Abstract

During the period 2012-2015, the photolysis frequencies were measured at the Peking University site (PKUERS), a representative site of urban Beijing. We present a study of the effects of aerosols on two key photolysis frequencies, $j(O^1D)$ and $j(NO_2)$. Both $j(O^1D)$ and $j(NO_2)$ display significant dependence on AOD with a nonlinear negative correlation. With the increase in AOD, the slopes of photolysis frequencies vs AOD decrease, which indicates that the capacity of aerosols to reduce the actinic flux decreases with AOD. In addition, the slopes are equal to $4.21\text{-}6.93\blacksquare10^{-6}$ s^{-1} and $3.20\blacksquare10^{-3}$ s^{-1}per AOD unit for $j(O^1D)$ and $j(NO_2)$ respectively at SZA of 60°, both of which are larger than those observed in the Mediterranean. This indicates that the aerosols in urban Beijing have a stronger extinction on actinic flux than absorptive dust aerosols in the Mediterranean. Since the photolysis frequencies strongly depended on the AOD and the solar zenith angle (SZA), we established a parametric equation to quantitatively evaluate the effect of aerosols on photolysis frequencies in Beijing. According to the parametric equation, aerosols lead to a decrease in $j(NO_2)$ by 24.2% and 30.4% for summer and winter, respectively, and the corresponding decrease in $j(O^1D)$ by 27.3% and 32.6% respectively, compared to an aerosol-free atmosphere (AOD = 0). Based on an observation campaign in August 2012, we used the photochemical box model to simulate the ozone production rate ($P(O_3)$). The simulation results shows that the monthly average net ozone production rate is reduced by up to 25% due to the light extinction of aerosols. Through further in-depth analysis, it was found that particulate matter concentrations maintain high level under

the condition of high concentrations of ozone precursors (VOCs and NOx), which inhibits the production of ozone to a large extent. This phenomenon implies a negative feedback mechanism in the atmospheric environment of urban Beijing.

1. Introduction

Solar radiation plays an important role in atmospheric photochemistry, driving the photolysis of many key species. The photolysis of ozone (O_3), gaseous nitrous acid (HONO), and carbonyl species, which contributes to the primary production of HOx (Volkamer et al., 2010). The photolysis of ozone produces O^1D, which then reacts with H_2O to form OH radicals; these radicals are the main source of OH radicals in the troposphere, as shown by reactions R1 and R2. The strong dependence of OH concentration on $j(O^1D)$ was found in a number of field measurements (Ehhalt et al., 2000; Rohrer et al., 2014; Stone et al., 2012). In addition, the photolysis of NO_2 produces O^3P, and then O^3P reacts with O_2 to produce O_3, as shown by reactions R3 and R4, which is the only significant source of ozone in the troposphere (Finlayson-Pitts et al., 2000). The photolysis frequencies of R1 and R3 are $j(O^1D)$ and $j(NO_2)$, respectively.

$$O_3 + h\nu \ (\lambda < 330\ nm) \rightarrow O^1D + O_2 \quad \text{(R1)}$$

$$O^1D + H_2O \rightarrow 2OH \quad \text{(R2)}$$

$$NO_2 + h\nu \ (\lambda < 430\ nm) \rightarrow NO + O(^3P) \quad \text{(R3)}$$

$$O\left(^3P\right) + O_2 \rightarrow O_3 \quad \text{(R4)}$$

The photolysis frequencies are calculated by the following formula:

$$j = \int_{\lambda_1}^{\lambda_2} F(\lambda)\sigma(\lambda, S, T)\varphi(\lambda, S, T)\,\mathrm{d}\lambda \quad \text{(E1)}$$

F(λ) is the actinic flux dependent on wavelength. Since the photolysis rates are proportional to the actinic flux and not all stations acquire a 2π spectroradiometer or chemical actinometers for J measurements, several methods have been developed to determine actinic flux and photolysis frequencies from ground based measurements of irradiance (Kylling et al 2003, Kazadzis et al. 2000, 2004, Topaloglou et al. 2005, Trebs et al. 2009). σ(λ, S, T) is the absorption cross section of the species that absorbs in the wavelength range λ_1-λ_2. φ(λ, S, T) is the quantum yield of the photodissociation reaction product. λ, S and T represent wavelength, species and temperature, respectively.

The effect of aerosols on photolysis frequencies depends on the aerosol optical properties, SZA and altitude (Liao et al., 1999). The aerosol optical depth (AOD) characterizes the integral of the extinction coefficient of aerosols in the vertical direction. The light extinction of aerosols includes scattering and absorption, which have different effects on the actinic flux. Scattering aerosols can enhance the actinic flux throughout the troposphere, while absorptive aerosols reduce the actinic flux throughout the boundary layer (Jacobson, 1998; Dickerson et al., 1997; Castro et al., 2001). To distinguish between these two components, single scattering albedo (SSA) is defined as the ratio of the scattering coefficient to the total extinction coefficient. In areas with severe aerosol pollution, aerosols can significantly affect photolysis

frequencies and ozone production. Studies in Los Angeles (Jacobson, 1998), Mexico City (Castro et al., 2001; Raga et al., 2001; Li et al., 2011), São Paulo (de Miranda et al., 2005), Huston (Flynn et al., 2010), Europe (Real et al., 2011) and Russia (Pere et al., 2015) have found that aerosols reduce ozone concentration by 5-30% by attenuating photolysis frequencies. Studies in the eastern United States have shown that scattering aerosols increase ozone concentration by 5-60% by increasing the photolysis frequencies (Dickerson et al., 1997; He and Carmichael, 1999). Therefore, it is necessary to quantitatively evaluate the effect of aerosols on photolysis frequencies for the purpose of effective ozone prevention.

Currently, the methods for quantitatively evaluating the influence of aerosols on photolysis frequencies mainly include radiative transfer model and parameterization method (Madronich et al., 1993). Radiative transfer model is based on an algorithm for calculating solar radiation and photolysis frequencies (Madronich et al., 1999). The observed data of related influential factors of the photolysis frequencies are taken as the model's input and the photolysis frequencies simulated are compared with the observed value to test the simulation effect. The method comprehensively considers the influence of aerosol optical properties on the photolysis frequencies, but it does not necessarily reflect the true quantitative relationship in the atmosphere due to complicated environmental conditions and thus the simulated results don't necessarily reproduce observed values well (Lefer et al., 2003; Shetter et al., 2003; Hofzumahaus et al., 2004). For example, the simulated slope of $j(O^1D)$ vs AOD by Fast-JX algorithm within the CHIMERE model was significantly smaller than the observed

slope, particularly for the high SZA values (Mailler et al., 2016). The parameterization method is based on the observation data taken from a certain region and is used to establish the parameterized relationship between the photolysis frequencies and optical properties of aerosols (such as AOD). The method can reflect the actual atmospheric environment conditions; it also considers less influential factors and thus is easy to apply (Casasanta et al., 2011; Gerasopoulos et al., 2012). The disadvantage of this method is that the established parametric equations apply only to a specific region and cannot be extended to other regions.

With rapid economic development and urbanization in past decades, China's atmospheric pollution has become more and more severe, characterized by high concentrations of particulate matter and ozone. Satellite observations indicates that both the particulate matter and the ozone of eastern China are at higher levels compared with other locations in the globe (Verstraeten et al., 2015; Ma et al., 2014). Levels of pollution in the Beijing–Tianjin–Hebei are even more severe (Chang et al., 2009; Che et al., 2008; Zhang et al., 2014, Zhang et al., 2016). Therefore, it is necessary to study the effects of aerosols on photolysis frequencies and ozone production in the urban areas of China.

Previous model studies have shown that aerosols in China can affect ozone production by changing the photolysis frequencies. Tang et al. (2004) used a sulfur transmission–emission model (STEM) to discover that ozone concentration in northeastern China was reduced by 0.1–0.8% in the sandstorm due to the change in photolysis frequencies. Tie et al. (2005) used a global aerosol–chemical model to

show that aerosols caused $j(O^1D)$ and $j(NO_2)$ to decrease in winter by 20%-30% and 10%-30%, respectively, and in summer by 5%-20% and 1%-10%, respectively, resulting in 2%-5% and 2% reductions in ozone concentration in winter and summer, respectively. Li et al. (2011) used an air quality model to estimate the changes in the photolysis rate caused by sulfate, nitrate, ammonium, and mineral dust aerosols in the central and eastern regions of China from June 1 to June 12, 2006. This study showed that the daily average $j(O^1D)$ in the troposphere at the altitude of 1 km, 3 km, and 10 km from the ground was reduced by 53.3%, 37.2%, and 20.9%, respectively, resulting in a decrease in the ozone concentration by 5.4%, 3.8%, and 0.1% in the three layers. Lou et al (2014) found that with aerosols, annual mean photolysis rates, $j(O^1D)$) and $j(NO_2)$, were simulated to be reduced by 6-18% in polluted eastern China, leading to reductions in O_3 of up to 0.5 ppbv in those regions in spring and summer by using the global chemical transport model (GEOS-Chem). However, all of these studies base their results on model simulations. Research using long-term observational data to evaluate the effects of aerosols on photolysis frequencies and ozone production in China has not yet been published.

