**Abstract.**  During the period 2012–2015, photolysis frequencies were measured at the Peking University site (PKUERS), a site representative of Beijing. We present a study of the effects of aerosols on two key photolysis frequencies,  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$ . Both  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  display significant dependence on aerosol optical depth (AOD; 380 nm) with a non-linear negative correlation. With the increase in AOD, the slopes of photolysis frequencies vs. AOD decrease, which indicates that the capacity of aerosols to reduce the actinic flux decreases with AOD. The absolute values of slopes are equal to  $4.2\text{--}6.9 \times 10^{-6}$  and  $3.4 \times 10^{-3} \text{ s}^{-1}$  per AOD unit for  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  respectively at a solar zenith angle (SZA) of  $60^\circ$  and AOD smaller than 0.7, both of which are larger than those observed in a similar, previous study in the Mediterranean. This indicates that the aerosols in Beijing have a stronger extinction effect on actinic flux than absorptive dust aerosols in the Mediterranean. Since the photolysis frequencies strongly depended on the AOD and the SZA, we established a parametric equation to quantitatively evaluate the effect of aerosols on photolysis frequencies in Beijing. According to the parametric equation, aerosols lead to a decrease in seasonal mean  $j(\text{NO}_2)$  by 24 % and 30 % for summer and winter, respectively, and a corresponding decrease in seasonal mean  $j(\text{O}^1\text{D})$  by 27 % and 33 %, respectively, compared to an aerosol-free atmosphere (AOD = 0). Based on an observation campaign in August 2012, we used a photochemical box model to simulate the ozone production rate ( $P(\text{O}_3)$ ). The simulation results shows that the monthly mean daytime net ozone production rate is reduced by up to 25 % due to the light extinction of aerosols. Through further in-depth analysis, it was found that particulate mat-

ter concentrations maintain a high level under the condition of high concentrations of ozone precursors (volatile organic compounds, VOCs, and  $\text{NO}_x$ ), which inhibits the production of ozone to a large extent. This phenomenon implies a negative feedback mechanism in the atmospheric environment of Beijing.

## 1 Introduction

Solar radiation plays an important role in atmospheric photochemistry, driving the photolysis of many key species. The photolysis of ozone ( $\text{O}_3$ ), gaseous nitrous acid ( $\text{HONO}$ ), and carbonyl species, contributes to the primary production of  $\text{HO}_x$  (Volkamer et al., 2010). The photolysis of ozone produces  $\text{O}^1\text{D}$ , which then reacts with  $\text{H}_2\text{O}$  to form OH radicals; these radicals are the main source of OH radicals in the troposphere, as shown by Reactions (R1) and (R2). The strong dependence of OH concentration on  $j(\text{O}^1\text{D})$  was found in a number of field measurements (Ehhalt et al., 2000; Rohrer et al., 2014; Stone et al., 2012). In addition, the photolysis of  $\text{NO}_2$  produces  $\text{O}^3\text{P}$ , and then  $\text{O}^3\text{P}$  reacts with  $\text{O}_2$  to produce  $\text{O}_3$ , as shown by Reactions (R3) and (R4), which is the only significant chemical source of ozone in the troposphere (Finlayson-Pitts et al., 2000). The photolysis frequencies of Reactions (R1) and (R3) are  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$ , respectively.

<sup>5</sup> The photolysis frequencies are calculated by the following formula:

$$j = \int_{\lambda_1}^{\lambda_2} F(\lambda) \sigma(\lambda, T) \varphi(\lambda, T) d\lambda. \quad (1)$$

$F(\lambda)$  is the actinic flux dependent on wavelength. Since the photolysis rates are proportional to the actinic flux, and not all stations acquire a  $2\pi$  spectroradiometer or chemical actinometer for  $J$  measurements, several methods have been developed to determine actinic flux and photolysis frequencies from ground-based measurements of irradiance (Kylling et al., 2003; Kazadzis et al., 2000, 2004; Topaloglou et al., 2005; Trebs et al., 2009).  $\sigma(\lambda, T)$  is the absorption cross section of the species that is absorbed in the wavelength range  $\lambda_1$ – $\lambda_2$ .  $\varphi(\lambda, T)$  is the quantum yield of the photodissociation reaction product.  $\lambda$  and  $T$  represent wavelength species and temperature, respectively.

<sup>20</sup> The effect of aerosols on photolysis frequencies depends on the aerosol optical properties, solar zenith angle (SZA), and altitude (Liao et al., 1999). The aerosol optical depth (AOD) characterizes the integral of the extinction coefficient of aerosols in the vertical direction. The light extinction of aerosols includes scattering and absorption, which have different effects on the actinic flux. Previous studies showed that scattering aerosols can enhance the actinic flux throughout the troposphere, while absorptive aerosols reduce the actinic flux throughout the boundary layer (Jacobson, 1998; Dickerson et al., 1997; Castro et al., 2001; Flynn et al., 2010). To distinguish between these two components, single scattering albedo (SSA) is defined as the ratio of the scattering coefficient to the total extinction coefficient. In areas with severe aerosol pollution, aerosols can significantly affect photolysis frequencies and ozone production. Studies in Los Angeles (Jacobson, 1998), Mexico City (Castro et al., 2001; Raga et al., 2001; Li et al., 2011), São Paulo (de Miranda et al., 2005), Houston (Flynn et al., 2010), Europe (Real et al., 2011<sup>TSS9</sup>), and Russia (Péré et al., 2015) have found that aerosols reduce ozone concentration by 5 %–30 % by attenuating photolysis frequencies. Studies in the eastern United States have shown that scattering aerosols increase ozone concentration by 5 %–60 % by increasing the photolysis frequencies (Dickerson et al., 1997; He and Carmichael, 1999). Therefore, it is necessary to quantitatively evaluate the effect of aerosols on photolysis frequencies for a better understanding of ozone formation under highly polluted conditions.

