our understanding of cloud phase characteristics can help to interpret satellite products and benefit future field campaign preparation in this area. By fusing the CC-MODIS data, this study explores the following questions:

1. What are the spatial patterns of cloud phases and their overlaps and how do these patterns relate to large-scale dynamics?
2. To what extent do the spectral and spatial heterogeneity signatures correlate with cloud phase and their vertical overlap structure using the CC-MODIS observations?
3. How do cloud phase characteristics vary at intraseasonal and interannual scales, i.e. their association with MJO and ENSO?

## 2. Data and Methodology

CloudSat, CALIPSO and Aqua were operated together in the A-train satellite constellation between May 2006 and Feb. 2018. The A-train is in a sun-synchronous orbit with an equator-crossing time around 1:30 pm in the daytime and 1:30 am at night. The tight formation of these satellites allows the radar, lidar and MODIS to observe nearly the same point on Earth within 1 minute (Stephens et al., 2018), and thus a straightforward match between these instruments can be performed. The information of all data used in this study is summarized in Table 1. The SEA region is delineated with latitudes between 10°S and 30°N and longitudes between 80°-150°E.

### 2.1. The Combined CloudSat-CALIPSO Data

Launched in June 2006, the CloudSat satellite carries a cloud profiling radar operated at 94 GHz with a minimum sensitivity of -28 dBZ (Stephens et al., 2002, 2008). The radar's vertical resolution is 480 m but resampled to 240 m, while its horizontal resolution is 1.8 km along track by 1.4 km cross track. The radar is able to penetrate thick clouds but misses optically

thin clouds and shallow clouds lower than 1 km altitude (Stephens et al., 2008). The lidar onboard CALIPSO launched in April 2006 has vertical and horizontal resolutions of 30 m and 333 m in the lower troposphere (i.e., below 8.2 km), and 60 m and 1 km in the upper troposphere (i.e., above 8.2 km) (Winker et al., 2003). The lidar operates at 532 and 1064 nm and is suitable to detect optically thin clouds and aerosols, but its signal is easily attenuated, which limits its ability to penetrate optically thick clouds and to detect anything below. Nevertheless, the lidar has distinct advantages in detecting liquid clouds because 1) the backscattering ( $\beta_c$ ) from water droplets is much less depolarized than that from ice particles and 2) water layers produce strong lidar returns that attenuate rapidly with altitude at cloud top (Hu et al., 2009; Wang and Sassen, 2001). In cases where thin clouds at any altitudes or shallow clouds near Earth's surface are missed by CloudSat, the CALIPSO lidar can detect these clouds if the lidar attenuation above these clouds is sufficiently small.

To utilize the complementary features of the CloudSat radar and the CALIPSO lidar, the CloudSat Data Processing Center provides a combined radar and lidar cloud classification product called 2B-CLDCLASS-LIDAR (Wang, 2019). This product reports the lidar cloud fraction that records how many lidar profiles are contained in a radar resolution. The cloud top and base heights are also reported for up to five layers in the CloudSat pixels. The cloud layer here extends from cloud top to its base, and the vertical space between two layers is more than 500 m (Sassen and Wang, 2008). Each cloud layer is assigned one thermodynamic phase, either liquid, ice or mixed. The 2B-CLDCLASS-LIDAR algorithm utilizes cloud top and base temperatures from reanalysis as a first cut for cloud phase determination. If cloud base temperature is lower than  $-38.5^\circ\text{C}$ , this cloud layer is regarded as ice phase. Liquid phase is determined if cloud top and base temperatures are greater than  $1^\circ$  and  $-4^\circ\text{C}$ , respectively. While in the temperature range ( $-40^\circ - 0^\circ\text{C}$ ) where supercooled and mixed clouds would exist, potential liquid layers are first located using the feature of strong vertical gradient in lidar signals near liquid tops. If a liquid layer is detected by the lidar, the radar reflectivity factor ( $Z_e$ ) is further adopted to discriminate supercooled liquid from mixed cloud because  $Z_e$  in mixed cloud is primarily contributed by ice particles. Temperature dependent  $Z_e$  thresholds were generated to judge whether ice particles occur in the cloud layer with lidar detected liquid phase (Fig.2 in Zhang et al. (2010)). When the maximum  $Z_e$  of the cloud layer is greater than the given threshold, the layer will be classified as mixed cloud, otherwise, it is classified as liquid cloud. When the lidar signal is totally attenuated, the cloud phase is determined only by  $Z_e$  and temperature, which lowers down the confidence level. Also, in cases of thick ice clouds attenuating lidar signals over shallow liquid clouds that are missed by the radar, only ice clouds are reported in the profiles. Biases due to instrument limitations are kept in mind in our analysis.

Despite these limitations, the combined radar-lidar measurements provide comprehensive cloud phase and overlap information. Four years of 2B-CLDCLASS-LIDAR data, version P1\_R05 (2007-2010) with lidar cloud fraction greater than zero are used in order to include small size clouds.

The CloudSat level-2C ice cloud property product (2C-ICE) is also used. This product provides ice cloud optical (extinction coefficient in the visible) and microphysical (IWC and Re) properties retrieved from combined CC measurements (Deng et al., 2010). The 2C-ICE algorithm first identifies ice clouds based on the cloud layer and phase from 2B-CLDCLASS-LIDAR. The vertical profiles of Re and IWC are retrieved based on an optimal estimation framework that minimizes a cost function linking the observed and estimated lidar backscatter

and Ze via Gauss-Newton iteration. To retrieve ice cloud properties, a modified gamma particle size distribution is adopted. To estimate lidar backscatter and Ze, parameterization of ice habits from Yang et al. (2000) is employed. The 2C-ICE product was evaluated in Deng et al. (2013) by comparing ice cloud properties to field campaign measurements. It was found that the flight-measured to 2C-ICE retrieved Re ratio is about 1.05 and the extinction coefficient ratio is about 1.03, hence suggesting excellent consistency between 2C-ICE retrievals with in-situ observations. In this study, we integrate the retrieved extinction coefficient profile over depth of the ice layer to obtain ice cloud optical depth ( $\tau$ ). 2C-ICE data (R05) from 2007-2010 is used.

Meteorological data is also adopted to interpret the environment for different cloud phases. Temperature, wind and moisture are from the CloudSat's European Center for Medium-Range Weather Forecasts auxiliary product (ECMWF-AUX, 2007-2010), which interpolates the ECMWF variables to each CloudSat profile (Cronk and Partain, 2017).

## 2.2. CC Profile Classification

The CC profiles that contain clouds are classified into five groups (Fig. 1), according to the cloud layer and thermodynamic phase information from the 2B-CLDCLASS-LIDAR product. The first group is ice-only cloud which refers to only ice phase identified in the profile. When ice layers occur above liquid layers, we classify the profile as ice-above-liquid cloud. Similarly, mixed-only, liquid-only and ice-above-mixed clouds are classified, respectively. We do not focus on liquid-above-ice, mixed-above-ice, mixed-above-liquid or liquid-above-mixed clouds, collectively referred to as 'other clouds', due to their low frequencies (~0.74%) over SEA. Note that one cloud phase in each cloud category may contain multiple layers of the same phase. For example, for ice-above-liquid group, there could be more than one ice or liquid layers. While we quantify the frequencies of same-phase overlaps in Sect. 3.1.3, the majority of our analysis groups them into one of the classes listed above to simplify the number of classifications to work with. We lose some intricate cloud vertical structures, but still capture the main features of cloud phase overlap.

## 2.3. The Aqua MODIS Data

The Aqua satellite, launched in May 2002, carries MODIS. MODIS has 36 discrete spectral bands, ranging from 0.415 to 14.235  $\mu\text{m}$ , with spatial resolutions varying between 250 m to 1 km (Barnes et al., 1998; King et al., 1992; Platnick et al., 2003). To allow collocating CC and MODIS pixels, the MYD03 product, which includes longitude, latitude, solar zenith angle and land/sea mask, is used to obtain MODIS geolocation information. The nearest MODIS 1 km resolution pixels are assigned to the CC data from 2007-2010. The distance of the collocated CC-MODIS pixels is usually smaller than 700 m, allowing them to observe nearly the same cloud less than a minute apart. Uncertainties due to collocation are kept in mind during the analysis.

To investigate the spectral signatures of different cloud phases, the MODIS Collection 6.1 level 1B calibrated radiance data (MYD021KM) is used. The bands selected in this research have center wavelengths at 0.645, 1.375, 1.64, 2.13, 8.55 and 11.03  $\mu\text{m}$ . Ice crystals are more absorptive at the shortwave infrared (SWIR) (e.g., 1.64, 2.13  $\mu\text{m}$ ) than liquid droplets and thus ice clouds have smaller reflectance (R) at the TOA; whereas ice and liquid clouds are about equal in reflectance in the visible (0.645  $\mu\text{m}$ ) for the same cloud optical depth and particle size – this forms the basis for cloud optical and microphysical retrievals and cloud phase classification for MODIS (Marchant et al., 2016).  $R_{1.375}$  depends on cloud optical thickness and the amount of

water vapor above the cloud, since  $1.375 \mu\text{m}$  lies at the center of a strong water vapor absorption band. If cloud top is at a low altitude, the solar photons at  $1.375 \mu\text{m}$  will be largely absorbed by water vapor above cloud leading to near-zero  $R_{1.375}$  (Marchant et al., 2016). In the IR, we convert the radiances of  $8.55$  and  $11.03 \mu\text{m}$  to brightness temperature (BT).  $BT_{8.5}$ ,  $BT_{11}$  and the difference between  $BT_{8.5}$  and  $BT_{11}$  (BTD) are sensitive to cloud top temperature, thickness and phase (Baum et al., 2012).

The MODIS Level 2 cloud product (MYD06) provides cloud phase information identified according to three different IR channel pairs, i.e.  $8.5$  and  $11 \mu\text{m}$ ,  $11$  and  $12 \mu\text{m}$ , and  $7.3$  and  $11 \mu\text{m}$ , known as the IR-only algorithm (Baum et al., 2012). The product contains three cloud phases: ice, water and undetermined. Cho et al. (2009) evaluated Collection 5 MODIS IR-only cloud phase using CALIPSO observations. They found that agreements of MODIS to the CALIPSO top layers are  $64\%$  and  $34.7\%$  respectively for CALIPSO detected liquid and ice clouds over the globe. We revisited the comparisons of the latest version of MODIS IR-only cloud (C6.1) to the CC cloud phase (Fig. 1) over SEA in a similar way as Cho et al. (2009). About  $66\%$  CC liquid-only clouds agree with MODIS liquid clouds, which is similar to the global results of Cho et al. (2009). About  $62\%$  of CC ice-only clouds are reported to be ice by MODIS over SEA, agreeing better than the global results of Cho et al. (2009). In addition, most of CC ice-above-liquid ( $55\%$ ), ice-above-mixed ( $73\%$ ) and mixed-only clouds ( $65\%$ ) are reported to be ice phase by MODIS. We also found that  $29\%$  of CC ice-only clouds are reported as clear sky by MODIS, indicating that MODIS misses some thin cirrus in the SEA region -- a point also made in Reid et al. (2013). More details about the CC and MODIS cloud phase comparison is displayed in Table 2. In this study, MODIS cloud phase is also adopted to obtain additional cloud phase properties over a wider swath ( $2330 \text{ km}$ ) and longer time period than the CC data.