Our overall goal is to quantitatively evaluate the effect of aerosols in urban Beijing on photolysis frequencies and thus on ozone production. First, the relationship between $PM_{2.5}$ and AOD was investigated. Second, based on long-term observations (2012-2015) of photolysis frequencies, we discussed the impact of AOD on photolysis frequencies ($j(O^1D)$ and $j(NO_2)$) in urban Beijing in detail. Then, the quantitative relationship between photolysis frequencies, AOD, and SZA was acquired by the

parameterization method, which could be used to quantitatively evaluate the effect of AOD on photolysis frequencies in Beijing. Finally, a photochemistry box model was used to evaluate the effect of aerosols on ozone production.

2. Methodology

2.1. Measurement

From 2012 to 2015, $j(O^1D)$ and $j(NO_2)$ were measured continuously at PKUERS site. The site (39.99°N, 116.31°E) is located on the sixth floor of a campus building at the Peking University, 20 km northwest of Tiananmen Square. The height from the ground is about 30 m. The sampling point is surrounded by classroom buildings. Concentration level and composition of air pollutants were thought to be similar to the downtown so as to be representative for the whole of Beijing (Wang et al., 2010; Xu et al., 2011; Zhang et al., 2012; Zhang et al., 2014).

The actinic flux was measured using a spectroradiometer and the photolysis frequencies were calculated from the absorption cross section and quantum yield of each species (Shetter and Muller, 1999). The spectroradiometer consisted of a single monochromator with a fixed grating (CARL ZEISS), an entrance optic with a 2π steradian (sr) solid angle quartz diffusor and a flexible optical quartz fiber bundle connecting both components. The spectral measurements were performed with a wavelength resolution of 2 nm, covering a wavelength range of 290-650 nm (Hofzumahaus et al., 1999). The measured spectra were corrected for dark signal and

stray light. Descriptions of the calibration procedure and calculation of photolysis frequencies are given in Bohn et al.(2008). The calculated photolysis frequencies had a time resolution of 10 s and an uncertainty of ±10%.

The optical properties of aerosols were measured by a CIMEL solar photometer (AERONET level 2 data collection, http://aeronet.gsfc.nasa.gov/) and the site selected was the Beijing-CAMS site (39.933°N, 116.317°E), which is close to the PKUERS site. The CIMEL solar photometer is an automatic solar-sky scanning radiometer that uses selected spectral channels. The instrumentation, data acquisition, retrieval algorithms, and calibration procedure conform to the standards of the AERONET global network and have been described in detail by Fotiadi et al. (2006). The solar extinction measurement was performed every 3 minutes in the spectral range 340–1020 nm for the calculation of AOD at wavelengths 340, 380, 440, 500, 675, 870, 970, and 1020 nm. Under cloudless conditions, the overall uncertainty of AOD data is ± 1% at $\lambda > 440$ nm and ± 0.02 at shorter wavelengths. In this study, AOD at the wavelength of 380 nm was chosen for analysis. This wavelength was selected as it is more representative of $j(NO_2)$. The SSA data were derived from a field campaign undertaken in August 2012. The absorption and scattering coefficients were measured with an Aethalometer (AE-31, Magee) and a Single Wavelength Integrating Nephelometer (Aurora-1000), respectively, with a time resolution of 1 minute. Five-minute averages of ozone column concentration, SSA, and photolysis frequencies were analyzed in this study. The total ozone column was obtained by OMI (Ozone Monitoring Instrument) for the year 2012-2015, using overpass data.

The analysis of the effects of aerosols on ozone production (Section 3.4) was based on the field campaign undertaken in August 2012. The relevant contents and methods of observation are shown in Table 1. In addition, meteorological parameters such as temperature, humidity, and pressure were simultaneously observed at the site. Since the time resolution of VOCs is 1 hour, all data analyzed in Section 3.4 was processed as 1-hour average values. In this study, we focused on the effects of aerosols on photolysis frequencies and ozone production under cloudless conditions.

2.2 Radiative Transfer Model Description

We use the Tropospheric Ultraviolet and Visible (TUV) radiation model (version 5.3) provided by Sasha Madronich (Madronich, 1993). In order to solve the radiative transfer equation, TUV uses the discrete-ordinates algorithm (DISORT) with 4 streams and calculates actinic flux spectra with wavelength range of 280-420 nm in 1 nm steps and resolution. Measured temperatures were used to calculate the absorption cross sections and quantum yields. The key aerosol optical properties including AOD, SSA and AE are input into the model to test the effect of aerosols on photolysis frequencies. AE(380/550nm) is taken from AERONET and the mean value of 1.3 during June 2012 - December 2015 is used in TUV model.

2.3 Photochemical box model

The photochemical box model used in this study is based on a regional atmospheric chemical mechanism (RACM2) described by Goliff et al. (2013). The

mechanism includes 17 stable inorganic compounds, 4 intermediate inorganic compounds, 55 stable organic compounds, and 43 intermediate organic compounds. Compounds not specifically treated in RACM are incorporated into species with similar functional groups. The isoprene-related mechanism used in this model is LIM mechanism proposed by Peeters et al. (2009). In this study, the observed NO_2, CO, SO_2, C2–C12 NMHCs, HCHO, photolysis frequencies, temperature, pressure, and relative humidity were used as constraints to simulate the concentrations of reactive radicals (RO_2, HO_2, and OH), intermediate species, and associated reaction rate constants. HONO wasn't measured during the period and was calculated according to the concentration of NO_2 and the observed ratio of HONO to NO_2 at an urban site in Beijing, which had a marked diurnal cycle, a maximum in the early morning (ratio values up to ~0.05–0.08 in summer) and a decrease during daytime to values around 0.01–0.02 (Hendrick et al., 2014). The model was spun up for two days once it started running in order to ensure that the simulation was stable. It was assumed that the lifetime of simulated species removed by dry deposit was 24 hours. The lifetime corresponds to the assumed deposit rate of 1.2 cm s^{-1} and a well-mixed boundary layer height of about 1 km (Lu et al., 2012). Net ozone production is equal to the reaction rate between peroxy radicals (RO_2 and HO_2) and NO minus the loss rate of NO_2 and O_3 as shown in E2, E3, and E4. The ozone production rate ($P(O_3)$), the ozone loss rate ($D(O_3)$), and the net $P(O_3)$ were calculated from the simulation results.

$$P(O_3) = k_{HO2+NO}[HO_2][NO] + \sum\left(k^i{}_{RO2+NO}\left[RO^i{}_2\right][NO]\right) \quad \text{(E2)}$$

$$D(O_3) = (\theta j(O^1D) + k_{OH+O3}[OH] + k_{HO2+O3}[HO_2] + \sum(k^j{}_{alkene+O3}[alkene^j]))[O_3] + k_{OH+NO2}[OH][NO_2] \quad \text{(E3)}$$

$$net\ P(O_3) = P(O_3) - D(O_3) \quad \text{(E4)}$$

3. Results and discussion

3.1 The correlation between $PM_{2.5}$ and AOD

In order to evaluate the extinction capacity of near-surface $PM_{2.5}$, we investigated the relationship between $PM_{2.5}$ and AOD (at 380nm). The factors that affect this relationship include aerosol type, aerosol size distribution, aerosol distribution in the vertical direction, relative humidity (RH) and planetary boundary layer height (PBLH) (van Donkelaar et al., 2010). Figure 1 shows the correlation between AOD and $PM_{2.5}$ in four different seasons. The determination coefficient (r^2) is 0.53, 0.58, 0.62 and 0.59 for spring (March, April and May), summer (June, July and August), autumn (September, October and November) and winter (December, January and February), respectively. Meanwhile, the correlation exhibits significant seasonal differences, having relatively smaller slope (23.56) in summer and relatively larger slope (73.76) in winter. This implies that the aerosols in summer have stronger extinction capacity than in winter. One reason for the seasonal differences is the

variation in RH among different seasons (Table 2). There is higher RH in summer (57.2% on average) than in winter (30.4% on average), leading to stronger hygroscopic growth of aerosol particles, and thus resulting in higher scattering ability of aerosol particles. According to another study in urban Beijing, the higher the RH, the smaller the slope, and the higher the PBLH, the smaller the slope (Zheng, C. W et al., 2017). In addition, the slope was smaller for scattering-dominant aerosols than for absorbing-dominant aerosols, and smaller for coarse mode aerosols than for fine mode aerosols (Zheng, C. W et al., 2017). The slopes of the correlation between AOD (at 550nm) and $PM_{2.5}$ in this study in summer and winter are equal to 42.2μg m^{-3} and 119.2μg m^{-3}, respectively, close to that from Ma et al. (2016) (54.9μg m^{-3} and 110.5μg m^{-3}) and Xin et al. (2016) (55.2 μg m^{-3} and 93.4μg m^{-3}), but smaller significantly than that from Zheng et al. (2017) (65~74μg m^{-3} and 143~158μg m^{-3}). The differences mainly depend on the aerosol composition and size distribution at different observational sites in Beijing. Compared with other cities in North China (Tianjin, Shijiazhuang and Baoding) (Ma et al., 2016), the slope in Beijing for winter is significantly higher, indicating that the extinction capacity of aerosols in Beijing is weaker in winter.