Currently, the methods for quantitatively evaluating the influence of aerosols on photolysis frequencies mainly include the radiative transfer model and the parameterization method (Madronich et al., 1993<sup>TSS5</sup>). The radiative transfer model is based on an algorithm for calculating solar radiation and photolysis frequencies (Madronich et al., 1999<sup>TSS6</sup>). The observed data of related influential factors of the photolysis frequencies are taken as the model's input to calculate the photolysis frequencies. This method comprehensively considers the influence of aerosol optical properties on the photolysis frequencies, but it does not necessarily reflect the true quantitative relationship in the atmosphere due to complicated environmental conditions, and thus the simulated results do not necessarily reproduce observed values well (Lefer et al., 2003; Stetter et al., 2003<sup>TSS7</sup>; Hofzumahaus et al., 2004). For example, the simulated slope of  $j(\text{O}^1\text{D})$  vs. AOD by the Fast-JX algorithm within the CHIMERE model was significantly smaller than the observed slope, particularly for the high SZA values (Mailler et al., 2016). The parameterization method is based on the observation data taken from a certain region and is used to establish the parameterized relationship between the photolysis frequencies and optical properties of aerosols (such as AOD). The method can reflect the actual atmospheric environment conditions; it also considers less influential factors and thus is easy to apply (Casasanta et al., 2011; Gerasopoulos et al., 2012). The disadvantage of this method is that the established parametric equations apply only to a specific region and cannot be extended to other regions.

With rapid economic development and urbanization in past decades, China's atmospheric pollution has become more and more severe, characterized by high concentrations of particulate matter and ozone. Satellite observations indicate that both the particulate matter and the ozone of eastern China are at higher levels compared with other locations around the globe (Verstraeten et al., 2015; Ma et al., 2014). Levels of pollution in the Beijing–Tianjin–Hebei region are even more severe (Chang et al., 2009; Che et al., 2008; Zhang et al., 2014, 2016). Therefore, it is necessary to study the effects of aerosols on photolysis frequencies and ozone production in the urban areas of China.

Previous model studies have shown that aerosols in China can affect ozone production by changing the photolysis frequencies. Tang et al. (2004) used a sulfur transmission–emission model (STEM) to discover that ozone concentration in north-eastern China was reduced by 0.1 %–0.8 % in the sandstorm due to the change in photolysis frequencies. Tie et al. (2005) used a global aerosol–chemical model to show that aerosols caused  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  to decrease in winter by 20 %–30 % and 10 %–30 %, respectively, and in summer by 5 %–20 % and 1 %–10 %, respectively, resulting in 2 %–5 % and 2 % reductions in ozone concentration in winter and summer, respectively. Li et al. (2011) used an air quality model to estimate the changes in the photolysis frequencies caused by sulfate, nitrate, ammonium, and min-

eral dust aerosols in the central and eastern regions of China from 1 June to 12 June 2006. This study showed that the daily average  $j(\text{O}^1\text{D})$  in the troposphere at altitudes of 1, 3, and 10 km from the ground was reduced by 53 %, 37 %, and 21 %, respectively, resulting in a decrease in the ozone concentration by 5.4 %, 3.8 %, and 0.10 % in the three layers. Lou et al. (2014) found that with aerosols, annual mean photolysis frequencies,  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$ , were simulated to be reduced by 6 %–18 % in polluted eastern China, leading to reductions in  $\text{O}_3$  of up to 0.5 ppbv in those regions in spring and summer using a global chemical transport model (GEOS-Chem). However, all of these studies base their results on model simulations. Research using long-term observational data to evaluate the effects of aerosols on photolysis frequencies and ozone production in China has not yet been published.

Our overall goal is to quantitatively evaluate the effect of aerosols in Beijing on photolysis frequencies and thus on ozone production. First, the relationship between  $\text{PM}_{2.5}$  and AOD was investigated. Second, based on long-term observations (2012–2015) of photolysis frequencies, we discussed the impact of AOD on photolysis frequencies ( $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$ ) in Beijing in detail. The relationship between photolysis frequencies and AOD is adequately compared with a previous study in the Mediterranean (Casasanta et al., 2011; Gerasopoulos et al., 2012). Then, the quantitative relationship between photolysis frequencies, AOD, and SZA was acquired by the parameterization method, which could be used to quantitatively evaluate the effect of AOD on photolysis frequencies in Beijing. Finally, a photochemistry box model was used to evaluate the effect of aerosols on ozone production.

## 2 Methodology

### 2.1 Measurement

From August 2012 to December 2015,  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  were measured continuously at the Peking University site (PKUERS). The data of the period during October 2012 to March 2013 and August 2015 are missed due to instrument maintenance and other measurement campaigns. The site (39.99° N, 116.31° E) is located on the sixth floor of a campus building at Peking University, 20 km north-west of Tiananmen Square. The height from the ground is about 30 m. The sampling point is surrounded by classroom buildings. Concentration level and composition of air pollutants were thought to be similar to the downtown area and thus representative of the whole of Beijing (Wang et al., 2010; Xu et al., 2011; Zhang et al., 2012, 2014).

The actinic flux was measured using a spectroradiometer, and the photolysis frequencies were calculated from the absorption cross section and quantum yield of each species (Shetter and Müller, 1999; TS9). The spectroradiometer con-

sisted of a single monochromator with a fixed grating (Carl Zeiss), an entrance optic with a  $2\pi$  steradian (sr) solid angle quartz diffusor, and a 2048 pixel  $\times$  64 pixel photodiode array detector. The spectral measurements were performed with a wavelength resolution of 2 nm, covering a wavelength range of 290–650 nm (Hofzumahaus et al., 1999). A 1000 W National Institute of Standard and Technology (NIST) traceable lamp was used for calibration under laboratory conditions (Bohn et al., 2008). The measured spectra were corrected for dark signal and stray light. For  $j(\text{O}^1\text{D})$ , the quantum yields used were taken from Matsumi et al. (2002), while the ozone cross section was derived from Daumont et al. (1992) and Malicet et al. (1995). Measured temperatures were used to retrieve the ozone absorption cross section and quantum yield. For  $j(\text{NO}_2)$ , the quantum yields used were taken from Bass et al. (1976) and Davenport et al. (1978) (TS10), while the cross section was derived from Jones and Bayes (1973), Harker et al. (1977), and Davenport (1978). The calculated photolysis frequencies had a time resolution of 10 s and an accuracy of  $\pm 10$  % including uncertainties associated with the quartz receiver and stray-light effects (Edwards and Monks, 2003) (TS11).