The spatial heterogeneity index ( $H_\sigma$ ) defined as the standard deviation over the mean of measured radiances of sixteen  $250 \text{ m}$  pixels within a  $1\text{-km}$  pixel (Liang et al., 2009) is also included in the MYD06 product. The  $H_\sigma$  usually increases with subpixel-level inhomogeneity and correlates with radiation and remote sensing biases rooted in the plane-parallel assumption (Cho et al., 2015; Fu et al., 2019).  $H_\sigma$  is reported at  $0.645$  and  $0.865 \mu\text{m}$ . Here, we adopt  $H_\sigma$  at  $0.645 \mu\text{m}$  because  $H_\sigma$  for  $0.865 \mu\text{m}$  is reported to be zero for saturated pixels, which occurs for thick clouds under certain sun-view geometries encountered in the MODIS data.

The matched  $H_\sigma$  values and MODIS radiances are assigned to cloud phase from 2B-CLDCLASS-LIDAR to investigate cloud spatial heterogeneity and spectral radiation features. Longer MODIS data (2003-2017) is used for analysis of interannual variations of cloud phase. Considering that no visible and SWIR radiances are available at night, only daytime data is considered.

## 2.4. Meteorological indices

The MJO (Madden and Julian, 1971) consists of large-scale coupled atmospheric circulation and deep convection in the tropical atmosphere. It forms in Indian Ocean and propagates eastward at a speed around  $5 \text{ m s}^{-1}$  across the Maritime Continent and into the equatorial western/central Pacific oceans with an intraseasonal variability of 30-90 days (Zhang, 2005). To understand cloud phase evolution with the MJO, we adopt the Real-time Multivariate MJO (RMM) index (Wheeler and Hendon, 2004), which defines eight MJO phases using two

leading Empirical Orthogonal Functions (EOFs) of combined 850, 200 hPa zonal wind from NCEP reanalysis and satellite-observed outgoing longwave radiation (OLR) over the tropical belt. We only focus on strong MJO events with amplitude greater than one. The RMM index is available at <http://www.bom.gov.au/climate/mjo/>.

5           The ENSO has a interannual variability of 3-5 years, and the multivariate ENSO index (MEI) is well suited to identify ENSO events (Wolter and Timlin, 1993, 1998). The new version of MEI is created by the EOF analysis of five variables including sea level pressure, sea surface temperature, surface zonal and meridional winds, and OLR. The ENSO index is available at <https://www.esrl.noaa.gov/psd/enso/mei/>.

## 10   **3. Results**

### **3.1. Seasonal Variations**

#### **3.1.1 Meteorological Conditions**

To better understand the linkages between cloud properties and large-scale dynamics, meteorological fields are presented in Fig. 2. It shows temperature, specific humidity, wind field, and static stability at the lower (~ 850 hPa) and upper (~ 180 hPa) troposphere over SEA in four seasons: boreal spring (March, April and May (MAM)), summer (June, July, and August (JJA)), autumn (September, October and November (SON)) and winter (December, January and February (DJF)). In the lower troposphere, relatively high and homogeneous temperatures are observed all year around (~290 K) corresponding to the Indo-Pacific warm pool. However, temperatures drop in boreal winter (< 285 K, Fig. 2a4) and raise in summer (> 290 K, Fig. 2a2) over Southeast China and South China Sea. In the upper troposphere, temperatures are relatively low at latitudes between 10°S-10°N (< 213 K), while temperatures over South Asia in summer are 1-3 K higher than in other seasons. Similarly, high humidity (> 10 g kg<sup>-1</sup> at lower troposphere and > 0.03 g kg<sup>-1</sup> at upper troposphere) is located south of 10°N latitude during spring and winter (Figs. 2b1, b4), while in autumn (Fig. 2b3), the humidity pattern is quite symmetric about the equator. Also, air is especially moist over South Asia during summer than other seasons at both lower and upper troposphere. The summer high temperature and humidity over South Asia are related to the heating and convection over Tibetan Plateau, which maintains a hot and humid upper troposphere, and the South Asian Anticyclone (Yeh, 1982). The summer monsoon also helps transfer a large amount of moisture from the Indian ocean to Asia (Figs. 2c2).

The seasonality of the wind field is evident (Figs. 2c1-c4). In the lower troposphere, the southwesterly wind flow brings warm and humid air to South Asia in summer when ITCZ is located at the North of equator, providing favorable conditions to form clouds and precipitation (summer monsoon). The wind direction in the upper troposphere is northeasterly, which is nearly opposite to that at the lower troposphere. In DJF, the ITCZ shifts to the southern hemisphere and the wind flow reverses. The prevailing northeasterly flow near the lower troposphere (winter monsoon) is also opposite to the wind direction at the upper troposphere (southwesterly). However, the upper troposphere wind is much weaker in winter than in summer because the summer South Asian Anticyclone above Tibetan Plateau enhances the upper troposphere wind flow (Yeh, 1982). The spring and autumn are two transition seasons of summer and winter monsoonal flows.

The lower-troposphere static stability ( $LTSS = (\theta_{z=3\text{ km}} - \theta_{z=0})/3\text{ km}$ ) and the upper-troposphere static stability ( $UTSS = (\theta_{z=\text{tropopause}} - \theta_{z=\text{tropopause}-3\text{ km}})/3\text{ km}$ ) are shown in Figs. 2d1-d4, where the  $\theta$  is potential temperature in unit of K. The tropopause height is defined following the World Meteorological Organization, i.e. the lowest level where lapse rate is  $2^\circ\text{ C km}^{-1}$  or less and the average lapse rate between this level and all higher levels within 2 km is smaller than  $2^\circ\text{ C km}^{-1}$  (Grise et al., 2010). Figures 2d1-d4 reveal that LTSS is usually smaller over land than over ocean. Small LTSS values ( $< 4\text{ K km}^{-1}$ , yellow-green color) over ocean correspond to a wetter atmosphere (Fig. 2b). Relatively larger LTSS ( $> 4\text{ K km}^{-1}$ ) occurs in winter and spring such as over East and South China sea. The LTSS has been proven to be an important parameter indicating low-level cloud formations. For instance, Klein and Hartmann (1993) showed that  $1^\circ\text{C}$  increase in stability associates with a 6% increase in stratus cloud area coverage. The spatial pattern of UTSS is similar with that of LTSS.

### 3.1.2 Occurrence of All Clouds

This sections focuses on cloud spatial distributions over SEA. The horizontal occurrence frequency, defined as the ratio of total cloudy number to the total observation sample in each  $5^\circ$  long x  $2^\circ$  lat grid derived from the 2B-CLDCLASS-LIDAR data, is shown in the upper panels of Fig. 3. The zonal latitude-altitude cross sections, obtained by cloudy number in each  $2^\circ$  lat x 250 m height cell divided by the observation sample in that cell, are displayed in the lower panels of Fig. 3.

Over SEA, the annual mean cloud frequency is about 81.4%, being smaller in winter and larger in summer (Table 3). As expected, seasonal variations of cloud occurrence are generally associated with the movement of large humidity, warm temperature and low stability in the lower and upper troposphere (Figs. 2, 3). Clouds frequently occur in Indochina during the summer monsoon season, while their frequency shifts to the Malaysia and Indonesia regions as the summer monsoon retreats and the ITCZ shifts southward. The cross sections (Figs. 3b1-b4) display prevailing high-level clouds located at around 10-15 km, matching to the ubiquitous nature of cirrus over the Warm Pool regions (Sassen et al., 2008). These ice clouds have their largest frequencies centered  $\sim 12^\circ\text{N}$  in summer, but shifts to the south of the equator in winter, i.e. moving with the ITCZ and the monsoon.

While it is clear that clouds favor a warm, humid and unstable condition, large cloud occurrences are found in other conditions in the region. Frequent cloud occurrence ( $\sim 70\%$ ) is also observed over southeast China and the East China Sea during winter when the atmosphere is cold, dry and stable (Figs. 2, 3a4). These winter clouds north of  $10^\circ\text{N}$  usually have low cloud heights ( $< 5\text{ km}$ ) with little cirrus above as seen from the cross section (Fig. 3b4).

While Fig. 3b displays a vertical cross section of cloud occurrence frequencies, it says little about cloud overlap frequencies. As shown in Yuan and Oreopoulos, (2013), low-level clouds have a high chance to be overlapped by upper clouds in the warm pool region. In the next section, we will examine cloud overlap with a focus on cloud phase.

### 3.1.3 Occurrence of Cloud Phase

As stated in Sect. 2.2, we classify clouds according to cloud phase and cloud layer in five main groups: ice-only, liquid-only, mixed-only, ice-above-liquid, ice-above-mixed clouds. Each

group contains both single and multiple layers of the same phase. Our analysis (Table 3) shows that one-layer-one-phase clouds have much larger frequency than multi-layer-same-phase clouds. For example, multi-layer ice-only cloud (~8.6%) occurs less frequently than one-layer ice-only cloud (20%). Liquid-only clouds mostly form in a single layer (14%) and the frequency of multi-layer liquid-only cloud is only 2%. A careful comparison between single and multiple layers of the same phase clouds shows no significant difference in the properties that we're interpreting, which justifies our simpler classification.

Figure 4 shows horizontal and vertical distributions of the five cloud groups as defined in Fig. 1. The mean occurrence frequency of each cloud class in four seasons over ocean and land is summarized in Table 3. The five cloud groups display visible differences in both of their mean frequencies and spatial distributions. Ice-only clouds (Fig. 4a) occur the most frequent (~ 28.6%) among all cloud classes. These clouds widely spread in the tropical belt, and prefer the locations at north of the equator in summer but move to the south in winter. Ice-only clouds mainly locate at high altitudes between 10-15 km (Fig.4b), corresponding to the prevalent tropical cirrus discussed in many other studies (Hong and Liu, 2015; Reid et al., 2013; Sassen et al., 2008).

In contrast, liquid-only clouds (Fig. 4a) are widely distributed over southeast China and the East China Sea and show large seasonality. These liquid-only clouds mostly have their cloud tops lower than 3 km (Fig. 4b). They are the so called 'Chinese stratus' by Klein and Hartmann (1993) associated with lower-troposphere cold and dry air and large LTSS (Fig. 2). Elsewhere, liquid-only clouds have very small frequencies (< 10%). The annual mean frequency of liquid-only cloud is ~16.0%.

Ice-above-liquid clouds have an annual mean occurrence frequency of ~ 20.1% (Fig. 4a). Ice layers located at 10-15 km cover the underlying liquid clouds mostly with height below 3 km (Fig. 4b). These clouds occur frequently over South China and Indochina during the summer monsoon season and move to West Pacific Ocean and Malaysia-Indonesia regions in winter.

The areas where widely distribute ice-only and ice-above-liquid clouds are also associated with relatively frequent mixed-only (annual frequency ~ 6.7%) and ice-above-mixed clouds (annual frequency ~9.3%) (Table 3) such as Indochina in summer and Malaysia-Indonesia regions in winter. Mixed-only clouds are mature convective clouds as seen from their cross sections (Fig. 4b) which extend from near surface up to above 15 km. Nevertheless, near 30°N from fall through spring where liquid-only clouds dominate, there exist relatively frequent mixed-only clouds with their top below 10 km. The ice-above-mixed clouds, frequently occurring at 6 km, are more likely under development with mixed layer tops reaching to around 10 km. If the mixed layers develop higher, they would merge with the overlying ice clouds and are classified into mixed-only cloud class. Overall, liquid-only clouds are associated with high LTSS and lower temperature in the lower troposphere, agreeing with the relationship of low-level cloud with stability (Klein and Hartmann, 1993; Li et al., 2014). In contrast, ice-only, ice-above-liquid, ice-above-mixed and mixed-only clouds, collectively named as 'ice-contained clouds', favor a humid, warm and unstable environment.