3.2 Seasonal and diurnal variability of AOD and photolysis frequencies

The diurnal cycles of AOD is shown in Figure 2. AOD displays obvious diurnal variation, with relatively high level at noon and low level at dawn and evening. The

diurnal variation of $PM_{2.5}$ is opposite to AOD. The opposite diurnal variation of AOD and $PM_{2.5}$ is mainly due to higher development of planetary boundary layer at noon, resulting in more complete mixture of particulate matter in the vertical direction. In addition, AOD has obvious seasonal differences, with the highest AOD in summer and the lowest AOD in winter. Conversely, $PM_{2.5}$ in winter (66.9μg m^{-3}) is significantly higher than in summer (45.5μg m^{-3}). In spite of lower $PM_{2.5}$ in summer, AOD in summer is higher due to stronger extinction capacity of $PM_{2.5}$ as discussed in 3.1. Figure 3 shows the diurnal variation of the photolysis frequencies under cloudless conditions for each season. $j(O^1D)$ and $j(NO_2)$ are both highest in summer, followed by spring and autumn, and lowest in winter. This seasonal difference is mainly determined by the difference in SZA for the four seasons.

The observed photolysis frequencies at this site are lower than that observed in the eastern Mediterranean (Crete, Greece, 35°20′N,25°40′E) (Gerasopoulos et al., 2012) by 7.8×10^{-6} s^{-1} and 4.9×10^{-6} s^{-1} for $j(O^1D)$, and 1.9×10^{-3} s^{-1} and 3.3×10^{-3} s^{-1} for $j(NO_2)$, in summer and winter respectively. The corresponding lower photolysis frequencies of Beijing than the eastern Mediterranean due to SZA difference is 1.7×10^{-6} s^{-1} and 3.0×10^{-6} s^{-1} for $j(O^1D)$, and 8.0×10^{-5} s^{-1} and 6.6×10^{-4} s^{-1} for $j(NO_2)$ according to TUV model, which are significantly lower than observed decreased magnitudes. Taking into account the similar levels of ozone column concentration in the two sites, the large gap of photolysis frequencies in the two sites is mainly attributed to the higher AOD in Beijing (0.76±0.75) than in the eastern Mediterranean (0.27±0.13).

It can be seen from Figure 3 that the difference between winter and summer for $j(O^1D)$ is significantly larger than that for $j(NO_2)$, where the summer midday averages of $j(O^1D)$ and $j(NO_2)$ are 5 times and 2 times those of winter, respectively. There are two reasons for this phenomenon. One, compared with $j(NO_2)$, $j(O^1D)$ is more sensitive to the change in SZA and the same change in SZA results in a larger change in $j(O^1D)$ than $j(NO_2)$. Two, the main influential factors of $j(NO_2)$ under cloudless conditions are SZA and AOD, and the influence of ozone column concentration and temperature on $j(NO_2)$ is negligible. However, $j(O^1D)$ is affected significantly by the ozone column concentration and temperature, in addition to SZA and AOD. The higher ozone column concentration and lower temperature in winter than in summer lead to the difference in $j(O^1D)$ further increasing (Table 2).

3.3 The correlation between photolysis frequencies and AOD

3.3.1 The correlation between $j(O^1D)$ and AOD

In order to rule out the effect of SZA on photolysis frequencies, we chose SZA equal to 30° and 60° (± 1°) for analysis. Figure 4 presents the dependence of $j(O^1D)$ on AOD at different levels of ozone column concentration at SZA of 30° and 60° (± 1°). The ozone column concentration has a classification width of 30 DU. This relatively large classification width is chosen to make sure that there is enough points to fit the relationship between $j(O^1D)$ and AOD. $j(O^1D)$ exhibits a clear dependence

on AOD, with a nonlinear negative correlation. The scatter of these points is mainly due to variations in ozone column and temperature. As AOD increased, the slope of $j(O^1D)$-AOD gradually decreases, indicating that the ability of aerosols to reduce $j(O^1D)$ gradually decreases with AOD. This result differs from that found in Mediterranean, where $j(O^1D)$ was linearly negatively correlated with AOD (Casasanta et al., 2011; Gerasopoulos., 2012). A larger variation range of AOD in Beijing (0-3) compared with Mediterranean (0-0.6) is one reason for the difference.

For further analysis, the observed relation between $j(O^1D)$ and AOD was compared with TUV-simulated results. Panels a and b of Figure 5 present the comparison between observed and TUV-simulated $j(O^1D)$ against AOD at a SZA of 30° and 60° respectively and ozone column concentration of 330-360 DU. At low AOD level (< 0.8), the observed slope of $j(O^1D)$ vs AOD is significantly larger than the simulated slope at SSA of 0.95, and slightly larger than the simulated slope at SSA of 0.85. With AOD increasing, the observed slope decreases rapidly to the level smaller than the simulated slopes. The rapid change of the slope with AOD can be related to the variation of SSA at different AOD level. Figure 6 presents the relationship between SSA and AOD based on observed data in August 2012. The result suggests a significant correlation between SSA and AOD. With the increase in AOD, SSA is elevated; meanwhile, the slope of SSA vs AOD is gradually reduced. Similar results have been obtained by Bais et al., 2005, Krotkov et al., 2005 and Kazadzis et al., 2012. SSA characterizes the ratio of the scattering extinction coefficient to the total extinction coefficient (scattering extinction coefficient plus

absorptive extinction coefficient) of aerosols. The smaller the SSA, the higher the absorptive component and lower the scattering component of the aerosol, and the stronger the ability of the aerosol to reduce the actinic flux (Dickerson et al., 1997). Figure 6 indicates that aerosols in Beijing under low AOD conditions had a higher proportion of absorptive aerosol components than under high AOD conditions, and, as a result, had a stronger ability to reduce the photolysis frequencies, which contributed to the rapidly reduced slope of $j(O^1D)$ vs AOD with AOD. However, due to absence of more SSA data of the period 2012-2015, we can't give more sufficient evidence for the dependence of SSA on AOD. For another perspective, Owing to the biomass burning and soot emission generated from heating, the fine mode heavily-absorbing aerosol percentage is higher in winter than in summer (Zheng et al., 2017; Liu et al., 2016; Zhang et al., 2013), and thus aerosols in winter have stronger ability to reduce the photolysis frequencies. High AOD levels often appeared in summer and low AOD levels occurred mostly in winter (Figure 2), another fact that may also explains the rapidly reduced slope of $j(O^1D)$ vs AOD with AOD.

Comparing panels a and b of Figure 4, we see that at AOD smaller than 1, the slope of $j(O^1D)$ vs AOD exhibits a significant dependence on SZA and the slope at 30° of SZA is about 1.5-2.0 times larger than that at 60° of SZA. This result is similar to that of the observations made in the central Mediterranean (Casasanta et al., 2011). For the purpose of comparison with the study in the Mediterranean, the slope of $j(O^1D)$ vs AOD was calculated at AOD smaller than 0.7.

Table 3 presents slope, intercept and the determination coefficient (r^2) of linear fits of correlation between $j(O^1D)$ and AOD for each ozone column class at AOD smaller than 0.7. At SZA of 60° and O_3 column concentration of 300-330 DU, the respective slope of the linear regression indicates a reduction of $j(O^1D)$ by $4.21 \cdot 10^{-6}$ s^{-1} per AOD unit. Gerasopoulos et al. (2012) reported that the observed slope in the eastern Mediterranean was equal to $2.44 \cdot 10^{-6}$ s^{-1} at O_3 column of 300-320 DU. Casasanta et al. (2011) reported that the observed slope in the central Mediterranean varied from $2.66 \cdot 10^{-6}$ s^{-1} to $3.87 \cdot 10^{-6}$ at O_3 column of 300-330 DU. All of these results are smaller than the value of the present study, indicating that aerosols in urban Beijing had a stronger extinction capacity on $j(O^1D)$ than those in the Mediterranean that was influenced by both natural absorptive aerosols and anthropogenic aerosols. Previous study indicated that SSA in Beijing ranged from 0.80 to 0.86 (Garland et al., 2009;Han et al., 2015b; Han et al., 2017; Tian et al., 2015). The relatively low SSA in Beijing could be an important reason for the stronger extinction capacity.

3.3.2 The correlation between $j(NO_2)$ and AOD

Unlike $j(O^1D)$, $j(NO_2)$ is negligibly affected by ozone column concentration and depends mainly on AOD and SZA under cloudless conditions. Figure 7 presents the dependence of $j(NO_2)$ on AOD at different SZA levels under cloudless conditions. The cosine of SZA (cos (SZA)) is categorized according to a width of 0.2. In the same

category of cos (SZA), $j(NO_2)$ displays a strong dependence on AOD. The scatter of these points is due to the relatively large classification width of SZA to a large extent. When cos(SZA) is at its maximum level (0.8–1), the correlation between $j(NO_2)$ and AOD is close to linear. When cos(SZA) decreases, the correlation tends to be nonlinear. Similar to $j(O^1D)$, the observed slopes of $j(NO_2)$ vs AOD are also larger than TUV-simulated slope at SSA of 0.95 and 0.85 when AOD is smaller than 0.8, and decreased rapidly with increasing AOD (panels c and d of Figure 5). The reason for this result is the same with that for $j(O^1D)$ as explained above.