The optical properties of aerosols were measured by a CIMEL solar photometer (AERONET level 2 data collection; <http://aeronet.gsfc.nasa.gov/> (TS12)), and the site selected is Beijing-CAMS site (39.93° N, 116.32° E), which is 6.4 km from PKUERS. The CIMEL solar photometer is an automatic solar-sky scanning radiometer that uses selected spectral channels. The instrumentation, data acquisition, retrieval algorithms, and calibration procedure conform to the standards of the global AERosol RObotic NETwork (AERONET) and have been described in detail by Fottiadi et al. (2006). The solar extinction measurement was performed every 3 min in the spectral range 340–1020 nm for the calculation of AOD at wavelengths 340, 380, 440, 500, 675, 870, 970, and 1020 nm. Under cloudless conditions, the overall uncertainty of AOD data is  $\pm 0.01$  at  $\lambda > 440$  nm and  $\pm 0.02$  at shorter wavelengths. In this study, AOD at the wavelength of 380 nm was chosen for analysis. This wavelength was selected as it is more representative of  $j(\text{NO}_2)$ . Additionally, at this wavelength we can better compare AOD with the results of Gerasopoulos et al. (2012). The daytime clear-sky conditions were identified according to the presence of AOD data of AERONET since AOD data are unavailable under cloudy conditions (TS13). AE and SSA (440 nm) were also acquired from AERONET. In addition, the SSA (525 nm) data were derived from a field campaign undertaken in August 2012. The absorption and scattering coefficients were measured with an aethalometer (AE-31, Magee) and a Single Wavelength Integrating Nephelometer (Aurora-1000), respectively, with a time resolution of 1 min. As aerosol particles were dried by decreasing relative humidity (RH) to  $< 40$  % when SSA was measured, we used the measured hygroscopic factor (Liu et al., 2009) and measured RH to correct the SSA. The 5 min averages of AOD, SSA,

and photolysis frequencies were analysed in this study. The total ozone column was obtained by OMI (Ozone Monitoring Instrument) for years 2012–2015, using overpass data (<http://www.temis.nl/protocols/O3global.html>) (Hofmann et al., 2003). In addition, meteorological parameters such as temperature, relative humidity, and pressure were simultaneously observed at this site. Table 1 presents total O<sub>3</sub> column, temperature, relative humidity, daytime clear-sky fraction, and respective standard deviation for different seasons.

The analysis of the effects of aerosols on ozone production (Sect. 3.4) was based on the field campaign undertaken in August 2012. The relevant contents and methods of observation are shown in Table 2. Since the time resolution of volatile organic compounds (VOCs) is 1 h, all data analysed in Sect. 3.4 were processed as 1 h average values. In this study, we focused on the effects of aerosols on photolysis frequencies and ozone production under cloudless conditions.

## 2.2 Radiative transfer model description

We use the Tropospheric Ultraviolet and Visible (TUV) radiation model (version 5.3) provided by Sasha Madronich (Madronich, 1993). In order to solve the radiative transfer equation, TUV uses the discrete-ordinate algorithm (DISORT) with four streams and calculates the actinic flux spectra with a wavelength range of 280–420 nm in 1 nm steps and resolution. Measured temperatures were used to calculate the absorption cross sections and quantum yields. The key aerosol optical properties including AOD, SSA, and AE were input into the model to test the effect of aerosols on photolysis frequencies. AE(380/550 nm) is taken from AERONET, and the mean value of 1.2 during June 2012–December 2015 is used in the TUV model.

## 2.3 Photochemical box model

The photochemical box model used in this study is based on a regional atmospheric chemical mechanism (RACM2) described by Goliff et al. (2013). The mechanism includes 17 stable inorganic compounds, 4 intermediate inorganic compounds, 55 stable organic compounds, and 43 intermediate organic compounds. Compounds not specifically treated in RACM2 are incorporated into species with similar functional groups. The isoprene-related mechanism used in this model is the LIM mechanism proposed by Peeters et al. (2009). In this study, the observed NO<sub>2</sub>, CO, SO<sub>2</sub>, C<sub>2</sub>–C<sub>12</sub> non-methane hydrocarbons (NMHCs), HCHO, photolysis frequencies, temperature, pressure, and relative humidity were used as constraints to simulate the concentrations of reactive radicals (RO<sub>2</sub>, HO<sub>2</sub>, and OH), intermediate species, and associated reaction rate constants. HONO was not measured during the period and was calculated according to the concentration of NO<sub>2</sub> and the observed ratio of HONO to NO<sub>2</sub> at a site in Beijing, which had a marked diurnal cycle, a maximum in the early morning (ratio values up to ~0.05–0.08

in summer) and a decrease during daytime to values around 0.01–0.02 (Hendrick et al., 2014). The model was spun up for 2 d once it started running in order to ensure that the simulation was stable. It was assumed that the lifetime of simulated species removed by dry deposit was 24 h. The lifetime corresponds to the assumed deposit rate of 1.2 cm s<sup>−1</sup> and a well-mixed boundary layer height of about 1 km (Lu et al., 2012). Net ozone production is equal to the reaction rate between peroxy radicals (RO<sub>2</sub> and HO<sub>2</sub>) and NO minus the loss rate of NO<sub>2</sub> and O<sub>3</sub> as shown in Eqs. (2), (3), and (4) as derived by Mihelcic et al. (2003). The ozone production rate ( $P(\text{O}_3)$ ), the ozone loss rate ( $D(\text{O}_3)$ ), and the net  $P(\text{O}_3)$  were calculated from the simulation results.

$$P(\text{O}_3) = k_{\text{HO}_2+\text{NO}} [\text{HO}_2] [\text{NO}] + \sum \left( k_{\text{RO}_2+\text{NO}}^i [\text{RO}_2^i] [\text{NO}] \right) \quad (2)$$

$$D(\text{O}_3) = (\theta j (\text{O}^1\text{D}) + k_{\text{OH}+\text{O}_3} [\text{OH}] + k_{\text{HO}_2+\text{O}_3} [\text{HO}_2] + \sum (k^j \text{alkene} + \text{O}_3 [\text{alkene}^j])) [\text{O}_3] + k_{\text{OH}+\text{NO}_2} [\text{OH}] [\text{NO}_2] \quad (3)$$

$$\text{net } P(\text{O}_3) = P(\text{O}_3) - D(\text{O}_3), \quad (4)$$

where  $\theta$  is the fraction of O<sup>1</sup>D from ozone photolysis that reacts with water vapour, and  $i$  and  $j$  represent the number of species of RO<sub>2</sub> and alkenes, respectively.