Figure 5 further summarizes the mean and standard deviation of the meteorological variables discussed in Fig. 2 from the ECMWF-AUX product for the five cloud groups in summer and winter seasons over ocean (to avoid the low static stability over land). In the lower troposphere, all cloud groups in summer tend to have smaller LTSS, higher temperature and humidity than in winter (Figs. 5a, b). The standard deviations in summer are also smaller, being

consistent with a more homogeneous spatial pattern of the meteorological fields (Fig. 2). In winter the liquid-only clouds tend to have a much smaller humidity and colder temperature corresponding to the occurrence of the ‘Chinese stratus’ (Klein and Hartmann, 1993). For those ‘ice-contained clouds’, they are still located in a relatively warm, moist and unstable atmosphere but their standard deviations are much larger than that in summer, agreeing with the less homogeneous spatial pattern of meteorology in winter (Fig. 2).

In the upper troposphere (Figs. 5c, d), the relationship between the five cloud types and meteorology is similar in both summer and winter with liquid-only clouds deviating from ‘ice-contained clouds’. The ‘ice-contained clouds’ relate to smaller UTSS as reported in Li et al., (2014). Also, ice-only and ice-above-liquid clouds share very similar upper tropospheric meteorology as their mean and standard deviations are nearly the same, which is not surprising because the low stability and high moisture are essential to maintain cirrus (Christensen et al., 2013; Li et al., 2014). However, the specific humidity in the upper troposphere of ice-above-mixed clouds is larger than both ice-only and ice-above-liquid clouds (Figs. 5c, d), which may reveal that convection below brings moisture to the upper troposphere.

### 3.1.4 Distributions of Cloud Phase Properties

Figure 6 presents the probability distribution function (PDF) of cloud properties including cloud top for all cloud phases, and base, geometric thickness,  $\tau$  and Re for ice layers from the 2C-ICE product. The averages of the cloud properties in the four seasons are summarized in Table 4.

The properties of ice layers in the three categories: ice-only, ice-above-liquid and ice-above-mixed clouds are displayed in Figs. 6a-e. We combine both land and ocean data to investigate the distributions of ice layer properties, because their PDFs display similar shapes between that over land and ocean (Figure not shown); however, their averages are separately summarized in Table 4. The three categories of ice layers share many similarities in their PDFs: the modes of ice top PDFs ( $\sim 16$  km) and base ( $\sim 12.5$  km) slightly greater than their means and medians (Table 4 and vertical dashed lines in Fig. 6). The modes of geometrical thickness PDFs are around 1 km, which are smaller than their mean and median values of 2-4 km (Fig. 6c and Table 4). These statistics demonstrate that the distributions of ice clouds skew to higher locations and thinner thickness, corresponding well to the properties of cirrus near tropopause (Haladay and Stephens, 2009; McFarquhar et al., 2000). In addition, the  $\tau$  PDFs show two modes for the three types of ice layers, and the Re PDFs with their modes slightly greater than  $15 \mu\text{m}$ .

There also exist differences between the three groups of ice layers. For example, ice-only clouds tend to locate 0.4-1.4 km lower over land than ocean, and the lower location may allow more moisture to feed into ice clouds, which may explain the reason that ice clouds over land have mean  $\tau$  values of 0.6-1.6 and Re of 3-5  $\mu\text{m}$  larger than those over ocean (Table 4). Compared to ice-only clouds, the ice layers above liquid or mixed clouds show much less land-ocean contrast in these properties (Table 4). Also, the ice layers above liquid clouds contain about 73.8% samples with geometrical thickness  $< 3.0$  km and about 91.5% samples with ice  $\tau < 3.0$ —the threshold often used to define cirrus (Sassen et al., 2008) (Figs. 6 c, d). In contrast, ice-only clouds are thicker with larger means, medians, and Re (Table 4), which are contributed by more ice-only cloud samples with geometrical thickness  $> 3.5$  km,  $\tau > 1.6$  and Re  $> 60 \mu\text{m}$  (Fig. 6). Due to the fact that lidar signals are attenuated when cloud  $\tau > 3.0$  and the radar fails in

detecting shallow clouds, some ice-above-liquid clouds (e.g., thick ice over shallow liquid) could be classified into ice-only group, leading to some sampling biases to the mean ice  $\tau$  and Re. However, in the ice  $\tau$  range of 1.6-3.0 where CALIPSO can penetrate the cloud, ice-only clouds have a total frequency of  $\sim 0.11$  in this  $\tau$  range, being higher than the frequency ( $\sim 0.07$ ) of the other two groups and demonstrating a higher probability of ice-only clouds being thicker.

For liquid or mixed layers, we only focus on cloud tops, because the determination of cloud base suffers from larger uncertainties than cloud top due to the limitation of instruments, i.e. CloudSat radar has difficulty in distinguishing the cloud base near Earth's surface and the CALIPSO lidar signal is attenuated by clouds with optical thickness greater than 3 (Hu et al., 2009; Stephens et al., 2008). For the liquid top PDFs (Fig. 6f), there are two modes for the liquid below ice clouds (green). One mode is located at 1 km for ocean (2-3 km for land), and the other is located at  $\sim 6$  km for both ocean and land. We further obtain the spatial distributions of the liquid below ice clouds with liquid top greater and lower than 5 km, respectively (Figure not shown). It is shown that liquid clouds with top  $< 5$  km are widely distributed over SEA, while those with liquid top  $> 5$  km are more concentrated in locations with latitude  $< 10^\circ$ , corresponding to a more unstable environment as shown in Fig. 2. In another word, larger moisture and small LTSS allow liquid clouds to develop deeper. For liquid-only clouds, they have a much higher frequency at the PDF mode of 1 km, and the second mode is not evident. The averaged top value of the liquid below ice clouds is higher than liquid-only clouds (Table 4).

For the mixed layers below ice clouds (Fig. 6g), the mode of cloud top PDF (cyan) is at around 6 km and the mean is about 8.5 km with the values over ocean about several hundred meters higher than that over land (Table 4). Note that as the mixed layers develop deeper, e.g. top  $> 10$  km, and merge with the upper ice layers, these clouds would be grouped as mixed-only clouds. For mixed-only clouds, the primary mode of cloud top PDF is at around 16 km and the secondary mode is at around 6 km. The primary mode is much higher over ocean than over land, while the secondary mode is higher over land, indicating that more mixed clouds over land are under development around 1:30 pm local time. This agrees with the results in Nesbitt and Zipser (2003) that convective clouds keep developing in the early afternoon and reaching to intensity maximum in the late afternoon over land, while diurnal variation of convection intensity is insignificant over ocean.

### 3.1.5 Spatial Heterogeneity of Cloud Phase

Sections 3.1.1 – 3.1.4 have discussed the macrophysical properties including spatial distributions, cloud thickness, top and base heights for five cloud groups and their relationship with meteorology based only on CC data. In this section, by combining the MODIS and 2B-CLDCLASS-LIDAR data, we investigate how the spatial heterogeneity index ( $H_\sigma$ ) relates to cloud phase. The  $H_\sigma$  is not only closely related to cloud micro and macrophysical properties but also affects the accuracy of cloud retrievals from passive sensors and radiative transfer modeling (Ham et al., 2015; Zhang and Platnick, 2011). Only ocean data is considered to avoid complications with the effects of land surface heterogeneity on interpreting results.

The  $H_\sigma$  PDFs for the CC clear sky and the five cloud groups are shown in Fig. 7a. The PDF of CC clear sky has a sharp peak at  $H_\sigma \sim 0.01$ , indicating that clear sky is usually spatially homogeneous. For cloudy sky, liquid-only clouds are the most heterogeneous among all cloud groups, with  $H_\sigma$  ranging from 0.01 to 1 and with a peak  $\sim 0.5$ . The ice-only clouds in contrast are

homogeneous as the PDF has a peak close to that of clear sky. This suggests that the biases in retrieved optical and microphysical properties of clouds from passive sensors caused by the plane-parallel assumption will be larger for water clouds compared to ice clouds in the SEA region. Indeed, MODIS liquid Re differences retrieved from three wavelengths (1.6, 2.1 and 3.7  $\mu\text{m}$ ) are especially large over this region (up to 10  $\mu\text{m}$ ) (Zhang and Platnick, 2011; Fu et al. 2019). Care is therefore recommended when using the MODIS cloud microphysical products in this region, for example in interpreting the cloud-aerosol relationship over SEA (e.g., Ross et al., 2018).

For ice-above-liquid clouds, the PDF curve moves slightly to a smaller  $H_\sigma$  region compared to liquid-only clouds as the overlying ice clouds have a spatial smoothing effect on the radiation emerging from the liquid clouds below. However, due to the small optical thickness of the overlying ice clouds, radiation from underlying liquid clouds dominate (Sect. 3.1.4). The  $H_\sigma$  PDF of ice-above-mixed clouds is similar with that of ice-only clouds but with some samples having  $H_\sigma$  smaller than clear sky (e.g.,  $H_\sigma < 0.01$ ). This feature is more obvious for the mixed-only clouds, which have about 50% of its samples with  $H_\sigma < 0.01$  (Fig. 7b), indicating that these clouds are extremely homogeneous. These cases of very smooth ice-above-mixed and mixed-only clouds correspond to high mixed layer tops and large reflectance at 0.645  $\mu\text{m}$  (discussed in next section) that are associated with deep convection. These clouds are locally homogeneous and hence favor the plane-parallel assumption in radiation computation (Ham et al., 2015).

Note that CC clear sky, ice-only, ice-above-mixed and mixed-only clouds are usually homogeneous, but there exist some heterogeneous cases. The PDF of clear sky has a long tail of  $H_\sigma$  values extending up to 1 (Fig. 7a) and has about 20% samples with  $H_\sigma$  values greater than 0.1 (Fig. 7b). Mismatch of pixels in collocation or difference in spatial resolutions of CC (1.8 km x 1.4 km) and MODIS (1 km) can contribute uncertainties to the  $H_\sigma$  of CC clear sky. Yet with a focus on the clear-sky pixels that both CC and MODIS agree, they behave nearly the same as that of CC clear sky as shown in Fig. 7a, indicating that the long tail is due to the significant amount of misdetection of small subpixel clouds by both MODIS and CC. Indeed, many small liquid clouds with size ranging in a few tens to hundreds of meters can go undetected by MODIS (Zhao and Di Girolamo 2006). We revisit the MODIS and Advanced Space Thermal Emission and Reflection Radiometer (ASTER) data (15-m resolution) used in Zhao and Di Girolamo (2006) over the tropical western Atlantic. The long tail of  $H_\sigma$  PDF is significantly reduced, i.e. frequency change from 0.3% to 0.1% at  $H_\sigma \sim 0.1$ , when the ASTER data is applied to exclude the MODIS clear sky pixels that contain ASTER reported clouds. This further affirms that the undetected clouds in MODIS and CC clear sky pixels contribute to large  $H_\sigma$  values, which may at least impact 20% clear-sky samples whose  $H_\sigma > 0.1$  (Figs. 7a,b).

To further investigate this last point, we calculate the MODIS liquid cloud fraction, defined as the ratio of liquid cloud samples based on the MYD06 product to the total 25 pixels in a 5 km by 5 km surrounding of the collocated CC-MODIS pixel. As shown in Fig. 7c, as  $H_\sigma$  increases, larger fraction of MODIS liquid clouds is observed around the CC clear sky, ice-only, mixed-only and ice-above-mixed clouds. This indicates that the heterogeneous pixels could also be due to undetected liquid clouds in the subpixels.