Table 4 presents the slope, intercept and the determination coefficient (r^2) of linear fits of correlation between $j(NO_2)$ and AOD for each ozone column class at AOD smaller than 0.7. The slope of $j(NO_2)$ vs AOD also displays a significant dependence on cos(SZA). The slope increases as cos(SZA) increases from 0 to 0.5 and then decreases as cos(SZA) increases from 0.5 to 1. At SZA of 60°±1 (cos (SZA)=0.5±0.015), the respective slope of the linear regression indicates a reduction of $j(NO_2)$ by $3.2 \cdot 10^{-3}$ s^{-1} per AOD unit. This result is larger than the value for non-dust aerosols ($2.2 \cdot 10^{-3}$ s^{-1}) and close to the value for dust aerosols ($3.1 \cdot 10^{-3}$ s^{-1}) in the eastern Mediterranean reported by Gerasopoulos et al. (2012).

3.4 The parameterization relationship between photolysis frequencies, AOD, and SZA

As analyzed above, the photolysis frequencies ($j(O^1D)$ and $j(NO_2)$) strongly depended on AOD and cos(SZA) and could be fit into expression E5 using a quadratic polynomial form. Table 5 and Table 6 presents the fitting parametric equations and the corresponding coefficients of determination (R^2) at different O_3 column ranges. The coefficients of determination of the fitting equations are greater than 0.95 for $j(NO_2)$ and $j(O^1D)$, indicating that both of the photolysis frequencies strongly depended on AOD and cos(SZA) at a certain O_3 column, and the effect of other factors such as SSA and AE are integrated into the constant term in the parametric equation. Since the ozone column concentration has greater influence on $j(O^1D)$ than on $j(NO_2)$, the parameters of fitting equations for $j(NO_2)$ are similar, but the parameters of fitting equations for $j(O^1D)$ have a large fluctuation at different O_3 column ranges (especially a_1 and a_2). The parametric equations can be used to quantitatively evaluate the effect of AOD on photolysis frequencies in Beijing. According to the parametric equations, aerosols lead to a decrease in $j(NO_2)$ by 24.2% and 30.4% and a decrease in $j(O^1D)$ by 27.3% and 32.6% in summer and winter, respectively, compared to an aerosol-free atmosphere. The decreasing ratio of the photolysis frequencies in winter is higher than in summer due to the higher SZA and lower SSA in winter.

The effect of aerosols on photolysis frequencies in Beijing is compared with other studies. Real and Sartelet (2011) reported a reduction in $j(NO_2)$ and $j(O^1D)$ of 13%-14% due to aerosols by using the radiative transfer code Fast-J during summer 2001 over European regions. Flynn et al (2010) reported that aerosols reduced $j(NO_2)$ by 3% in Huston during 2006 by using TUV model. Gerasopoulos et al (2012)

reported that aerosols reduced j(NO_2) and j(O^1D) by 5%-15% with 5-yr mean AOD at 380nm equal to 0.27. All of these results are lower than the reduction ratio of this study mainly due to higher aerosol level in Beijing (4-yr mean AOD equal to 0.76± 0.75). Hodzic et al. (2007) simulated a 15–30% j(NO_2) photolysis reduction during the 2003 European summer heatwave in the case of absorbing biomass burning aerosols with AOD at 550 nm equal to 0.7-0.8 and SSA at 532 nm equal to 0.83-0.87. The result of Hodzic et al. (2007) is comparable with the reduction ratio of this study possibly due to the equivalent levels of AOD and SSA. In addition, Péré et al (2015) simulated a higher reduction (20–50%) in j(NO_2) and j(O^1D) along the transport of the aerosol plume during the 2010 Russian summer wildfires episode. The higher reduction is due to the higher level of AOD (peak value of AOD at 400nm reached 2-4), even though SSA is very high (0.97).

$$j = a_1 + a_2 AOD + a_3 cos(SZA) + a_4 (AOD)^2 + a_5 AOD cos(SZA) + a_6 (cos(SZA))^2 \quad \text{...E5}$$

The above established parametric relationship of $PM_{2.5}$-AOD and j(NO_2)-AOD-SZA gives us a chance to estimate the effect of $PM_{2.5}$ on photolysis frequencies due to aerosol light extinction.

3.5 The influence of AOD on ozone production

In order to explain the effect of aerosol light extinction on ozone production, we used the data from the field observation campaign undertaken in August 2012. Ozone

production depends on its precursors (NOx and VOCs), meteorological factors, and solar radiation. Solar radiation is the driving force for tropospheric photochemical reactions, in which $j(O^1D)$ and $j(NO_2)$ are both important for ozone production. On the one hand, the increase in $j(NO_2)$ promotes the photolysis of NO_2, thereby accelerating the formation of ozone. On the other hand, the increase in $j(O^1D)$ accelerates the photolysis of ozone. In addition, the increase in the photolysis frequencies will accelerate the photolysis of OVOC (especially formaldehyde and acetaldehyde), HONO, and H_2O_2, resulting in increases in OH and HO_2, which will promote the reaction between OH and VOCs and thus produce more RO_2. As a result, more ozone is produced by increasing the reaction rate between RO_2 (or HO_2) and NO. However, the increase in OH and HO_2 also consumes ozone and NO_2, which contributes to the increase in $D(O_3)$. In brief, the overall effect of changes in photolysis frequencies on sources and sinks of ozone determines the change in the net ozone production rate.

Ozone production (HO_2 + NO, RO_2 + NO), ozone loss ($O^1D + H_2O$, $HO_2 + O_3$, O_3 + OH, NO_2 + OH, and O_3 + alkenes), and net ozone production rate during August 2012 were calculated by using the box model. We used the observed photolysis frequencies (i.e. j_obs) and the calculated photolysis frequencies by parametric equation under the condition of AOD equal to 0 (i.e. j_AOD=0), were used to constrain the box model. The difference of simulated results in the two scenarios can be attributed to the effect of aerosol light extinction. As a result, the presence of aerosols causes a decrease in both ozone production rate and loss rate, as is shown in

Figure 8. Since the decreasing amplitude of the ozone production rate is far larger than that of the ozone loss rate, the net production rate of ozone is reduced by 25%. This reduction is comparable with the results of the study in Mexico City, where aerosols caused a 20% reduction in the ozone concentrations (Castro et al., 2001). Studies in Houston and Crete have shown that aerosols cause ozone production rates to decrease by about 4% and 12%, respectively, which are lower than that found in this study (Flynn et al., 2010; Gerasopoulos et al., 2012).

The ratio of the observed photolysis frequencies to the photolysis frequencies at AOD equal to 0 is defined as JIF (Flynn et al., 2010). A JIF of less than 1 indicates that the aerosols cause a decrease in the photolysis frequencies. Figure 9 shows the relation between $P(O_3)_{j\_obs}/P(O_3)_{j\_AOD=0}$ (or $D(O_3)_{j\_obs}/D(O_3)_{j\_AOD=0}$) and JIF. The majority of JIF values were less than 1, with an average of 0.72, indicating that aerosols greatly attenuated photolysis frequencies due to high levels of AOD (average of 1.07) and low levels of SSA (average of 0.84) during the observation period. $P(O_3)_{j\_obs}/P(O_3)_{j\_AOD=0}$ and $D(O_3)_{j\_obs}/D(O_3)_{j\_AOD=0}$ are both linearly positively correlated with JIF and the scatters are mostly above the 1:1 line. As can be seen from the figure 9, a 30% reduction in photolysis frequencies (JIF = 0.7) due to the presence of aerosols results in a decrease in ozone production rate and loss rate by about 26% and 15%, respectively. The decreasing amplitude in the ozone production rate is greater than the decrease in the ozone loss rate because the corresponding processes of ozone production are all light-driven, but the corresponding processes of ozone loss are not all light-driven because the reaction of O_3 with alkenes does not depend on

497 solar radiation. According to the simulated results, the reaction of ozone with alkenes
498 during this campaign accounts for 17% of total ozone loss.

499 The diurnal profile of the mean ozone production and loss rate is shown in
500 Figure 10. $P(O_3)$ peak midday in the 12:00-14:00 local hours at 31 ppb/h without
501 aerosol impact and 23 ppb/h with aerosol impact. The maximum $D(O_3)$ also occurrs
502 between 12:00 and 14:00 at 4.2 ppb/h without aerosol impact and 3.5 ppb/h with
503 aerosol impact. There is little difference between aerosol-impact and aerosol-free
504 $P(O_3)$ (or $D(O_3)$) in the hours of 6:00-11:00, but the difference in the afternoon
505 (12:00-18:00) is large, indicating that the reduction effect of aerosol on ozone
506 production mainly occurs during the afternoon.