## 3 Results and discussion

### 3.1 The correlation between PM<sub>2.5</sub> and AOD

Compared with AOD, PM<sub>2.5</sub> is a more common proxy for evaluating the level of particulate matter pollution in spite of AOD being a more closely related parameter of photolysis frequencies. As a result, we attempted to analyse the quantitative relationship between PM<sub>2.5</sub> and AOD to evaluate the influence of PM<sub>2.5</sub> on AOD and thus on photolysis frequencies. The factors that affect this relationship include aerosol type, aerosol size distribution, aerosol distribution in the vertical direction, relative humidity (RH), and planetary boundary layer height (PBLH) (van Donkelaar et al., 2010). Figure 1 shows the correlation between AOD and PM<sub>2.5</sub> in four different seasons. The determination coefficient ( $r^2$ ) is 0.53, 0.58, 0.62, and 0.59 for spring (March, April, and May), summer (June, July, and August), autumn (September, October, and November), and winter (December, January, and February), respectively. Meanwhile, the correlation exhibits significant seasonal differences, having a relatively smaller slope (23.56) in summer and a relatively larger slope (73.76) in winter. This implies that PM<sub>2.5</sub> in summer has a stronger light extinction capacity than in winter. One reason for the seasonal differences is the variation in RH among different seasons (Table 1). There is higher RH in summer (57.2 % on average) than in winter (30.4 % on aver-

**Table 1.** O<sub>3</sub> column concentration, temperature, relative humidity, daytime clear-sky fraction and respective standard deviation for different seasons (spring: March, April, and May; summer: June, July, and August; autumn: September, October, and November; winter: December, January, and February).

Season	O <sub>3</sub> column (DU <sub>TSIS</sub> )	Temperature (°)	Relative humidity (%)	Clear-sky fraction (%)
Spring	355 ± 37	16 ± 7.8	33 ± 18	41
Summer	310 ± 24	28 ± 4.2	57 ± 18	36
Autumn	304 ± 23	16 ± 7.4	46 ± 21	42
Winter	347 ± 28	0.53 ± 4.2	30 ± 18	41

**Table 2.** Instruments deployed in the field campaign undertaken in August 2012 and used for data analysis.

Parameters	Measurement technique	Time resolution	Detection limit	Accuracy
$j(\text{O}^1\text{D})$ and $j(\text{NO}_2)$	Spectroradiometer	10 s	–	±10 %
O <sub>3</sub>	UV photometry	60 s	0.5 ppbv	±5 %
NO	Chemiluminescence	60 s	60 pptv	±20 %
NO <sub>2</sub>	Chemiluminescence	60 s	300 pptv	±20 %
CO	IR photometry	60 s	4 ppb	±5 %
SO <sub>2</sub>	Pulsed UV fluorescence	60 s	0.1 ppbv	±5 %
HCHO	Hantzsch fluorimetry	60 s	25 pptv	±5 %
VOCs	GC-FID/MS	1 h	20–300 pptv	±15 %–20 %

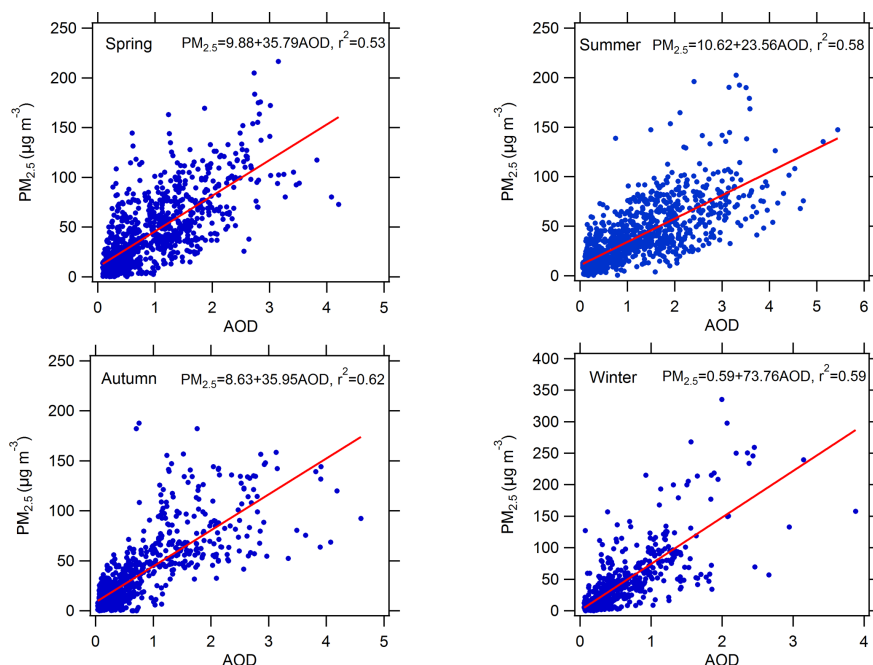

age), leading to stronger hygroscopic growth of aerosol particles and thus resulting in a higher scattering ability of aerosol particles. According to another study in Beijing, the higher the RH, the smaller the slope, and the higher the PBLH, the smaller the slope (Zheng et al., 2017). In addition, the slope was smaller for scattering-dominant aerosols than for absorbing-dominant aerosols and smaller for coarse-mode aerosols than for fine-mode aerosols (Zheng et al., 2017). The slopes of the correlation between AOD (at 550 nm) and PM<sub>2.5</sub> in this study in summer and winter are equal to 42.2 and 119.2  $\mu\text{g m}^{-3}$ , respectively, close to those from Ma et al. (2016) (54.9 and 110.5  $\mu\text{g m}^{-3}$ ) and Xin et al. (2016) (55.2 and 93.4  $\mu\text{g m}^{-3}$ ) but significantly smaller than those from Zheng et al. (2017) (65–74  $\mu\text{g m}^{-3}$  and 143–158  $\mu\text{g m}^{-3}$ ). The differences mainly depend on the aerosol composition and size distribution at different observational sites in Beijing. Compared with other cities in North China (Tianjin, Shijiazhuang, and Baoding) (Ma et al., 2016), the slope in Beijing for winter is significantly higher. Consequently, using PM<sub>2.5</sub> to estimate AOD has a large uncertainty due to multiple interference factors.