Figure 8 shows the mean  $H_\sigma$  for CC clear sky, the five cloud groups and all sky that includes both clear and cloudy sky. As expected, ice-only, ice-above-mixed, and mixed-only clouds are homogeneous everywhere ( $H_\sigma < \sim 0.05$ ) with some relatively large values ( $H_\sigma \sim 0.1$ )

in the liquid-only cloud prevailing regions such as the East China Sea in winter (Figs. 4, 8b4, 8d4, 8f4). As liquid-only clouds are the most heterogenous, they show the largest spatial  $H_\sigma$  values over SEA (Figs. 8c1-c4). Also, the  $H_\sigma$  values over the East China Sea in spring, fall and winter are relatively smaller than the  $H_\sigma$  in other regions, implying that the Chinese stratus that favor a dry and stable meteorological conditions are less heterogenous than other liquid-only clouds (Figs. 8c1-c4). Ice-above-liquid clouds (Figs. 8e1-e4) are smoother than liquid-only clouds, and their relatively small values tend to coincide with frequent ice-above-liquid cloud occurrence that associates with the monsoon and ITCZ, such as in Indonesia-Malaysia region in winter or North Indian Ocean in summer (Fig. 4). The  $H_\sigma$  pattern of CC clear sky (Figs. 8a1-a4) shows smaller values than ice-above-liquid clouds but larger values than ice-only, ice-above-mixed and mixed-only clouds. Also, the places with large  $H_\sigma$  values of CC clear sky are consistent with those with frequent occurrence of ice-above-liquid or liquid-only clouds, which in turn indicates the high chance of undetected liquid clouds increasing the subpixel variability.

For all sky (Figs. 8g1-g4), the small  $H_\sigma$  values occur north of the equator in summer, including Indian Ocean and South China sea. The pattern is quite symmetric about the equator in fall and moves south of the equator in winter – consistent with the shift of the monsoon and ITCZ. This is because the small  $H_\sigma$  values are primarily contributed by ice-only clouds due to their large occurrence frequency (Fig. 4) and spatial homogeneous features. In contrast, the pattern of large  $H_\sigma$  agrees more with that of liquid-only cloud occurrence (Fig. 4).

Overall, liquid clouds are spatially heterogeneous over SEA, whereas ice-only and mixed clouds are usually homogeneous. Due to the smoothness of the overlying ice clouds, ice-above-liquid clouds are less heterogenous than liquid-only clouds, but their  $H_\sigma$  values are still large because overlying ice clouds are optically thin and the emerging radiance from underlying liquid clouds dominates. Clear sky is smooth with  $H_\sigma \sim 0.01$ , but undetected liquid clouds increase its subpixel variability. The seasonal variations of all-sky  $H_\sigma$  spatial patterns are in accordance with cloud movements associated with the monsoon and ITCZ.

### 3.1.6 Spectral Radiative Feature

This section examines the spectral radiance at the TOA observed by MODIS for the CC clear sky and the five cloud groups defined in Fig. 1 to investigate how radiative features observed at the TOA relate to cloud phase. Similar to Sect. 3.1.5, only ocean data is adopted. The averages of the reflectance (R) and the brightness temperature (BT) (not weighted by cloud occurrence frequency) for each cloud group are shown over SEA in Fig. 9 and summarized in Table 5, while the PDFs and the cumulative distribution functions (CDFs) are displayed in Fig. 10.

The PDF of  $R_{0.645}$  for clear sky shows a narrow peak at  $R_{0.645} \sim 0.02$  (Fig. 10a1). Ice-only cloud shows its PDF peak near the clear sky peak and its CDF shows that about 80% of its samples have  $R_{0.645} < 0.2$ , proving the thin features of ice-only clouds over SEA and agreeing with their small optical depths in Fig. 6d. Similarly, for liquid-only cloud, the PDF also shows its mode near that of clear sky. A large fraction of liquid-only clouds are optically thin clouds (e.g., more than 75% of liquid-only clouds with  $R_{0.645} < 0.2$ ), being consistent with the findings of Leahy et al. (2012) that thin marine low-cloud fraction is greater than 80% for the SEA region. Ice-above-liquid clouds have larger mean  $R_{0.645}$  than either ice-only or liquid-only clouds in the column (Table 5 and Fig. 9), but ice-above-liquid clouds still contains more than 60% samples

with  $R_{0.645} < 0.2$ , further demonstrating the ubiquity of thin clouds over SEA. Many of these thin clouds often go undetected by MODIS as shown in Table 2, where around 11% of CC ice-above-liquid cloud, 30% of CC liquid-only and ice-only cloudy samples are reported to be clear sky by MODIS. The largest average  $R_{0.645}$  is seen in mixed-only clouds ( $\sim 0.59$ ), followed by  
 5 the ice-above-mixed clouds ( $\sim 0.45$ ). Their PDFs are broad and flat, but the frequencies at  $R_{0.645} > 0.4$  are evident as displayed in Fig. 10a1. Their CDFs reveal that 60% of ice-above-mixed and 80% of mixed-only clouds have  $R_{0.645} > 0.4$ , indicating that these clouds are geometrically deep (consistent with Fig. 4) and optically thick.

At  $1.64 \mu\text{m}$ , the average  $R_{1.64}$  of ice-above-liquid clouds is nearly same as liquid-only  
 10 clouds ( $\sim 0.13$ ) (Table 5 and Fig. 9). Both these cloud groups are more reflective than ice-only clouds (average  $R_{1.64} \sim 0.06$ ). The average  $R_{1.64}$  of ice-above-mixed and mixed-only clouds is about 0.20, implying that ice-above-mixed clouds are optically thick enough to reach the asymptotic reflectance and mixed-only clouds do not increase  $R_{1.64}$ . Similarly, the average  $R_{2.13}$   
 15 of both mixed-only and ice-above-mixed clouds is also nearly equal (0.11), which in turn demonstrates their large thickness. The curve of  $R_{2.13}$  across different cloud groups shows a similar shape with that of  $R_{1.64}$  but with a smaller magnitude owing to the larger imaginary part of refractive index of water and ice at  $2.13 \mu\text{m}$  than at  $1.64 \mu\text{m}$ . Particularly, the imaginary part of ice refractive index is larger than water at both wavelengths. Hence, when examining the reflectance ratio of SWIR ( $1.64$  or  $2.13 \mu\text{m}$ ) to the visible ( $0.645 \mu\text{m}$ ), we would expect that  
 20 liquid-only clouds show a larger ratio than any other cloud groups. Because the Aqua MODIS  $1.6 \mu\text{m}$  band has many dead detectors (King et al., 2013), we display the PDF and CDF of reflectance ratio of  $2.13$  to  $0.645 \mu\text{m}$  ( $\frac{R_{2.13}}{R_{0.645}}$ ) to further emphasize the spectral features of different cloud phases (Figs. 10b1 and b2). As expected, the PDF of liquid-only cloud extends to large reflectance ratio regions, and same as for ice-above-liquid cloud (Fig. 10b1). Moreover,  
 25 there are about 60% of liquid-only cloud and 50% of ice-above-liquid cloud with reflectance ratio greater than 0.4 (Fig. 10b2), indicating that the reflectance ratio of ice-above-liquid cloud is in accord with low-level liquid cloud because of the thin features of the overlying ice clouds as discussed in Sect. 3.1.4 and 3.1.5. In contrast, ice-only clouds have very small frequencies when reflectance ratio greater than 0.4 (Fig. 10b1), and same as mixed-only and ice-above-mixed clouds. For CC clear sky, the PDF shows its mode at the ratio  $\sim 0.1$  with its width ranging from  
 30 0.0 to 0.4. We also note that as the reflectance ratio of CC clear sky becomes larger, the corresponding  $H_\sigma$  increases as well, indicating that the undetected liquid clouds in clear sky pixels (Sect. 3.1.5) also enlarge the SWIR to the visible reflectance ratio.

At  $1.375 \mu\text{m}$ , liquid-only cloud and clear sky show near zero average reflectance as the  
 35 photons are nearly all absorbed by water vapor (Table 5). The mixed-only clouds have the largest average reflectance of 0.225 compared to other cloud groups, because these clouds are much higher and thicker as shown in Fig. 4 and Table 4. Also, the average  $R_{1.375}$  of ice-only cloud ( $\sim 0.06$ ) is greater than that of ice-above-liquid cloud ( $\sim 0.04$ ). Because the specific humidity at the upper troposphere is nearly the same for both cloud groups (Fig. 5), larger  $R_{1.375}$  of ice-only  
 40 clouds demonstrates an average larger thickness than the ice layers above liquid clouds. This agrees with the results from the CC observations as discussed in Sect. 3.1.4 (Table 4).

At the IR, the average  $BT_{8.5}$  and  $BT_{11}$  have similar magnitudes (Fig. 9 and Table 5). Only the PDF and CDF of  $BT_{11}$  are shown in Figs. 10c1 and c2, respectively. As expected, the average  $BT_{11}$  of mixed-only clouds is lowest ( $\sim 234.3 \text{ K}$ ), followed by ice-above-mixed clouds (average

BT<sub>11</sub> of ~ 247.7 K). The widths of BT<sub>11</sub> PDF of mixed-only and ice-above-mixed clouds are broad, but the frequencies are low when BT<sub>11</sub> > 260 K with about 20% samples at that BT<sub>11</sub> region (Fig. 10c2). The average BT<sub>11</sub> (~ 289.8 K) of liquid-only cloud is only slightly smaller than that of clear sky (~ 295.2 K) due to the low liquid cloud top (mode ~1 km, Fig. 6f) and thin features. For ice-above-liquid cloud, the average BT<sub>11</sub> (~ 276.8 K) is slightly larger than ice-only cloud (~ 272.4 K). This may be due to that the ice layers above liquid clouds do not absorb as strong as ice-only clouds because the former is averagely thinner than the latter over Ocean (Table 4). Also, the peaks of BT<sub>11</sub> PDF of ice-only and ice-above-liquid clouds are close to that of clear sky, and 50% samples of these two cloud groups with BT<sub>11</sub> > 280 K (Fig. 10c2), demonstrating the thin features of these clouds which agree with the conclusions from the CC data (Fig. 6) and R<sub>0.645</sub> analysis.

Another notable feature of the BT shown in Fig. 9 is that the BT<sub>8.5</sub> is averagely larger than the average BT<sub>11</sub> for ice-only, ice-above-liquid, ice-above-mixed and mixed-only clouds, i.e. ‘ice-contained clouds’, and vice versa for clear sky and liquid-only clouds. This is because in clear sky, absorption by the atmosphere at 8.5 μm is slightly greater than at 11 μm and hence, negative BTD between 8.5 and 11 μm (BT<sub>8.5</sub>-BT<sub>11</sub>) is observed (Fig 10d1). In cloudy sky, cloud absorption at 11 μm is larger than at 8.5 μm (Wolters et al., 2008), which decreases the BT<sub>11</sub>. The absorption difference between 11 and 8.5 μm is small for water, which explains that the PDF of liquid-only clouds locates closely with that of clear sky but at larger BTD regions (Fig. 10d1).. Ice cloud has larger absorption difference between 11 and 8.5 μm than liquid cloud (Wolters et al., 2008). This explains positive BTD values for the ‘ice-contained clouds’. However, ice-only and ice-above-liquid clouds have their BTD PDFs peak at around -1.4 K. The negative BTDs of these clouds also indicate their thin features over the SEA regions so that the absorption by ice clouds is insufficiently significant to produce positive BTD.

For seasonal variations (Fig. 9 and Table 5), the change of reflectance and brightness temperature of each cloud group is associated with cloud occurrence, thickness and cloud top. For example, ice-only clouds have larger average R<sub>0.645</sub> and smaller BT in summer due to that these clouds occur more frequently and thicker in this season. In contrast, liquid-only clouds over ocean have similar cloud tops but occur more frequently in winter and they show greater average R<sub>0.645</sub> in winter than in summer.