507 The above analysis focuses on the effect of aerosol on the ozone production due
508 to aerosol light extinction. However, it does not consider the close relationship
509 between aerosol and ozone's gaseous precursors in the actual atmosphere. To explain
510 this problem, we chose two adjacent days (small SZA effect) with obviously different
511 AOD levels: a clean day (A day: August 21, 2012; AOD = 0.21, $PM_{2.5}$=21.6 $\mu g\ m^{-3}$)
512 and a day with high aerosol pollution (B day; August 26, 2012; AOD = 3.2,
513 $PM_{2.5}$=125.0 $\mu g\ m^{-3}$) (Table 7). The difference in AOD between the two days can be
514 taken to represent the maximum daytime gap of AOD for this month. The ozone
515 column concentrations for these two days were 302 DU and 301 DU, respectively, of
516 which the effect on $j(O^1D)$ is negligible. Under these conditions, the $j(O^1D)$ value at
517 noon time decreases from $3.23 \times 10^5\ s^{-1}$ on A day to $1.29 \times 10^5\ s^{-1}$ on B day (i.e., a 60%
518 reduction) and the $j(NO_2)$ value at noon time decreases from $8.26 \times 10^{-3}\ s^{-1}$ on A day

519 to 4.19 × $10^{-3}s^{-1}$ on B day (i.e., a 49.2% reduction). As shown in Table 7, B day has
520 higher AOD and higher concentrations of gaseous pollutants. The concentrations of
521 CO, NO_2, HCHO and the OH reactivity of VOCs in B day are much higher than in A
522 day, with the ratio of 3.6, 2.3, and 2.0, respectively. The simultaneous increases of
523 gaseous pollutants and AOD are due to the fact that gaseous pollutants (NOx, SO_2,
524 and VOCs) emitted by major pollution sources in Beijing, including traffic and
525 industry, have undergone the processes of gas-phase oxidation and nucleation to
526 generate secondary particulate matter that contributes to aerosol light extinction.
527 Previous studies have reported that secondary particulate matter has accounted for
528 more than 60% of total particulate matter during severe smog pollution in Beijing
529 summers (Han et al., 2015a; Guo et al., 2014). In addition, several studies have shown
530 that secondary components in particulate matter (especially secondary organics and
531 ammonium sulfate) have dominated the aerosol light extinction (Han et al., 2014; Han
532 et al., 2017; Wang et al., 2015). Observations made in Beijing during the summer of
533 2006 showed that ammonium sulfate and ammonium nitrate contributed 44.6% and
534 22.3%, respectively, to the total extinction coefficient during a severe period of smog
535 (Han et al., 2014); in the summer of 2014 in Beijing, ammonium sulfate, secondary
536 organic aerosols, and ammonium nitrate contributed 30%, 22%, and 18%, respectively,
537 to the total extinction coefficient (Han et al., 2017).

538 As shown in Figure 11, the simulation results indicate that the net $P(O_3)$ of B day
539 is 36.2% higher than that of A day due to higher concentrations of ozone precursors
540 on B day. This result is consistent with the observed ozone concentrations, of which

the observed ozone concentration in B day is 2.2 times higher than that of A day. If we adjust the photolysis frequencies level of B day to the level of A day, the net $P(O_3)$ increases by 70.0%, which indicates that the high level of particulate matter in B day greatly inhibits ozone production. This result means that the system is under negative feedback, thus keeping O_3 at a relatively stable level. Table 8 summarizes the average levels of gaseous pollutants and photolysis frequencies for AOD less than 1 and greater than 1, as measured during August 2012. It shows that, the concentrations of ozone's precursors are higher and the photolysis frequencies are lower at high AOD levels (AOD > 1) than those at low AOD level (AOD < 1). This result means that the negative feedback mechanism is prevalent throughout the whole campaign period. Therefore, the prevention and control measures of air pollution in Beijing need to incorporate this coupling mechanism between particulate matter and ozone to achieve effective control of these two main pollutants.

4. Conclusion

Photolysis reactions are important driving forces for tropospheric photochemical oxidation processes and ozone production. In this study, we explored in detail the effects of aerosols on photolysis frequencies and ozone production in Beijing, based on a long observation period of 4 years. We have found that:

(1) There is a strong correlation between $PM_{2.5}$ and AOD, and the slope in summer is smaller significantly than in winter, which indicates that aerosols in summer have a more efficient extinction capacity than in winter.

(2) As AOD increased, the extinction effect of aerosol on photolysis frequencies was decreased; this result was related to a higher proportion of scattering aerosols under high AOD conditions than under low AOD conditions. The slope of the correlation between photolysis frequencies and AOD indicates that the aerosols in urban Beijing have a stronger extinction on actinic flux than absorptive dust aerosols in the Mediterranean.

(3) The influence of AOD on photolysis frequencies was evaluated quantitatively by establishing parametric equations. According to the parametric equation, aerosols lead to a decrease in $j(NO_2)$ by 24.2% and 30.4% for summer and winter, respectively, and the corresponding decrease in $j(O^1D)$ by 27.3% and 32.6% respectively, compared to an aerosol-free atmosphere.

(4) In order to evaluate the effects of aerosols on ozone production rate, we carried out an observation campaign in August 2012. The results show that aerosols reduced the net ozone production rate by 25% by reducing the photolysis frequencies. High concentrations of ozone gaseous precursors were often accompanied by high concentrations of particulate matter, which, to a large extent, inhibited excessive levels of ozone generation and reflected the negative feedback effect of the atmospheric system. Therefore, the influence of aerosol on photolysis frequencies and thus on the rate of oxidation of VOCs and NOx to ozone and secondary aerosol is important for determining the atmospheric effects of controlling the precursor emissions of these two important air pollutants (aerosols and ozone).

Table 1. Instruments deployed in the field campaign undertaken in August 2012 and used for data analysis.

Parameters	Measurement technique	Time resolution	Detection limit	Accuracy
$j(O^1D)$ and $j(NO_2)$	Spectroradiometer	10 s	/	± 10%
O_3	UV photometry	60 s	0.5 ppbv	± 5%
NO	Chemiluminescence	60 s	60 pptv	± 20%
NO_2	Chemiluminescence	60 s	300 pptv	± 20%
CO	IR photometry	60 s	4 ppb	± 5%
SO_2	Pulsed UV fluorescence	60 s	0.1 ppbv	± 5%
HCHO	Hantzsch fluorimetry	60 s	25 pptv	± 5%
VOCs	GC-FID/MS	1 h	20-300 pptv	± 15~20%

Table 2. O_3 column concentration, temperature, relative humidity and respective standard deviation for different seasons.

	O_3 column (Du)	Temperature (℃)	Relative humidity (%)
Spring	354.9±37.3	15.6±7.8	33.2±18.1
Summer	310.2±23.8	27.5±4.2	57.2±17.7
Autumn	303.8±22.8	15.5±7.4	46.4±20.6
Winter	347.2±28.2	0.53±4.24	30.4±17.6

Table 3. Slope, intercept and the square of correlation coefficient (r^2) of linear fits of correlation between $j(O^1D)$ and AOD for each ozone column class at AOD smaller than 0.7.

	SZA=30°			SZA=60°		
O_3 column (DU)	Slope ($10^{-6}s^{-1}$)	Intercept ($10^{-6}s^{-1}$)	r^2	Slope ($10^{-6}s^{-1}$)	Intercept ($10^{-6}s^{-1}$)	r^2
300-330	-6.24±1.52	25.7±0.8	0.34	-4.21±0.43	7.67±0.33	0.41
330-360	-6.50±1.43	23.2±0.6	0.40	-5.01±0.34	7.15±0.21	0.52

981 Table 7. Mean and standard deviation of observed data during daytime (6:00–18:00)

982 for A day and B day.

Observed data	A day: August 21, 2012	B day: August 26, 2012
AOD	0.21 ± 0.05	3.2 ± 0.4
$PM_{2.5}$ ($\mu g\ m^{-3}$)	21.6 ± 9.0	125.0 ± 15.7
O_3 column (Du)	302 ± 3.0	301± 3.0
Temperature(°C)	27.6 ± 3.3	27.6 ± 3.2
Relative humidity (%)	47.6 ± 10.1	54.5 ± 11.8
$j(O^1D)(s^{-1})$	$1.57\times 0^{-5} \pm 1.24\times10^{-5}$	$6.87\times10^{-6} \pm 5.2\times10^{-6}$
$j(NO_2)(s^{-1})$	$5.37\times10^{-3} \pm 2.88\times10^{-3}$	$2.87\times10^{-3}\pm 1.65\times10^{-3}$
O_3 (ppb)	39.7 ± 16.56	86.8 ± 52.82
NO_2 (ppb)	10.7 ± 5.0	24.9 ± 9.6
CO (ppm)	0.24 ± 0.05	0.85 ± 0.14
VOC reactivity (s^{-1})	3.0 ± 0.7	6.4 ± 1.7
HCHO (ppb)	2.7± 1.1	7.4± 1.9

983

984

985

986

Table 8. Monthly mean and standard deviation of observed data during daytime (6:00–18:00) under the condition of AOD less than 1 and larger than 1 in August 2012