### 3.2 Seasonal and diurnal variability of AOD and photolysis frequencies

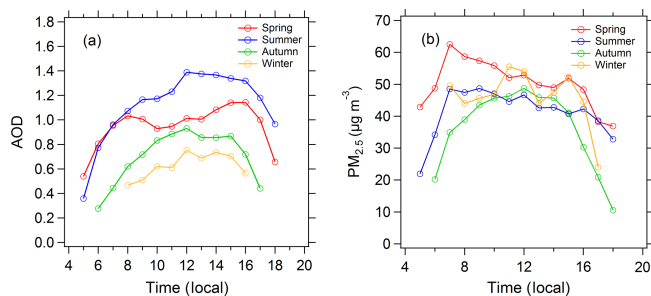

The diurnal cycles of AOD are shown in Fig. 2. AOD displays obvious diurnal variation, with a relatively high level at noon and a low level at dawn and in the evening. The diurnal variation of PM<sub>2.5</sub> is significantly different from AOD. In addition, AOD has obvious seasonal differences, with

the highest AOD in summer and the lowest AOD in winter. Conversely, PM<sub>2.5</sub> in winter (42  $\mu\text{g m}^{-3}$ ) is significantly higher than in summer (35  $\mu\text{g m}^{-3}$ ). In spite of lower PM<sub>2.5</sub> in summer, AOD in summer is higher due to the stronger extinction capacity of PM<sub>2.5</sub> as discussed in Sect. 3.1. Figure 3 shows the diurnal variation of the photolysis frequencies under cloudless conditions for each season.  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  are both highest in summer, followed by spring and autumn, and lowest in winter. This seasonal difference is mainly determined by the difference in SZA for the four seasons.

The observed mean daily maxima of photolysis frequencies at this site are lower than those observed in the eastern Mediterranean (Crete, Greece; 35°20' N, 25°40' E) (Gerasopoulos et al., 2012) by  $7.8 \times 10^{-6} \pm 5.5 \times 10^{-6}$  and  $5.5 \times 10^{-6} \pm 1.8 \times 10^{-6} \text{ s}^{-1}$  for  $j(\text{O}^1\text{D})$  and  $1.9 \times 10^{-3} \pm 1.2 \times 10^{-3}$  and  $3.3 \times 10^{-3} \pm 1.0 \times 10^{-3} \text{ s}^{-1}$  for  $j(\text{NO}_2)$ , in summer and winter respectively. The corresponding lower photolysis frequencies of Beijing than the eastern Mediterranean due to SZA difference are  $1.7 \times 10^{-6}$  and  $3.0 \times 10^{-6} \text{ s}^{-1}$  for  $j(\text{O}^1\text{D})$  and  $8.0 \times 10^{-5}$  and  $6.6 \times 10^{-4} \text{ s}^{-1}$  for  $j(\text{NO}_2)$  according to the TUV model under aerosol-free conditions, which are significantly lower than observed decreased magnitudes. Additionally, we know that the temperature is lower in Beijing during the winter compared to conditions in Crete. The measured mean temperature in Beijing during winter is equal to  $0.53 \pm 4.2^\circ$  (Table 1). When we consider the temperature in Crete is 10° higher than in Beijing, the lower  $j(\text{O}^1\text{D})$  of Beijing than Crete is  $5.5 \times 10^{-7} \text{ s}^{-1}$ , which is also not able to compensate for the  $j(\text{O}^1\text{D})$  gap between the two sites dur-

**Figure 1.** Scatter plots between AOD at 380 nm and  $PM_{2.5}$  in four different seasons. The slope, intercept, and determination coefficient ( $r^2$ ) were calculated.

**Figure 2.** Diurnal cycles of (a) mean AOD and (b) mean  $PM_{2.5}$  in the four seasons under cloudless conditions.

**Figure 3.** Diurnal cycles of (a) mean  $j(O^1D)$  and (b) mean  $j(NO_2)$  in the four seasons under cloudless conditions.

ing winter. Taking into account the similar levels of ozone column concentration in the two sites, the large gap of photolysis frequencies in the two sites is mainly attributed to the higher AOD in Beijing ( $0.76 \pm 0.75$ ) than in the eastern Mediterranean ( $0.27 \pm 0.13$ ).

It can be seen from Fig. 3 that the difference between winter and summer for  $j(O^1D)$  is significantly larger than that for  $j(NO_2)$ , for which the summer midday averages of  $j(O^1D)$  and  $j(NO_2)$  are 5 times and 2 times those of winter, respectively. There are two reasons for this phenomenon. One, compared with  $j(NO_2)$ ,  $j(O^1D)$  is more sensitive to the change in SZA, and the same change in SZA results in a larger change in  $j(O^1D)$  than  $j(NO_2)$ . Two, the main influential factors of  $j(NO_2)$  under cloudless conditions are SZA and AOD, and the influence of ozone column concentration and temperature on  $j(NO_2)$  is negligible. However,  $j(O^1D)$  is significantly af-

ected by the ozone column concentration and temperature, in addition to SZA and AOD. The higher ozone column concentration and lower temperature in winter than in summer lead to the difference in  $j(O^1D)$  further increasing (Table 1).

### 3.3 The correlation between photolysis frequencies and AOD

#### 3.3.1 The correlation between $j(O^1D)$ and AOD

In order to rule out the effect of SZA on photolysis frequencies, we chose SZAs equal to  $30^\circ$  and  $60^\circ (\pm 1^\circ)$  for analysis. Figure 4 presents the dependence of  $j(O^1D)$  on AOD at different levels of ozone column concentration at SZAs of  $30^\circ$  and  $60^\circ (\pm 1^\circ)$ . The ozone column concentration has a classification width of 30 DU. This relatively large classification width is chosen to make sure that there are enough points to

**Figure 4.** Dependence of  $j(\text{O}^1\text{D})$  on AOD (380 nm) at SZAs of (a)  $30^\circ$  and (b)  $60^\circ$  and at different classes of ozone column concentration: 300–330 DU (red), 330–360 DU (blue), and 360–390 DU (green). The full lines are fitted by the exponential function.