In summary, mixed-only and ice-above-mixed clouds are bright in the visible (i.e. large R<sub>0.645</sub>) and cold in the infrared (i.e. low BT). These clouds also have small reflectance ratio and positive BTD between 8.5 and 11 μm. Although liquid-only and ice-only clouds have similar R<sub>0.645</sub>, liquid-only clouds tend to have relatively larger BT<sub>11</sub> and larger reflectance ratio than ice-only clouds. Ice-above-liquid clouds show slightly larger R<sub>0.645</sub> than either liquid-only or ice-only cloud with reflectance ratio similar to liquid-only clouds, but BT<sub>11</sub> and BTD closer to ice-only clouds. The spectral radiative features of ice-only, liquid-only and ice-above-liquid clouds also demonstrate widespread thin clouds over SEA.

### 3.2. Cloud Phase Variations Associated with The Madden-Julian Oscillation

This section discusses the features of cloud phase associated with the intraseasonal 30-90 day MJO. Previous studies have provided full overviews of the radiative (in terms of OLR), dynamic and thermal dynamic characteristics of the MJO (Knutson et al., 1986; Riley et al.,

2011; Wheeler and Hendon, 2004; Zhang, 2005). The purpose of this study is to focus on how the cloud phase characteristics discussed in previous sections vary with MJO phases.

As seasonality is a basic feature of the MJO (Zhang and Dong, 2004), we first classify the MJO events during 2007-2010 into four seasons according to the MJO index from Wheeler and Hendon (2004) (Fig. 11). In total, 917 events with amplitude greater than one (i.e.  $(RMM1^2 + RMM2^2)^{0.5} > 1$ ) are selected to represent strong MJO. As shown in Fig. 11a, the occurrence of different MJO phases displays very strong seasonality. Specifically, more MJO events happen in Phase 1 and 2 in summer, while in fall, the MJO cases are concentrated in Phase 4, 5 and 6. When it moves to winter, the MJO prefers to occur in Phase 7, while in spring, more cases occur in Phase 1 and 8. Although the MJO amplitude is relatively flat across different phases, the weakest amplitude occurs in summer, while it is stronger towards winter, which is consistent with the statements in previous studies (Adames et al., 2016; Zhang and Dong, 2004).

To investigate the spatial heterogeneity associated with the MJO, Figure 12 shows the spatial distributions of all-sky  $H_\sigma$  over eight MJO phases. According to the spatial heterogeneity signatures derived in Sect. 3.1.5, the active MJO phase associated with deep convections and ice clouds is featured with small  $H_\sigma$  values. Areas surrounding the convective center are with relatively large  $H_\sigma$  values, indicating that the locations of suppressed MJO phase are associated with more liquid clouds. As displayed by Fig. 12, the  $H_\sigma$  pattern well reveals the propagation of MJO. That is, the center of convection associated with small  $H_\sigma$  is in the Indian Ocean in Phase 1 and 2, while the West of Pacific and Maritime Continents display large  $H_\sigma$  as convection is suppressed. The small  $H_\sigma$  pattern approaches to the Maritime Continent (indicated by the red dashed box in Fig. 12) in Phase 3 and centers at those regions in Phase 4, 5 and 6. After Phase 6, the convective center with small  $H_\sigma$  enters the West Pacific Ocean, and at the same time,  $H_\sigma$  becomes large over the Indian Ocean. Note that Phase 2 mainly occurs in summer, which relates to boreal summer monsoon, so the  $H_\sigma$  pattern here is quite similar with that in summer shown in Fig. 8g2. Similarly, the  $H_\sigma$  pattern of Phase 5 is in concert with the seasonal pattern in fall (Fig. 8g3) due to a high chance of Phase 5 occurring in that season. The preference of geographical location of MJO, featured by the small  $H_\sigma$ , moves from North of the equator in Phase 1 to the South of the Equator in Phase 6, indicating the seasonal cycle of MJO location.

To investigate more details of how  $H_\sigma$  pattern changes with cloud phase according with the MJO evolution, Figure 12i shows the PDF of all-sky  $H_\sigma$  sampling over the Maritime continent for the eight MJO phases from MODIS data. Two dashed lines from left to right indicate  $H_\sigma \sim 0.01$  and  $H_\sigma \sim 0.4$ , which are close to the mode position of  $H_\sigma$  PDF of CC clear sky and liquid-only clouds (Fig. 7a), respectively. Figures 12j and k show the average occurrence frequency of different cloud phases from the MYD06 and the 2B-CLDCLASS-LIDAR products in the same region. In Phase 8 (cyan) when suppressed MJO occurs over the Maritime continent, the  $H_\sigma$  PDF shows the largest frequency ( $\sim 0.38\%$ ) among all MJO phases at  $H_\sigma \sim 0.4$  but the smallest frequency when  $H_\sigma < 0.01$  (Fig. 12i). This corresponds to the largest frequency of clear sky and liquid clouds among all MJO phases but the smallest frequency of ice clouds indicated by MODIS (Fig. 12j), and at the same time, ice-only, ice-above-liquid, ice-above-mixed clouds from the 2B-CLDCLASS-LIDAR products occur the least frequently (Fig. 12k). In contrast, when active MJO phase locates in the Maritime continent (Phase 4, 5), the  $H_\sigma$  PDF has the largest frequency at  $H_\sigma < 0.01$  and the smallest frequency at  $H_\sigma \sim 0.4$ , due to the frequent

occurrence of ice or mixed clouds among all MJO phases but less frequent occurrence of clear sky and liquid clouds.

5 Overall, more ‘ice-contained clouds’ occurring during the active MJO phase results in smoother textures, i.e., small  $H_{\sigma}$  values, compared to the suppressed MJO phase. The eastward-propagating  $H_{\sigma}$  patterns vary with MJO, indicating that  $H_{\sigma}$  could be useful for MJO studies, such as serving as an observed-based parameter to track the MJO position. It can also serve as a basis for disentangling true space-time variability of cloud optical and microphysical properties associated with the MJO from space-time variability of the biases rooted in cloud retrievals from passive sensors that are caused by departures from the plane-parallel assumption (Di Girolamo et al., 2010).

### 3.3. Interannual Variations: El Niño Southern Oscillation

15 It is well known that the ENSO dominates the interannual variability of precipitation and clouds over the Western equatorial Pacific (As-Syakur et al., 2016; Park and Leovy, 2004; Reid et al., 2012), and accordingly, the observed broadband radiation at the TOA varies interannually as well (e.g., Loeb et al., 2012). Here we examine how the spectral radiances and spatial heterogeneity associated with cloud phase behave interannually.

20 The spatial distributions of all-sky spatial heterogeneity ( $H_{\sigma}$ ) anomaly is shown in Fig. 13 in El Niño and La Niña years based on the ENSO index and MODIS data from 2003-2017. Generally, all-sky  $H_{\sigma}$  anomaly is negative in La Niña year, indicating that more ice and mixed clouds occur in La Niña year causing the spatial heterogeneity to be more homogeneous than normal and vice versa in El Niño year. Also, the anomalies over the Maritime continent tend to be stronger in winter and spring than in summer and fall (Fig. 13). This demonstrates that the  $H_{\sigma}$  varies with ENSO.

25 Figure 14 displays the time series of monthly anomaly of clouds, radiances and spatial heterogeneity for the areas indicated by the red-dashed box in Fig. 13a1 – an area sensitive to ENSO signals. As displayed, ice clouds detected by MODIS show similar variations as MODIS all clouds with their anomalies ranging from -0.2-0.2, being positive in La Niña years and negative in El Niño years (Fig. 14b). The MODIS ice cloud anomaly correlates well with that of CC ice-only, ice-above-liquid, ice-above-mixed and mixed-only clouds (Fig. 14d) with correlation coefficients greater than 0.70 (significant at 99% confidence level). Conversely, the anomaly of liquid cloud occurrence is positive (negative) in El Niño (La Niña) year based on both the MODIS and CC data (Figs. 14b, d). Correspondingly,  $H_{\sigma}$  anomalies are observed to be negative in La Niña year due to the increase of ‘ice-contained clouds’ and positive in El Niño years because ‘ice-contained clouds’ decrease, exposing more liquid clouds (Figs. 14b, d).

35 Moreover, the correlation coefficient between  $H_{\sigma}$  and ENSO index is about 0.49 (significant at 99% confidence level), further indicating that the change of spatial heterogeneity is associated with ENSO.

40 Note that negative (positive) anomaly of CC liquid-only or MODIS liquid cloud associated with La Niña (El Niño) phase does not mean that total liquid clouds occur less (more) in La Niña (El Niño) year. The overlying clouds can conceal liquid clouds to be observed from space by passive sensors or by lidar if the overlying clouds are optically thicker than 3. Unlike CC liquid-only or MODIS liquid clouds, the CC ice-above-liquid clouds occur abnormally high

in La Niña year (Fig. 14d). When adding up the frequency of liquid-only and ice-above-liquid clouds (i.e. total CC liquid cloud frequency), the anomaly shows the relationship with ENSO less evident than the liquid-only cloud (the subfigure in Fig. 14d). For example, through the La Niña phase in 2007 winter through 2008 spring, the anomaly of total CC liquid cloud occurrence is close to be zero, blurring its relationship with ENSO. In Park and Leovy (2004), they showed negative anomalies of low-level clouds during positive ENSO phase using ship observations reported by the Extended Edited Cloud Report Archive (EECRA), i.e. less low-level clouds in El Niño year. While in our study, it is likely that MODIS data and four-year CC data is insufficient to support the relationship between liquid cloud occurrence and ENSO over SEA.

Overall, the cloud phase varies interannually, as does  $H_{\sigma}$ , i.e., being smoother in La Niña years compared to El Niño years. Also, the timeseries of all-sky  $H_{\sigma}$  anomalies vary with ENSO and it correlates well with that of  $R_{0.645}$  ( $r \sim -0.8$ , significant at 99% confidence level) and  $BT_{11}$  ( $r \sim 0.8$ , significant at 99% confidence level), indicating that  $H_{\sigma}$  can be one valuable observed parameter to investigate ENSO, including its basis for indicating the space-time variability, associated with the ENSO, of the biases of cloud optical/microphysical properties retrieved from passive sensors, caused by departures from the plane-parallel assumption.

#### 4. Discussions and Conclusions

This work contributes to a series of studies that examine cloud vertical structures. Li et al. (2015) explored the vertical distributions of cloud types using the 2B-CLDCLASS-LIDAR data, while Oreopoulos et al. (2017) interpreted the overlap feature of high, middle and low clouds. Considering the need of cloud phase information for improving GCMs (e.g., Cesana and Storelvmo, 2017), the current study focuses on investigating the characteristics of cloud vertical structures, spatial heterogeneity and spectral radiances from the perspective of cloud phases over Southeast Asia. Utilizing the state-of-the-art CloudSat and CALIPSO (CC) observations, five cloud groups have been classified: ice-only, ice-above-liquid, ice-above-mixed, liquid-only and mixed-only clouds to capture the main vertical structures of cloud phases. By collocating the CC-MODIS data, the spectral and spatial heterogeneity signatures at the TOA of each CC cloud group have been examined. Seasonal, intraseasonal and interannual variations of these cloud phase characteristics have also been shown in this work.

A general review on cloud spatial distributions and meteorology shows that the annual cloud occurrence frequency over SEA is about 81.4%, being more frequent in summer (86.5%) and less frequent in winter (78%) based on the CC observations. Ice-only (28.6%), ice-above-liquid (20.1%), ice-above-mixed (9.3%) and mixed-only (6.7%) clouds, i.e. ‘ice contained clouds’, preferentially occur in a warm, humid and unstable environment and are associated with the seasonal movement of the monsoon and ITCZ. It is noted that ice-only and ice-above-liquid clouds are associated with similar upper troposphere dynamics, i.e., comparable mean temperature, specific humidity and static stability, while ice-above-mixed clouds occur in an environment with larger specific humidity at the upper troposphere. Liquid-only clouds appear frequently in winter and spring over southeast China and East China sea where the lower troposphere is relatively cold, dry and stable.