Observed data	AOD<1	AOD>1
AOD	0.43 ± 0.24	2.0 ± 0.8
$PM_{2.5}$ ($\mu g\ m^{-3}$)	26.4 ± 12.4	76.9 ± 47.1
O_3 column (Du)	303 ± 4.0	302 ± 5.0
Temperature(°C)	29.6 ± 4.3	29.2 ± 4.1
Relative humidity (%)	42.1 ± 15.8	57.0 ± 12.8
$j(O^1D)(s^{-1})$	$1.62\times10^{-5} \pm 1.05\times10^{-5}$	$1.03\times10^{-5} \pm 0.67\times10^{-5}$
$j(NO_2)(s^{-1})$	$5.64\times10^{-3} \pm 2.42\times10^{-3}$	$3.80\times10^{-3} \pm 1.66\times10^{-3}$
O_3 (ppb)	52.4 ± 33.8	67.9 ± 45.7
NO_2 (ppb)	16.4 ± 7.8	24.4 ± 8.9
CO (ppm)	0.47 ± 0.20	0.95 ± 0.47
VOC reactivity (s^{-1})	4.3 ± 1.7	6.2 ± 2.2
HCHO (ppb)	4.0 ± 1.4	6.5± 1.9

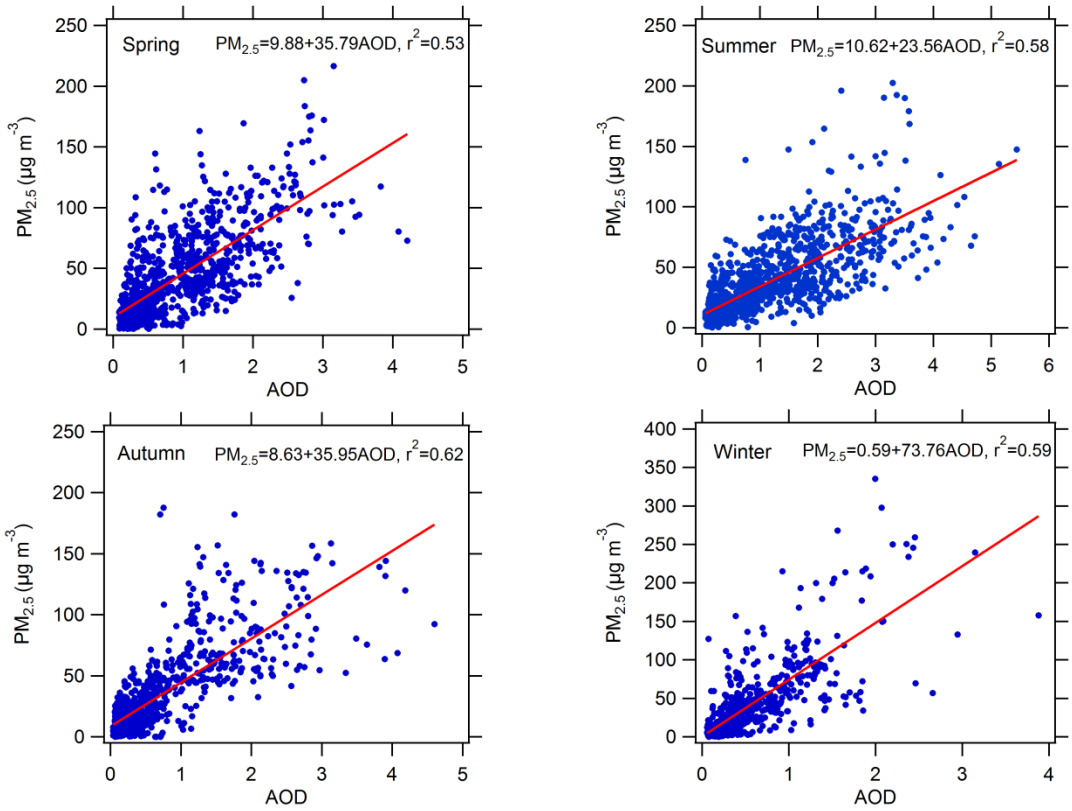

Figure 1. Scatter plots between AOD at 380nm and $PM_{2.5}$ in four different seasons. The slope, intercept and determination coefficient (r^2) were calculated.

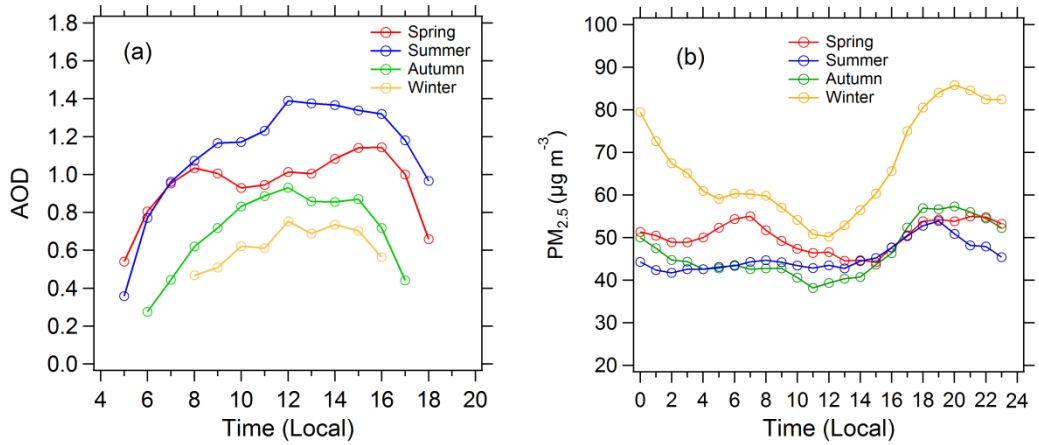

Figure 2. Diurnal cycles of (a) mean AOD (380nm) and (b) mean $PM_{2.5}$ in four seasons.

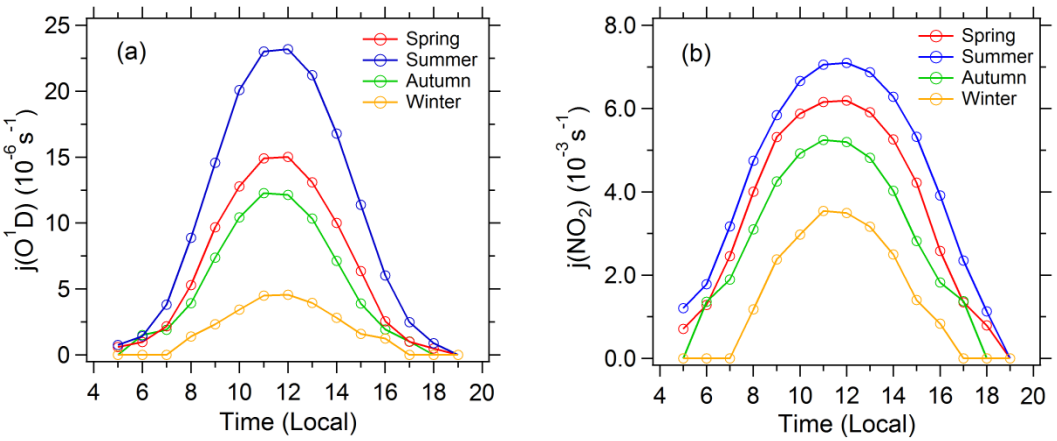

Figure 3. Diurnal cycles of (a) mean $j(O^1D)$ and (b) mean $j(NO_2)$ in four seasons under cloudless conditions.

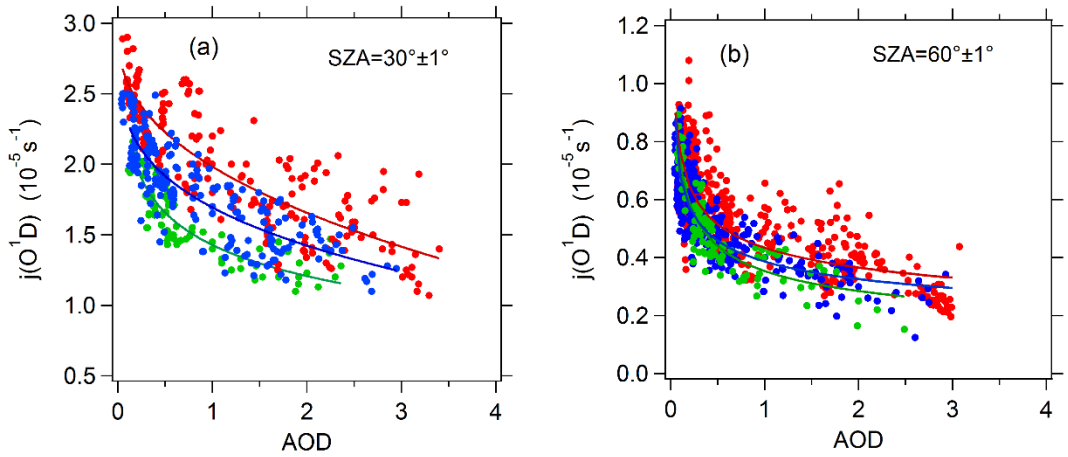

Figure 4. Dependence of $j(O^1D)$ on AOD at SZA of (a) 30° and (b) 60° and at different classes of ozone column concentration: 300-330 DU (red), 330-360 DU (blue), and 360-390 DU (green).