**Figure 5.** The relationship between observed or TUV-simulated photolysis frequencies and AOD (380 nm) at SZAs of 30 and  $60^\circ$ . For  $j(\text{O}^1\text{D})$ , a total ozone column classification of 330–360 DU is chosen. The red line represents observed average photolysis frequencies; the blue line and green line represent TUV-simulated average photolysis frequencies at SSAs of 0.95 and 0.85 respectively.

fit the relationship between  $j(\text{O}^1\text{D})$  and AOD.  $j(\text{O}^1\text{D})$  exhibits a clear dependence on AOD, with a non-linear negative correlation. The scatter of these points is mainly due to variations in ozone column and temperature. As AOD increased, the slope of  $j(\text{O}^1\text{D})$ –AOD gradually decreases, indicating that the ability of aerosols to reduce  $j(\text{O}^1\text{D})$  gradually decreases with AOD. This result differs from that found in Mediterranean, where  $j(\text{O}^1\text{D})$  was linearly negatively correlated with AOD (Casasanta et al., 2011; Gerasopoulos, 2012; USF). A larger variation range of AOD in Beijing (0–3) compared with Mediterranean (0–0.6) is one reason for the difference.

For further analysis, the observed relation between  $j(\text{O}^1\text{D})$  and AOD was compared with TUV-simulated results. Panels (a) and (b) of Fig. 5 present the comparison between observed and TUV-simulated  $j(\text{O}^1\text{D})$  against AOD at a SZA of 30 and  $60^\circ$  respectively and ozone column concentration of 330–360 DU. The observed  $j(\text{O}^1\text{D})$  was at ozone column of 330–360 DU and were scaled to the temperature of 298 K.  $\text{AE}(380/550 \text{ nm}) = 1.2$ , ozone column = 345 and temperature = 298 K were used in TUV model for all simulations. Mean Earth–Sun distance was used in the calculations of TUV model and measured  $j$  values were scaled to the mean Earth–Sun distance. At low AOD level ( $< 0.8$ ), the observed slope of  $j(\text{O}^1\text{D})$  vs. AOD is significantly larger than the simulated slope at a SSA of 0.95 and slightly larger than the simulated slope at a SSA of 0.85. With AOD increasing, the observed slope decreases rapidly to the level smaller than the simulated slopes.

The rapid change of the slope with AOD can be related to the variation of SSA at different AOD level. Figure 6 presents the relationship between SSA and AOD. Figure 6a presents the relationship between AERONET-based SSA (440 nm) and AOD during 2012–2015. The result suggests a significant positive correlation between SSA and AOD. Additionally, Fig. 6b also presents a significant positive correlation between near-ground SSA (525 nm) from measurement campaign in August 2012 and AOD. With the increase in AOD, SSA is elevated; meanwhile, the slope of SSA vs. AOD is

gradually reduced. Similar results in other regions have been obtained by Bais et al. (2005), Krotkov et al. (2005) and Kazadzis et al. (2012). SSA characterizes the ratio of the scattering extinction coefficient to the total extinction coefficient (scattering extinction coefficient plus absorptive extinction coefficient) of aerosols. The smaller the SSA, the higher the absorptive component and the lower the scattering component of the aerosol and the stronger the ability of the aerosol to reduce the actinic flux (Dickerson et al., 1997). Figure 6 indicates that aerosols in Beijing under low AOD conditions had a higher proportion of absorptive aerosol components than under high AOD conditions and, as a result, had a stronger ability to reduce the photolysis frequencies, which contributed to the rapidly reduced slope of  $j(\text{O}^1\text{D})$  vs. AOD with AOD. However, due to the absence of more SSA data of the period 2012–2015, we cannot give more sufficient evidence for the dependence of SSA on AOD. From another perspective, owing to the biomass burning and soot emission generated from heating, the fine-mode heavily absorbing aerosol percentage is higher in winter than in summer (Zheng et al., 2017; Liu et al., 2016; Zhang et al., 2013), and thus aerosols in winter have a stronger ability to reduce the photolysis frequencies. Table S1 in the Supplement indicates that SSA in summer is significantly higher than in winter. High AOD levels often appeared in summer, and low AOD levels occurred mostly in winter (Fig. 2 and Table S1), another fact that may also explain the rapidly reduced slope of  $j(\text{O}^1\text{D})$  vs. AOD with AOD.

It is worth noting that the mean near-ground SSA (525 nm) in August 2012 ( $0.88 \pm 0.08$ ) is significantly lower than the mean AERONET-based SSA (440 nm) in the same period

**Figure 6.** Correlation between SSA and AOD (380 nm). (a) SSA (440 nm) is acquired from AERONET during 2012–2015. (b) SSA (525 nm) is acquired from the near-ground measurement campaign in August 2012.

**Figure 7.** Dependence of  $j(\text{NO}_2)$  on AOD (380 nm) in different SZA classes. The classes of  $\cos(\text{SZA})$  are 0–0.2 (black), 0.2–0.4 (purple), 0.4–0.6 (green), 0.6–0.8 (blue), and 0.8–1 (red). The full lines are fitted by the exponential function.

( $0.94 \pm 0.02$ ) and in summer ( $0.94 \pm 0.02$ ). The different wavelength plays a minor role in the different SSA according to the wavelength dependence of AERONET-based SSA in the range of 440–1020 nm (Fig. S3). This difference is mainly because the AERONET-based SSA represents the column, and in situ SSA happens near the ground. The effect of the difference in SSA (0.88 vs. 0.94) results in photolysis frequencies changing by 11 %–16 % according to the TUV model. It means that due to the in situ SSA use, the photolysis frequencies tend to be underestimated. Krotkov et al. (2005) and Corr et al. (2009) pointed out that SSA in the UV can be lower than the visible. So in general this 11 %–16 % could be less. The AERONET-based SSA generally reproduces the slope of  $j(\text{O}^1\text{D})$  vs. AOD well in spite of it significantly underestimating the absolute value of the slope in the low AOD range ( $\text{AOD} < 0.7$ ), which is probably due to the uncertainty of AERONET-based SSA in the low AOD range. In addition to the uncertainty of SSA, SSA at both 440 nm and 525 nm differs from the 305–315 nm wavelength range of  $j(\text{O}^1\text{D})$ , which is likely to lead to some uncertainties for the analysis of the relationship between  $j(\text{O}^1\text{D})$  and AOD.

Comparing Fig. 4a and b, we see that at AOD smaller than 1, the slope of  $j(\text{O}^1\text{D})$  vs. AOD exhibits a significant dependence on SZA, and the slope at  $30^\circ$  of SZA is about 1.5–2.0 times larger than that at  $60^\circ$  of SZA. This result is similar to that of the observations made in the central Mediterranean (Casasanta et al., 2011). For the purpose of comparison with the study in the Mediterranean, the slope of  $j(\text{O}^1\text{D})$  vs. AOD was calculated at AOD smaller than 0.7.