It is shown that ice clouds over SEA are thin with about 60% and 80% samples with geometrical thickness smaller than 3.0 km and optical depth less than 3, respectively. Ice-only

clouds have larger mean thickness (geometrical and optical) and  $Re$  than the ice layers above liquid or mixed clouds. Although there could exist sampling biases due to instrument limitations, a higher frequency of ice-only clouds at  $1.6 < \tau < 3.0$  demonstrates that more ice-only clouds develop thicker than either the ice layers above liquid or mixed clouds. The tops of liquid-only clouds are on average lower than that of the liquid below ice clouds. As liquid-only clouds occur more frequently with increase of LTSS, their vertical development is likely to be inhibited. However, ice-above-liquid clouds more favorably distribute in a warm, humid and unstable environment, which allows the underlying liquid clouds to grow deeper. The tops of mixed layers below ice clouds are primarily located at about 6 km. For mixed-only clouds, their tops are primarily at 16 km over ocean, but over land, a large fraction of samples have cloud top around 6 km. These results suggest that ice-above-mixed and mixed-only clouds over land are under development in the early afternoon.

We also show that distinct spatial heterogeneity exists between the five cloud groups. Ice-only, ice-above-mixed and mixed-only clouds are usually homogeneous, i.e., small  $H_\sigma$  values. In contrast, liquid-only clouds show the largest  $H_\sigma$  among all cloud phase groups, being the most heterogeneous. Ice-above-liquid clouds have large but slightly smaller  $H_\sigma$  values than liquid-only clouds because the overlying homogenous and thin ice clouds slightly smooth the radiation emerging from the low-level liquid clouds. A typical  $H_\sigma$  value for clear sky is 0.01, however, clear sky  $H_\sigma$  can be as large as 1, resulting from the increase of subpixel variability due to undetected liquid clouds in the MODIS and CC pixels. As large  $H_\sigma$  values are reported to associate with the biases of cloud  $\tau$  and  $Re$  derived from passive sensors (Di Girolamo et al., 2010; Zhang and Platnick, 2011), biases resulted from plane-parallel assumption are expected to be larger for liquid than ice clouds. The seasonal patterns of all-sky  $H_\sigma$  show that small values are in north of the equator over Indian and West Pacific Ocean in summer but move southward in autumn and winter, being consistent with the seasonal shift of the ‘ice-contained clouds’.

Difference of cloud optical, micro and macrophysical properties leads to distinct spectral features between the five cloud groups. The liquid-only clouds show zero  $R_{1.375}$ , large reflectance ratio of the SWIR to the visible, high BTs and negative BTD between 8.5 and 11  $\mu\text{m}$ . Ice-only clouds in contrast show notable  $R_{1.375}$ , reflectance ratio generally smaller than 0.4, relatively low BTs and more than 50% samples with positive BTD. Ice-above-liquid clouds behave more like ice-only clouds in the IR because these two cloud groups have similar  $BT_{11}$  and BTD PDFs, but ice-above-liquid clouds act more like liquid-only clouds in the SW spectral due to their similar PDFs/CDFs of reflectance ratio. The average  $R_{1.375}$  of ice-above-liquid clouds, which is mainly contributed by the ice layers only, is smaller than that of ice-only clouds. Similarly, ice-above-liquid clouds have their average  $BT_{11}$  slightly larger than that of ice-only clouds. These results demonstrate that ice-only clouds are on average thicker than the ice layers above liquid clouds, being consistent with the conclusions derived from the CC observations. Mixed-only or ice-above-mixed clouds usually have large  $R_{0.64}$ , small reflectance ratio, low  $BT_{11}$  and positive BTD. It is also noted that the  $R_{0.645}$  and  $BT_{11}$  PDFs of ice-only, liquid-only and ice-above-liquid clouds show their frequency peak nearly same as that of clear sky, revealing ubiquitous thin clouds over SEA.

Cloud phases together with their spectral and spatial heterogeneity features have also been examined in different MJO and ENSO phases. In the MJO active phase, more frequent ‘ice-

contained clouds' contribute to a smooth MJO center. On both sides of the MJO convective center, large  $H_{\sigma}$  values are observed due to increase of liquid clouds and decrease of 'ice-contained clouds'. Thus, the  $H_{\sigma}$  pattern reveals the eastward-propagating MJO. Similarly, the interannual variation of clouds over SEA is primarily due to the change of 'ice-contained clouds'. Increased 'ice-contained clouds' in La Niña year result in more homogeneous spatial heterogeneity, stronger  $R_{0.645}$  and lower  $BT_{11}$ , and vice versa in El Niño year. The observed  $H_{\sigma}$  varies with the ENSO index with a correlation coefficient of 0.49 (significant at confidence level 0.99). The  $H_{\sigma}$  varying with the MJO and ENSO forms a basis for disentangling the true intraseasonal/interannual variability of cloud optical/microphysical properties from the space-time variability of cloud biases due to the plane-parallel assumption in cloud retrievals from passive sensors.

Finally, careful comparisons between model and observations can use  $H_{\sigma}$  as a measure of departure from the plane-parallel assumption in a manner similar to (Loveridge and Davies, 2019), where they used  $H_{\sigma}$  within their analysis in examining GCM clouds in different sectors of southern hemisphere cyclones.  $H_{\sigma}$  can also be used to gauge biases in other satellite products that are used in model evaluation (e.g. Gettelman et al., 2015; Song et al., 2018), such as cloud optical depth and effective radius, whose biases have been noted to covary with  $H_{\sigma}$  (Fu et al., 2019; Zhang et al., 2016).

*Data availability.* Data used in this study are summarized in Table 1 and their availability is provided in acknowledgements.

*Author contributions.* YH and LD conceived this study. YH analyzed the results and wrote the manuscript. LD joined result discussions and refined this manuscript.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* This research has been supported by the Cloud, Aerosol and Monsoon Processes Philippines Experiment (CAMP<sup>2</sup>Ex) under NASA Grant 80NSSC18K0144. We are grateful to Dr. Guangyu Zhao for his examination of clear sky  $H_{\sigma}$  derived from ASTER and MODIS. We acknowledge the members of the CloudSat Data Processing Center who provide CloudSat products, including 2B-CLDCLASS-LIDAR, 2C-ICE and ECMWF-AUX, available at <http://www.cloudsat.cira.colostate.edu/>. The MODIS products, MYD021KM, MYD03 and MYD06, are obtained via the Atmosphere Archive and Distribution System (LAADS) Distributed Active Archive Center (DAAC), which is available at <https://ladsweb.modaps.eosdis.nasa.gov/>. We also thank Bureau of Meteorology in Australia offering MJO index (available at <http://www.bom.gov.au/climate/mjo/>) and NOAA Earth System Research Laboratory providing Multivariate ENSO index that can be downloaded from <https://psl.noaa.gov/enso/mei/>.

## Tables

Table 1. Summary of datasets used in this study.

Products	Version	Parameters	Resolution (km)	Period	References
2B-CLDCLASS-LIDAR	P1_R05	Cloud layers, phases Extinction coefficient, effective	1.4 x 1.8	2007-2010	(Wang et al., 2012)
2C-ICE	P1_R05	radius	1.4 x 1.8 x 0.24	2007-2010	(Deng et al., 2010)
ECMWF-AUX	P_R05	Meteorology	1.4 x 1.8 x 0.24	2007-2010	(Cronk and Partain, 2017)
MYD021KM	C6.1 L1B	Reflectance, BT	1	2003-2017	(Savtchenko et al., 2004)
MYD03	C6.1 L2	Geolocation, Ocean/land Mask	1	2003-2017	(Savtchenko et al., 2004)
MYD06	C6.1 L2	Cloud Phase, spatial heterogeneity	1	2003-2017	(Savtchenko et al., 2004)
--	--	MJO index	--	2007-2010	(Wheeler and Hendon, 2004)
--	--	ENSO index	--	2003-2017	(Wolter and Timlin, 1998)

Table 2. Comparison of MODIS and CC cloud phase. Number in parentheses represents the percentage (%) of CC phase reported as to be MODIS cloud phase.

MODIS cloud phase	CloudSat-CALIPSO cloud phase						sum
	Clear	Ice only	Liquid only	Mixed only	Ice above liquid	Ice above mixed	
Clear	2 408 080 (93.1)	1 218 244 (29.2)	642 659 (28.6)	12 609 (1.23)	333 723 (11.1)	8 268 (0.59)	4 623 583
Liquid	168 625 (6.52)	265 985 (6.38)	1 485 900 (66.1)	144 441 (14.09)	854 024 (28.5)	90 234 (6.49)	3 009 209
ice	9 058 (0.35)	2 594 258 (62.21)	87 895 (3.91)	668 181 (65.2)	1 650 626 (55.1)	1 017 196 (73.2)	6 027 214
undetermined	1 872 (0.07)	91 511 (2.19)	32 207 (1.43)	200 050 (19.5)	158 352 (5.28)	274 433 (19.7)	758 425
sum	2 587 635	4 169 998	2 248 661	1 025 281	2 996 725	1 390 131	14 418 431

Table 3. Cloud occurrence frequency (%) derived from 2B-CLDCLASS-LIDAR. In ocean-vs-land section, the number outside parentheses represents both land and ocean. First number in parentheses is for ocean and the second one is for land. In the single-vs-multiple cloud layers section, first number in parentheses represents single layer and the second number is for multiple layer.

	Ice only	Liquid only	Mixed only	Ice above liquid	Ice above mixed	Others	All clouds
<b>Ocean vs. Land</b>

## Figures

Figure 1. Schematic of cloud classification based on the 2B-CLDCLASS-LIDAR product.

5

Figure 2. Temperature (a1-a4), specific humidity (b1-b4), wind field (c1-c4), and static stability (d1-d4) derived from the ECMWF-AUX data: shade for 850 hPa, contour for 180 hPa, grey vectors for wind field at 850 hPa and red vectors for 180 hPa.

10

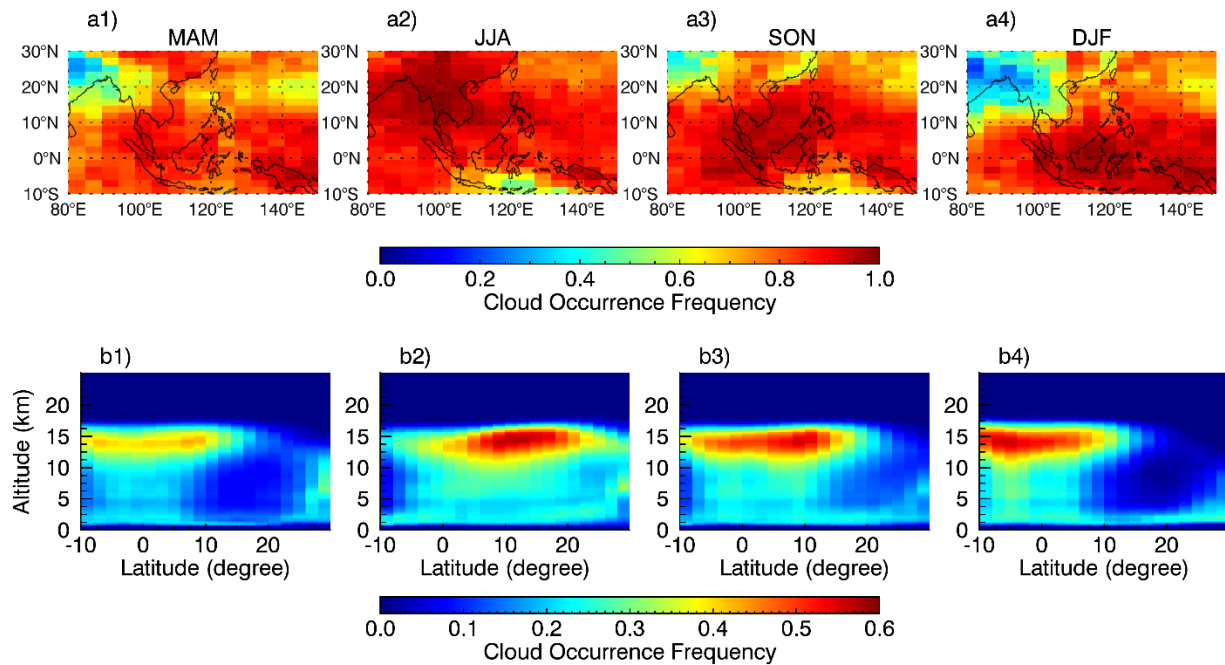

Figure 3. Cloud occurrence frequency derived from 2B-CLDCLASS-LIDAR: a1) -a4) for horizontal distribution and b1-b4) for zonal latitude-altitude cross section.