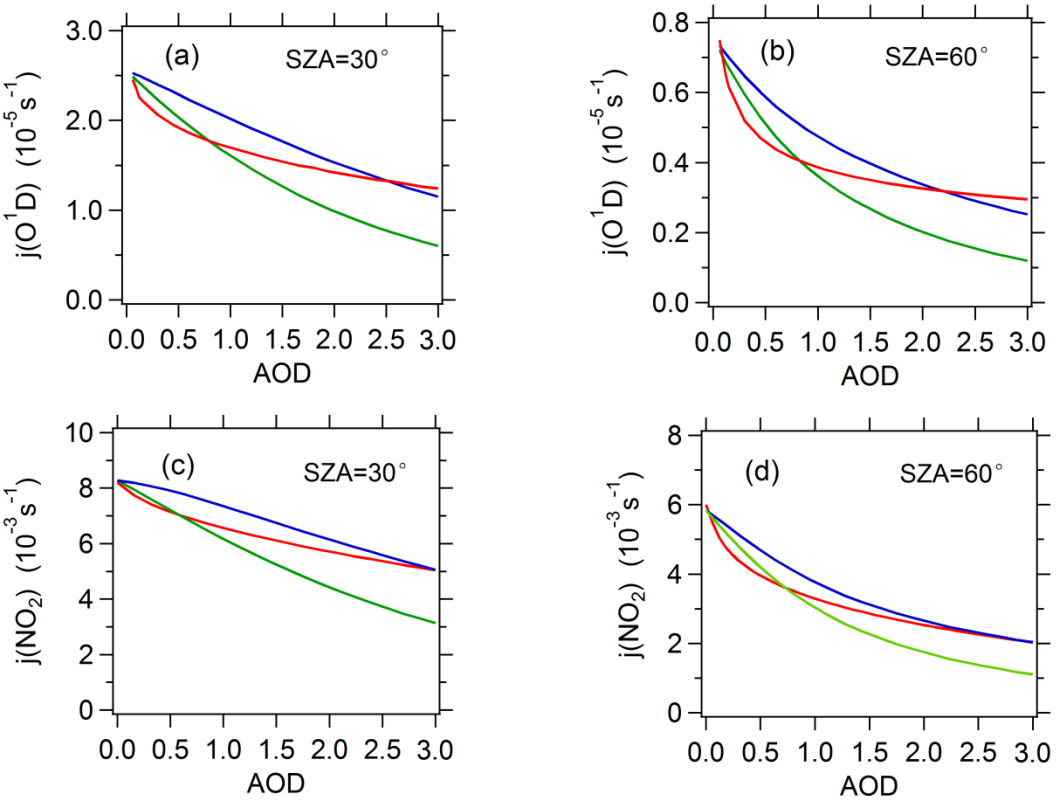

Figure 5. The relationship between observed or TUV-simulated photolysis frequencies and AOD at SZA of 30° and 60°. The red line represents observed average photolysis frequencies; the blue line and green line represents TUV-simulated photolysis frequencies at SSA of 0.95 and 0.85 respectively.

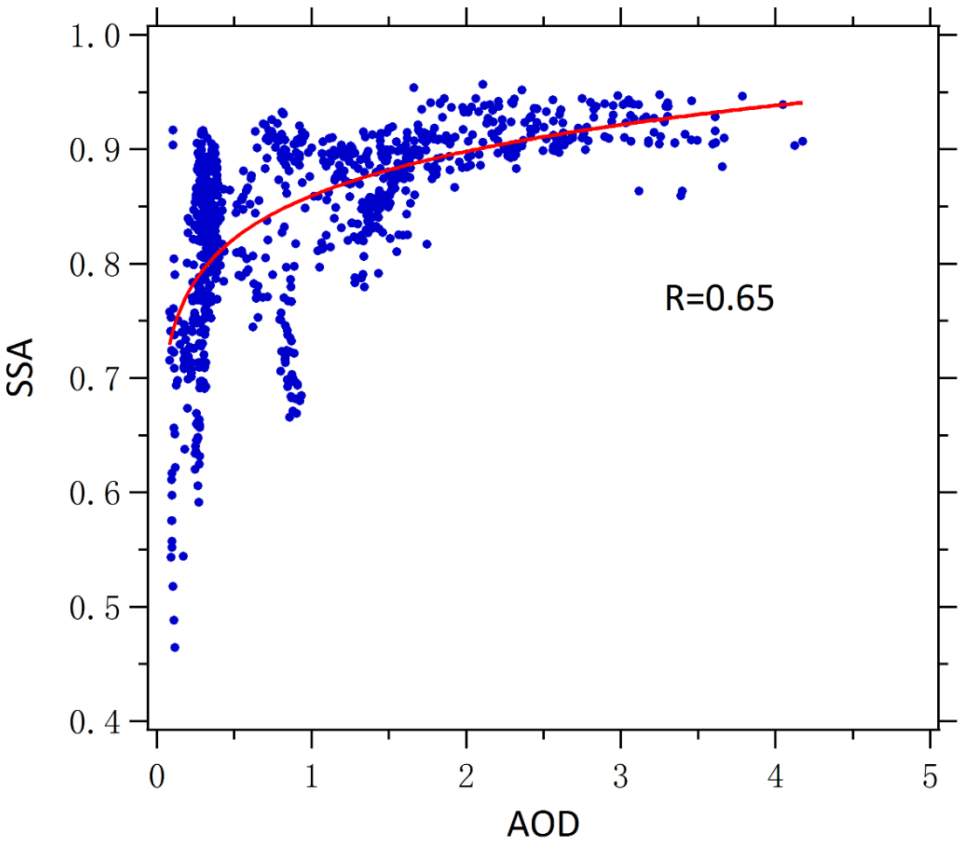

Figure 6. Correlation between SSA and AOD observed in August 2012.

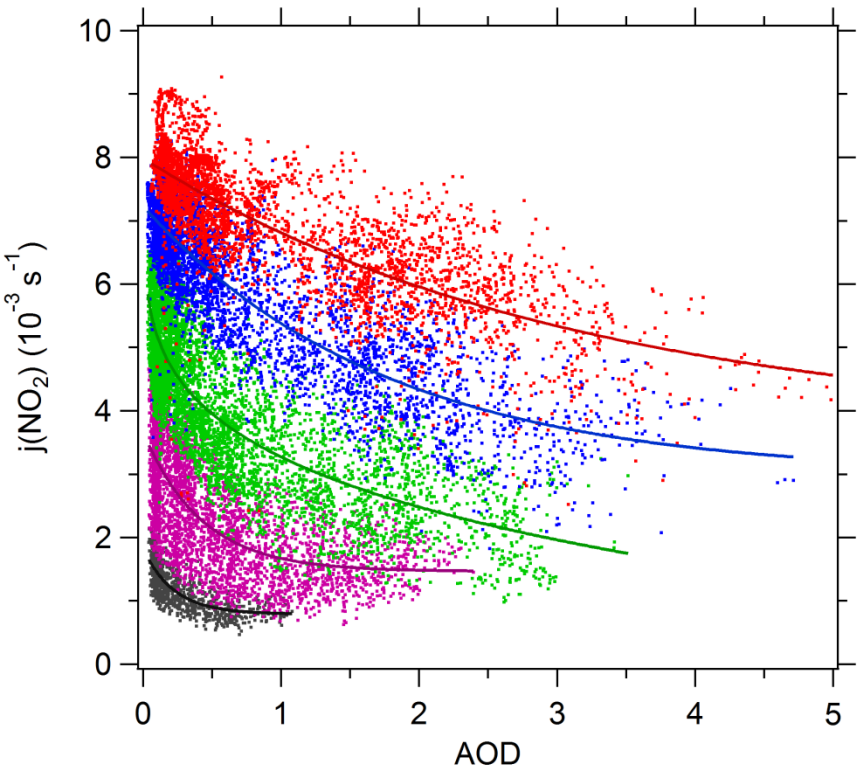

Figure 7. Dependence of $j(NO_2)$ on AOD at different SZA classes. The classes of cos(SZA) are 0–0.2 (black), 0.2–0.4 (purple), 0.4–0.6 (green), 0.6–0.8 (blue), and 0.8–1 (red).