Table 3 presents the slope, intercept and determination coefficient ( $r^2$ ) of linear fits of correlation between  $j(\text{O}^1\text{D})$  and AOD for each ozone column class at AOD smaller than 0.7. At a SZA of  $60^\circ$  and  $\text{O}_3$  column concentration of 300–330 DU, the respective slope of the linear regression indicates a reduction of  $j(\text{O}^1\text{D})$  by  $4.2 \times 10^{-6} \text{ s}^{-1}$  per AOD unit. Gerasopoulos et al. (2012) reported that the observed slope in the eastern Mediterranean was equal to  $2.4 \times 10^{-6} \text{ s}^{-1}$  at an  $\text{O}_3$  column of 300–320 DU. Casasanta et al. (2011) reported that the observed slope in the central Mediterranean varied from  $2.7 \times 10^{-6}$  to  $3.9 \times 10^{-6} \text{ s}^{-1}$  at an  $\text{O}_3$  column of

300–330 DU. All of these results are smaller than the value of the present study, indicating that aerosols in Beijing had a stronger extinction capacity on  $j(\text{O}^1\text{D})$  than those in the Mediterranean that was influenced by both natural absorptive aerosols and anthropogenic aerosols. A previous study indicated that SSA in Beijing ranged from 0.80 to 0.86 (Garland et al., 2009; T. T. Han et al., 2015, 2017; Tian et al., 2015). The relatively low SSA in Beijing could be an important reason for the stronger extinction capacity.

### 3.3.2 The correlation between $j(\text{NO}_2)$ and AOD

Unlike  $j(\text{O}^1\text{D})$ ,  $j(\text{NO}_2)$  is negligibly affected by ozone column concentration and depends mainly on AOD and SZA under cloudless conditions. Figure 7 presents the dependence of  $j(\text{NO}_2)$  on AOD at different SZA levels under cloudless conditions. The cosine of SZA ( $\cos(\text{SZA})$ ) is categorized according to a width of 0.2. In the same category of  $\cos(\text{SZA})$ ,  $j(\text{NO}_2)$  displays a strong dependence on AOD. The scatter of these points is due to the relatively large classification width of SZA to a large extent. When  $\cos(\text{SZA})$  is at its maximum level (0.8–1), the correlation between  $j(\text{NO}_2)$  and AOD is close to linear. When  $\cos(\text{SZA})$  decreases, the correlation tends to be non-linear. Similar to  $j(\text{O}^1\text{D})$ , the observed slopes of  $j(\text{NO}_2)$  vs. AOD are also larger than the TUV-simulated slope at SSA of 0.95 and 0.85 when AOD is smaller than 0.8 and decreased rapidly with increasing AOD (Fig. 5c and d). The reason for this result is the same as that for  $j(\text{O}^1\text{D})$  as explained above.

**Table 3.** Slope, intercept, and the square of correlation coefficient ( $r^2$ ) of linear fits of correlation between  $j(\text{O}^1\text{D})$  and AOD for each ozone column class at AOD smaller than 0.7.

O <sub>3</sub> column (DU)	SZA = 30°			SZA = 60°		
	Slope (10 <sup>-6</sup> s <sup>-1</sup> )	Intercept (10 <sup>-6</sup> s <sup>-1</sup> )	$r^2$	Slope (10 <sup>-6</sup> s <sup>-1</sup> )	Intercept (10 <sup>-6</sup> s <sup>-1</sup> )	$r^2$
300–330	-6.2 ± 1.5	26 ± 1	0.34	-4.2 ± 0.4	7.7 ± 0.3	0.41
330–360	-6.5 ± 1.4	23 ± 1	0.40	-5.0 ± 0.3	7.1 ± 0.2	0.52
360–390	-9.5 ± 1.6	21 ± 1	0.52	-6.9 ± 0.6	7.6 ± 0.3	0.66

**Table 4.** Slope, intercept, and the square of correlation coefficient ( $r^2$ ) of linear fits of correlation between  $j(\text{NO}_2)$  and AOD for each ozone column class at AOD smaller than 0.7.

cos(SZA)	Slope (10 <sup>-3</sup> s <sup>-1</sup> )	Intercept (10 <sup>-3</sup> s <sup>-1</sup> )	$r^2$
0–0.2	-1.3 ± 0.1	1.5 ± 0.0	0.52
0.2–0.4	-2.4 ± 0.1	3.4 ± 0.0	0.41
0.4–0.6	-3.2 ± 0.1	5.5 ± 0.0	0.49
0.6–0.8	-2.1 ± 0.1	7.2 ± 0.1	0.38
0.8–1.0	-1.8 ± 0.1	8.1 ± 0.1	0.26

Table 4 presents the slope, intercept, and determination coefficient ( $r^2$ ) of linear fits of correlation between  $j(\text{NO}_2)$  and AOD for each ozone column class at AOD smaller than 0.7. The slope of  $j(\text{NO}_2)$  vs. AOD also displays a significant dependence on cos(SZA). The slope increases as cos(SZA) increases from 0 to 0.5 and then decreases as cos(SZA) increases from 0.5 to 1. At a SZA of 60° ± 1° (cos(SZA) = 0.5 ± 0.015), the respective slope of the linear regression indicates a reduction of  $j(\text{NO}_2)$  by  $3.4 \times 10^{-3} \text{ s}^{-1}$  per AOD unit. This result is larger than the value for non-dust aerosols ( $2.2 \times 10^{-3} \text{ s}^{-1}$ ) and close to the value for dust aerosols ( $3.1 \times 10^{-3} \text{ s}^{-1}$ ) in the eastern Mediterranean reported by Gerasopoulos et al. (2012).

### 3.4 The parameterization relationship between photolysis frequencies, AOD, and SZA

As analysed above, the photolysis frequencies ( $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$ ) strongly depended on AOD and cos(SZA) and could be fit into Eq. (5) using a quadratic polynomial form. The fitting parametric equations for  $j(\text{NO}_2)$  are shown in Table 5. For  $j(\text{O}^1\text{D})$ , both the O<sub>3</sub> column and temperature affect  $j(\text{O}^1\text{D})$  significantly. Figure S1 presents the dependence of  $j(\text{O}^1\text{D})$  on ozone column at a low AOD level (AOD < 0.3) and SZAs of (a) 30° ± 1° and (b) 60° ± 1°, respectively. The ozone column ranging from 270 to 400 DU leads to  $j(\text{O}^1\text{D})$  reducing by about 50 %. In order to evaluate the impact of temperature on  $j(\text{O}^1\text{D})$ , we calculated the ratio of  $j(\text{O}^1\text{D})$  at measured temperature to  $j(\text{O}^1\text{D})$  at temperature = 298 K ( $j(\text{O}^1\text{D})/j(\text{O}^1\text{D})_{T=298 \text{ K}}$ ) (Fig. S2).