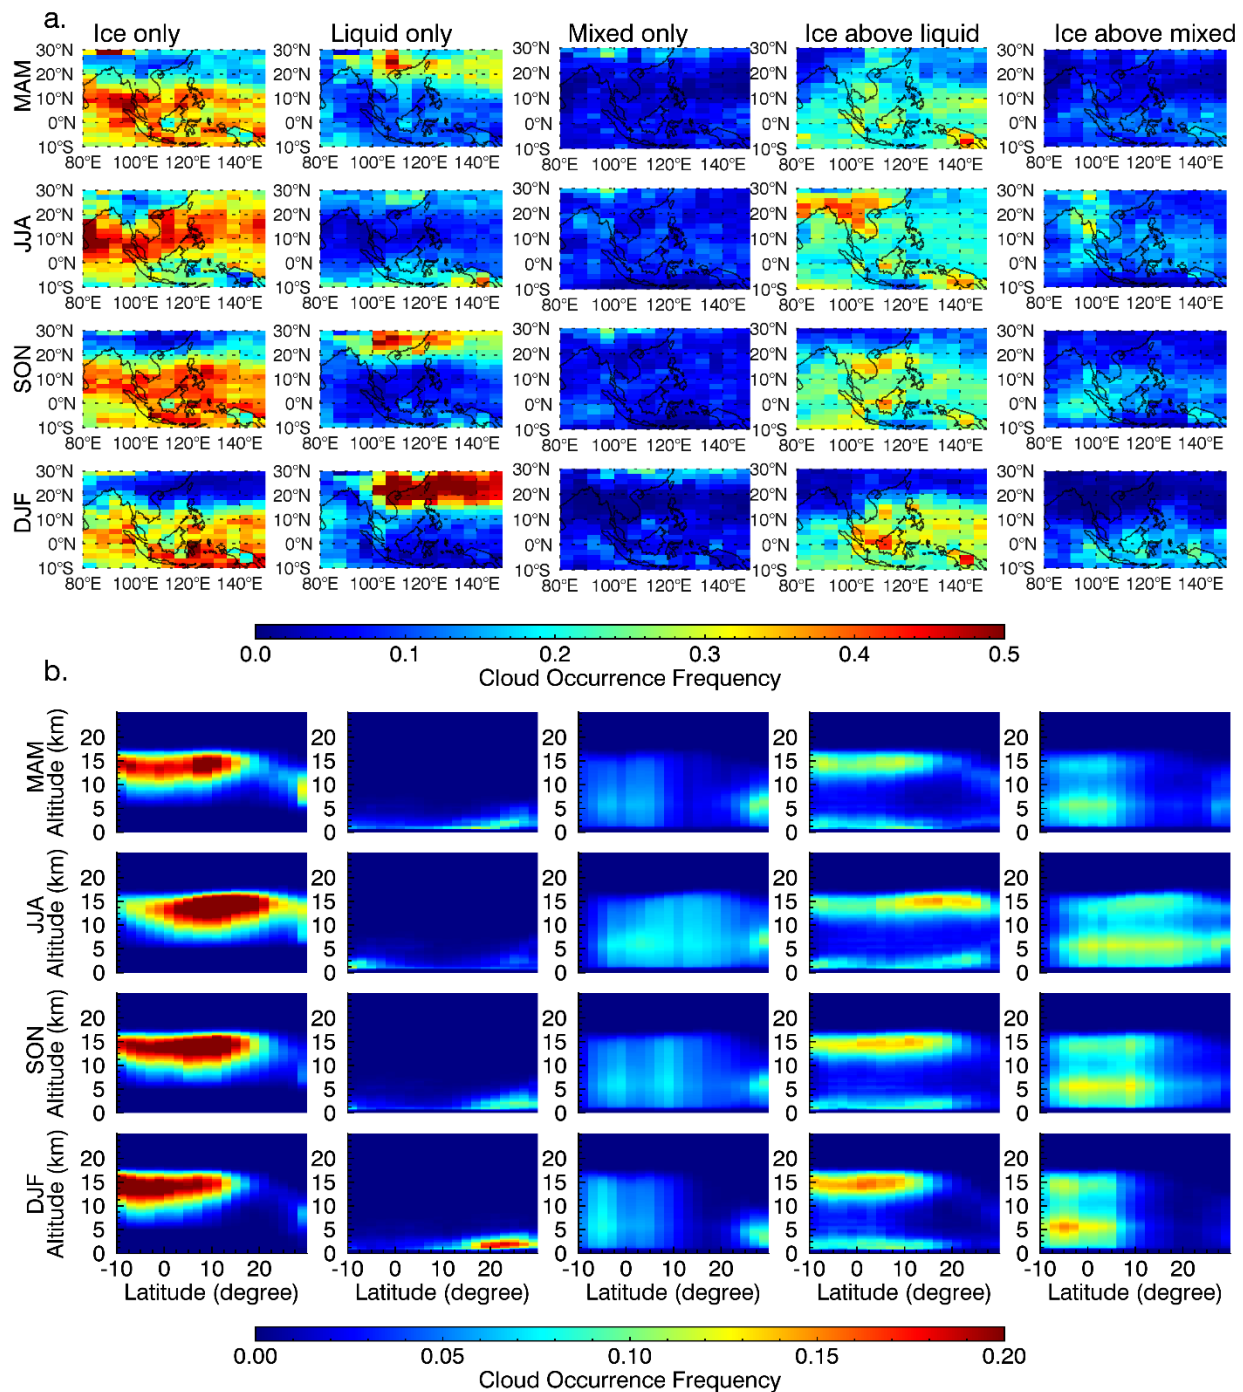

Figure 4. Occurrence frequency of the five cloud groups derived from 2B-CLDCLASS-LIDAR: a) for horizontal distribution and b) for zonal latitude-altitude cross section.

Figure 5. Mean and standard deviation of meteorological variables over ocean for the five cloud groups.

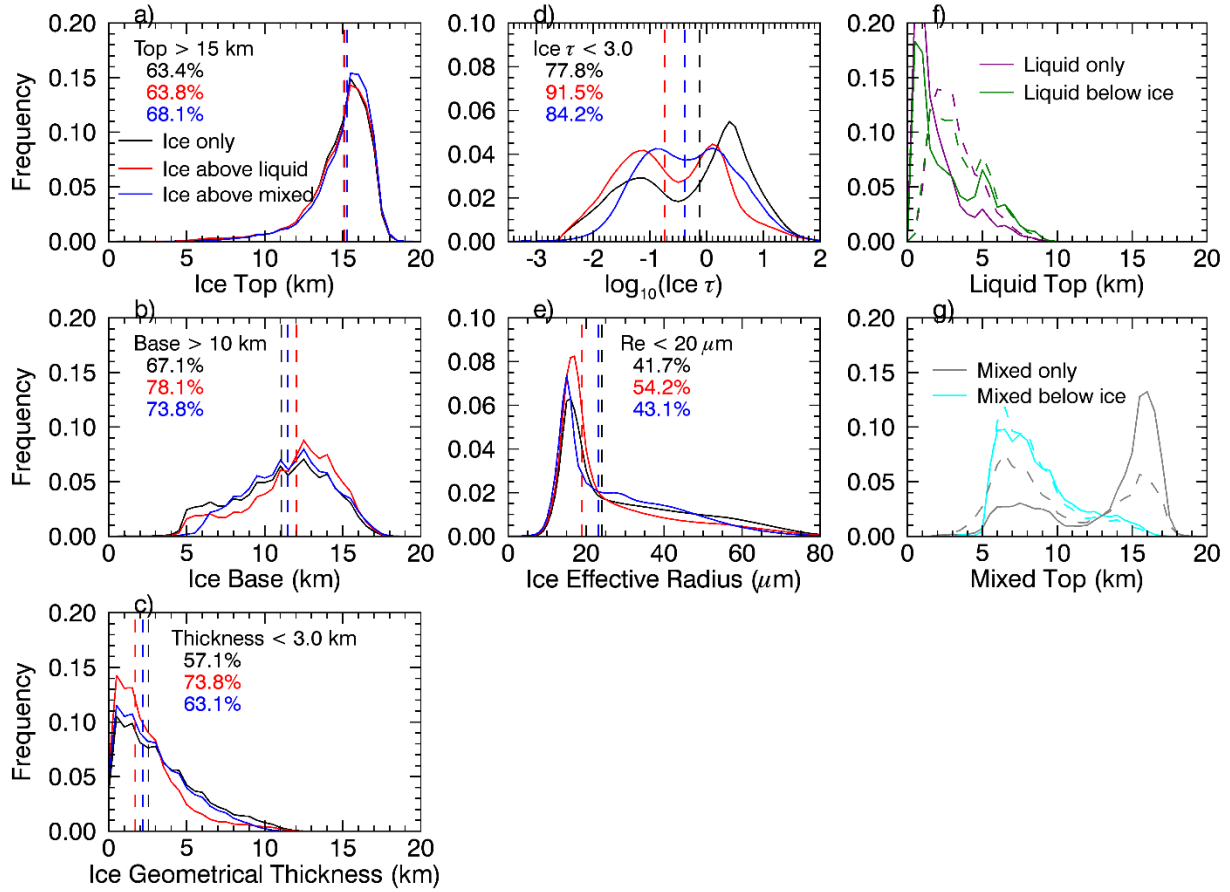

Figure 6. Annual PDFs of a) cloud top, b) base, c) geometric thickness, d) optical depth and e) effective radius for ice clouds including both ocean and land; The vertical dashed lines in a)-e) indicate the median values of the PDFs; f) cloud top for liquid-only cloud and the liquid below ice and g) cloud top for mixed-only and the mixed cloud below ice. In f) and g), solid and dashed curves are for ocean and land, respectively. Cloud top and base bins adopt an interval of 0.5 km. Ice  $\tau$  and Re bins use an interval of 0.1 in logscale and 1  $\mu\text{m}$ , respectively.