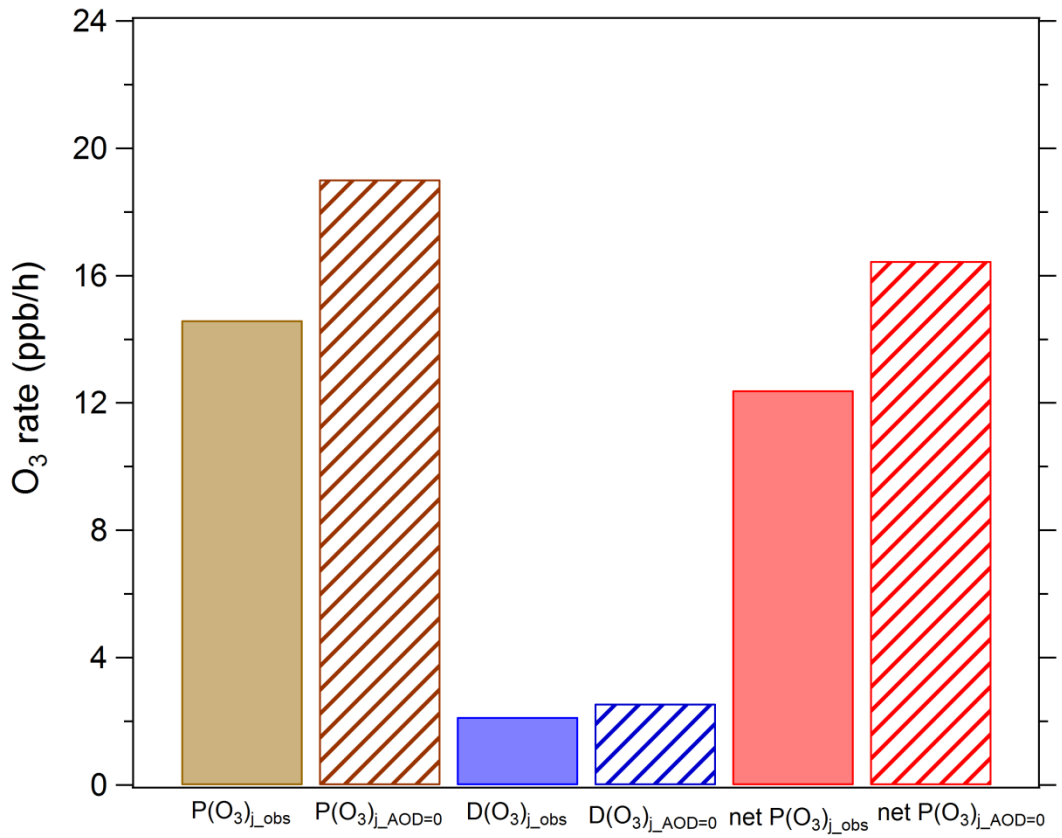

Figure 8. Average ozone production and loss terms in August 2012. $P(O_3)_{j\_obs}$, $D(O_3)_{j\_obs}$ and net $P(O_3)_{j\_obs}$ represents ozone production rate, ozone loss rate, and net ozone production rate under observed photolysis frequencies; $P(O_3)_{j\_AOD=0}$, $D(O_3)_{j\_AOD=0}$ and net $P(O_3)_{j\_AOD=0}$ represents ozone production rate, ozone loss rate, and net ozone production rate under calculated photolysis frequencies when AOD is equal to 0.

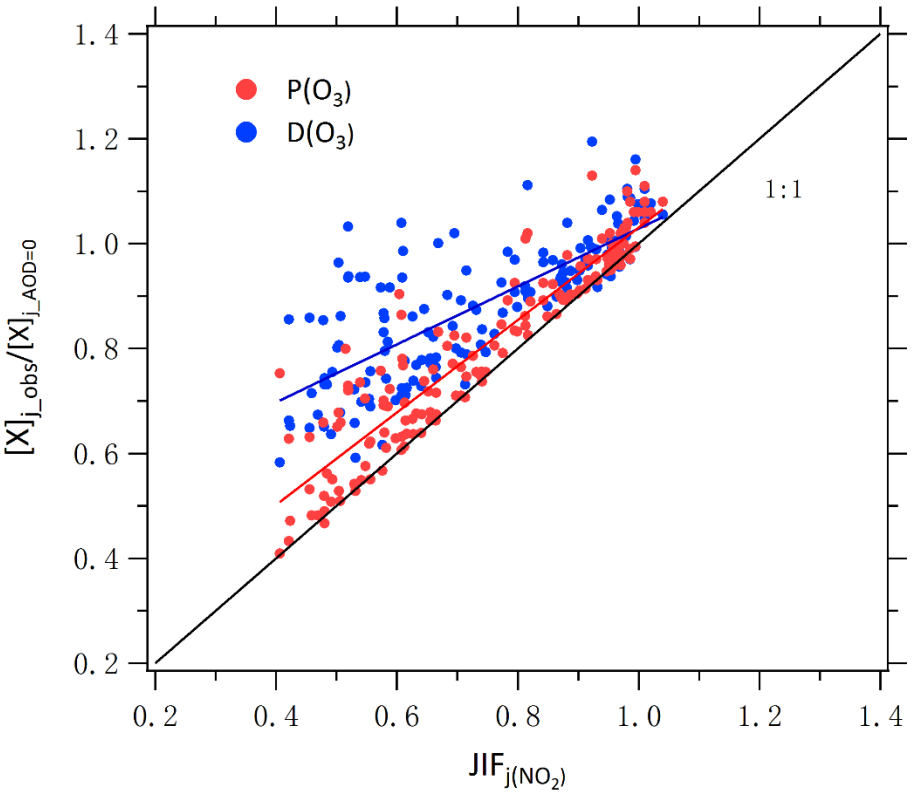

Figure 9. Correlation between $P(O_3)_{j\_obs}/P(O_3)_{j\_AOD=0}$ (or $D(O_3)_{j\_obs}/D(O_3)_{j\_AOD=0}$) and JIF of $j(NO_2)$.

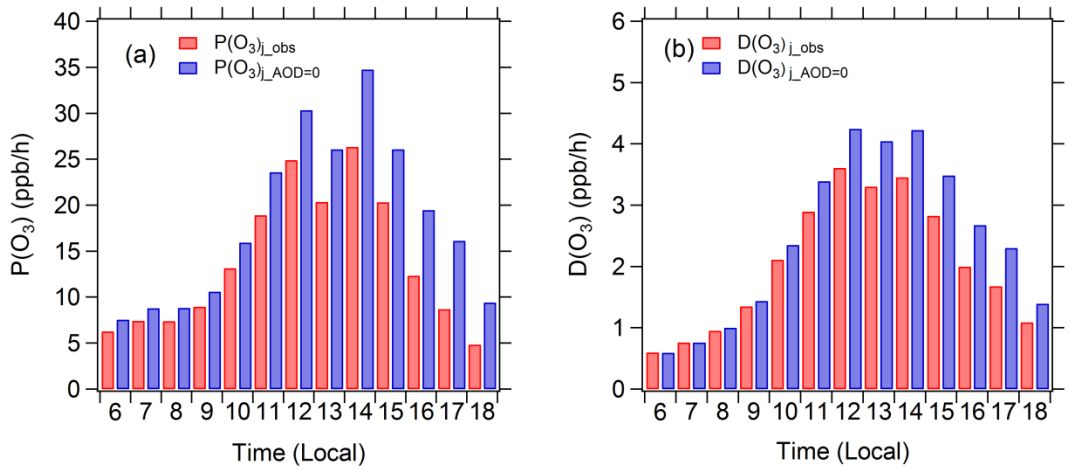

Figure 10. Diurnal profiles of mean $P(O_3)_{j\_obs}$, $P(O_3)_{j\_AOD=0}$, $D(O_3)_{j\_obs}$, and $D(O_3)_{j\_AOD=0}$.

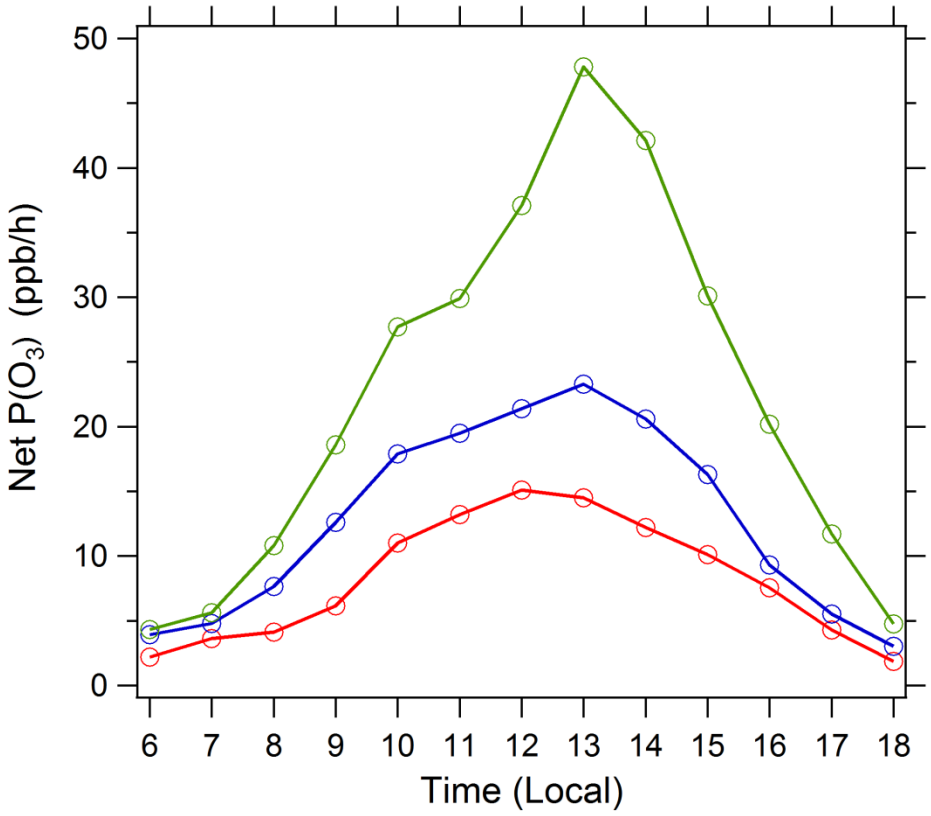

Figure 11. Diurnal profile of net $P(O_3)$ simulated by the box model. Three cases are displayed: (1) A day (red circles); (2) B day (blue circles); and (3) the photolysis frequencies of B day adjusted to the level of A day with other conditions unchanged (green circles).