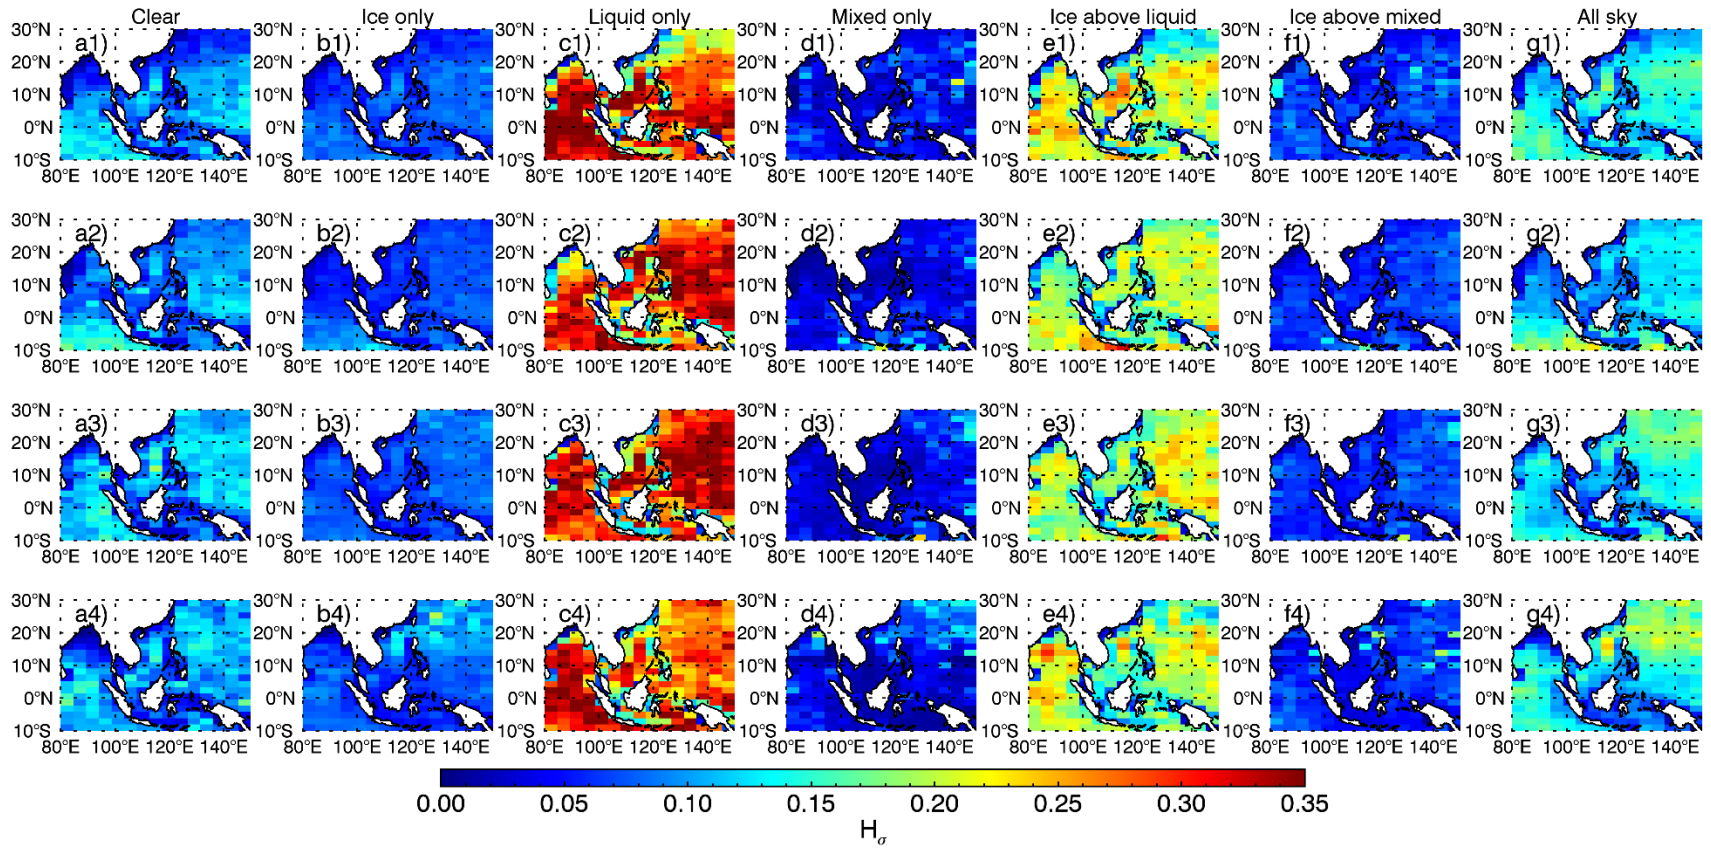

Figure 7. a) Annual PDFs of spatial heterogeneity for CC clear sky and the five cloud groups; b) same as a) but for CDF; c) liquid cloud fraction in the 5 km x5 km surrounding of the collocated CC-MODIS pixel derived from the MYD06 IR cloud phase retrievals.  $H_\sigma$  bin interval is 0.01 in log scale.

5

5 Figure 8. Spatial distributions of  $H_\sigma$  for clear sky, the five cloud groups and all sky: from top to bottom panels for MAM, JJA, SON and DJF, respectively.

5 Figure 9. Average reflectance and brightness temperatures over ocean for clear sky and the five cloud groups, including all solar zenith angles. The solid lines represent annual mean and symbols denote seasonal averages.

Figure 10. The annual PDFs and CDFs of reflectance at 0.645  $\mu\text{m}$ , reflectance ratio, BT at 11  $\mu\text{m}$  and BTD between 8.5 and 11  $\mu\text{m}$ . The intervals for reflectance, reflectance ratio, BT and BTD are 0.01, 0.01, 1 K and 0.1 K, respectively.

5

Figure 11. A statistical summary of strong MJO phases with amplitude  $> 1$  from 2007-2010.

Figure 12. Cloud phase characteristics in different MJO Phases: a)-h) spatial distributions of all-sky  $H_0$  derived from MYD06; i) PDF of all-sky  $H_0$  derived from MYD06 over the Maritime continents (the red dashed box in each panel); j) occurrence frequency of clear sky, ice, liquid and undetermined clouds from MYD06 (unit:%); k) same as j) but for clear sky and five groups derived from the 2B-CLDCLASS-LIDAR product.

Figure 13. Spatial heterogeneity anomaly in El Niño and La Niña year: from top to bottom for MAM, JJA, SON and DJF.

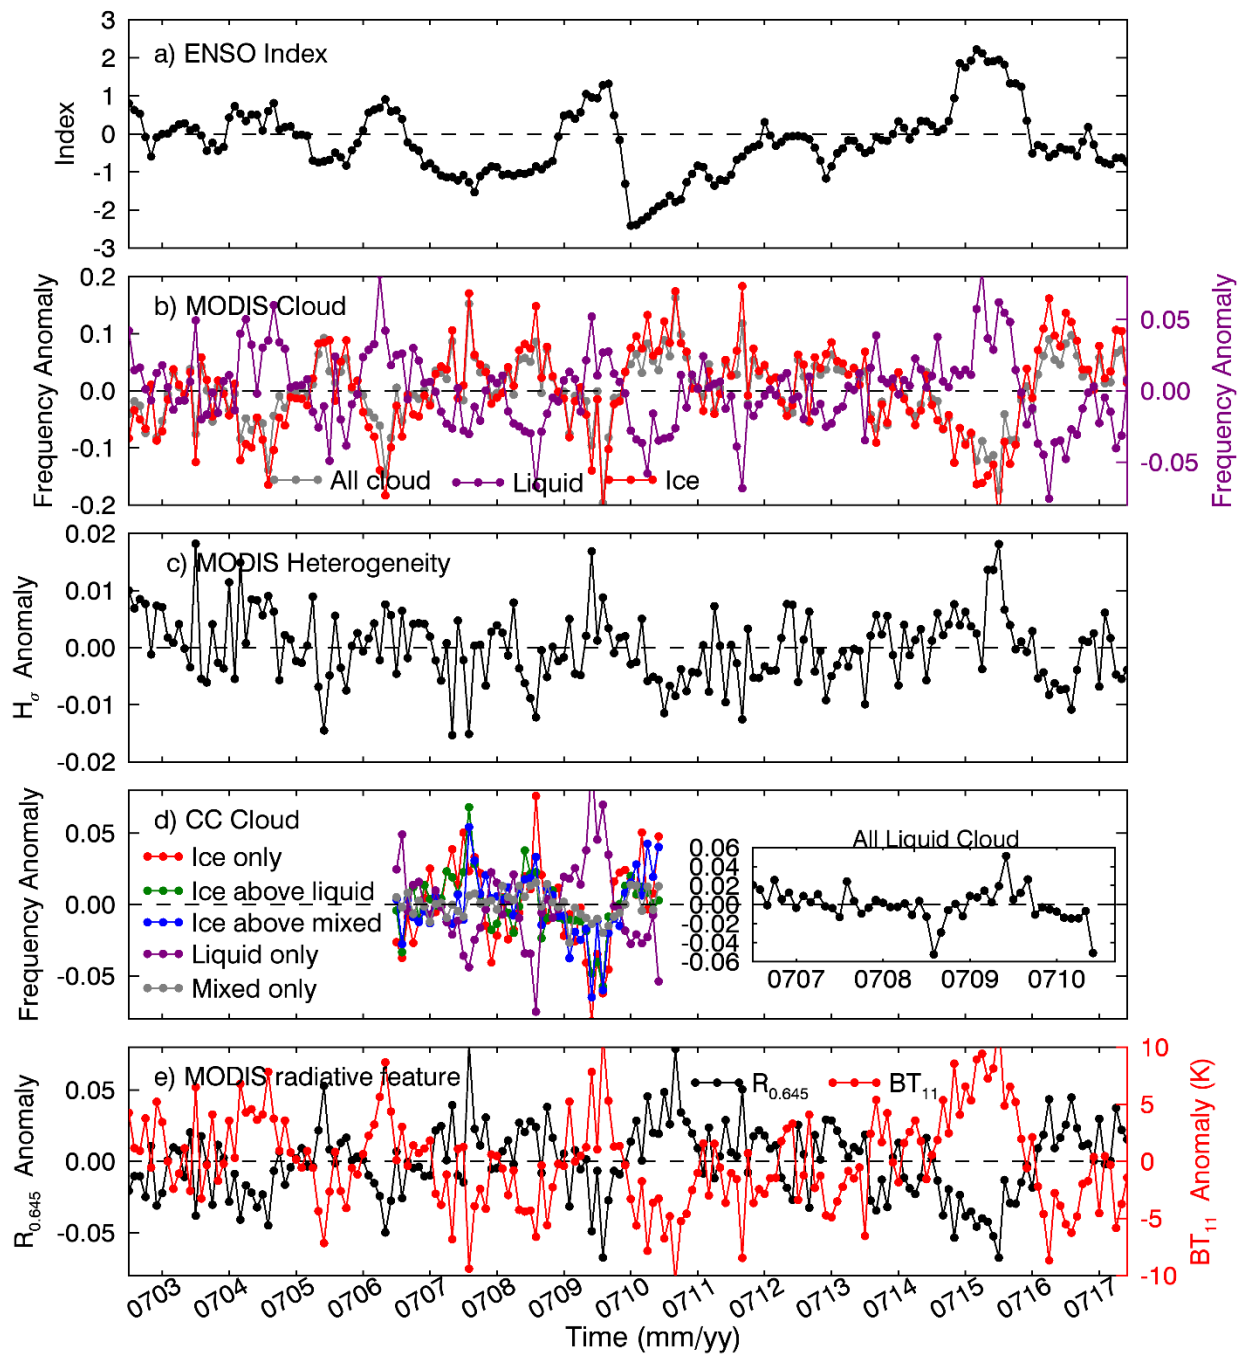

Figure 14. ENSO index and monthly anomaly of cloud, spatial heterogeneity and radiation in the region represented by the dashed-red box in Fig. 13a1.