$j(\text{O}^1\text{D})/j(\text{O}^1\text{D})_{T=298 \text{ K}}$  varied from 0.82 to 1.03, indicating that temperature changed  $j(\text{O}^1\text{D})$  by no more than 21 %. Therefore, temperature played a minor role in changing  $j(\text{O}^1\text{D})$  compared with the ozone column. As a result, when we fitted the relationship among  $j(\text{O}^1\text{D})$ , AOD, and cos(SZA), the effect of the ozone column is considered but the effect of temperature is not considered. By fitting the relationship in different ozone classes (classification width = 30 DU), we found that the ozone column increasing by 30 DU results in  $j(\text{O}^1\text{D})$  at a constant SZA and AOD decreasing by 18 %. Therefore, the parametric equation for  $j(\text{O}^1\text{D})$  is transformed into the form Eq. (6), which reflects the influence of ozone column. The parameters  $a_1$ – $a_6$  correspond to the ozone column range of 300–330 DU; thus we use 315 DU as the weighted standard of the ozone column. The fitting parameters  $a_1$ – $a_6$  for  $j(\text{O}^1\text{D})$  is shown in Table 6.

$$j(\text{NO}_2) = a_1 + a_2 \text{AOD} + a_3 \cos(\text{SZA}) + a_4 (\text{AOD})^2 + a_5 \text{AOD} \cos(\text{SZA}) + a_6 (\cos(\text{SZA}))^2 \quad (5)$$

$$j(\text{O}^1\text{D}) = [a_1 + a_2 \text{AOD} + a_3 \cos(\text{SZA}) + a_4 (\text{AOD})^2 + a_5 \text{AOD} \cos(\text{SZA}) + a_6 (\cos(\text{SZA}))^2] \times [1 + (315 - \text{O}_3 \text{ column}) \times 0.006] \quad (6)$$

The coefficients of determination of the fitting equations are greater than 0.95 for  $j(\text{NO}_2)$  and  $j(\text{O}^1\text{D})$  in a certain O<sub>3</sub> column, indicating that both of the photolysis frequencies strongly depended on AOD and cos(SZA), and the effect of other factors such as SSA and AE is integrated into the constant term in the parametric equation. Since the ozone column concentration has a greater influence on  $j(\text{O}^1\text{D})$  than on  $j(\text{NO}_2)$ , the parameters of fitting equations for  $j(\text{NO}_2)$  are similar, but the parameters of fitting equations for  $j(\text{O}^1\text{D})$  have a large fluctuation in different O<sub>3</sub> column ranges (especially  $a_1$  and  $a_2$ ). The parametric equations can be used to quantitatively evaluate the effect of AOD on photolysis frequencies in Beijing. According to the parametric equations, aerosols lead to a decrease in seasonal mean  $j(\text{NO}_2)$  by 24 % and 30 % and a decrease in seasonal mean  $j(\text{O}^1\text{D})$  by 27 % and 33 % in summer and winter under clear-sky conditions, respectively, compared to an aerosol-free atmosphere. The decreasing ratio of the photolysis frequencies in winter is

**Table 5.** The fitting parameters  $a_1$ – $a_6$  and determination coefficients of Eq. (5) for  $j(\text{NO}_2)$ .

$a_1$	$a_2$	$a_3$ $\times 10^{-3}$	$a_4$	$a_5$	$a_6$	$r^2$
$-0.46 \pm 0.05$	$-2.0 \pm 0.03$	$13 \pm 0.2$	$0.22 \pm 0.01$	$0.32 \pm 0.05$	$-4.0 \pm 0.1$	0.96

higher than in summer mainly due to the higher SZA in winter.

The effect of aerosols on photolysis frequencies in Beijing is compared with other studies. Real and Sartelet (2011) reported a reduction in  $j(\text{NO}_2)$  and  $j(\text{O}^1\text{D})$  of 13 %–14 % due to aerosols using the radiative transfer code Fast-J during summer 2001 over European regions. Flynn et al. (2010) reported that aerosols reduced  $j(\text{NO}_2)$  by 3 % in Houston during 2006 using the TUV model. Gerasopoulos et al. (2012) reported that aerosols reduced  $j(\text{NO}_2)$  and  $j(\text{O}^1\text{D})$  by 5 %–15 %, with a 5-year mean AOD at 380 nm equal to 0.27. All of these results are lower than the reduction ratio of this study, mainly due to the higher aerosol level in Beijing (4-year mean AOD equal to  $0.76 \pm 0.75$ ). Hodzic et al. (2007) simulated a 15 %–30 %  $j(\text{NO}_2)$  photolysis reduction during the 2003 European summer heatwave in the case of absorbing biomass burning aerosols, with AOD at 550 nm equal to 0.7–0.8 and SSA at 532 nm equal to 0.83–0.87. The result of Hodzic et al. (2007) is comparable with the reduction ratio of this study, possibly due to the equivalent levels of AOD and SSA. In addition, Péré et al. (2015) simulated a higher reduction (20 %–50 %) in  $j(\text{NO}_2)$  and  $j(\text{O}^1\text{D})$  along the transport of the aerosol plume during the 2010 Russian summer wildfires episode. The higher reduction is due to the higher level of AOD (peak value of AOD at 400 nm reached 2–4), even though SSA is very high (0.97).

### 3.5 The influence of AOD on ozone production

In order to explain the effect of aerosol light extinction on ozone production, we used the data from the field observation campaign undertaken in August 2012. Ozone production depends on its precursors ( $\text{NO}_x$  and VOCs), meteorological factors, and solar radiation. Solar radiation is the driving force for tropospheric photochemical reactions, in which  $j(\text{O}^1\text{D})$  and  $j(\text{NO}_2)$  are both important for ozone production. On the one hand, the increase in  $j(\text{NO}_2)$  promotes the photolysis of  $\text{NO}_2$ , thereby accelerating the formation of ozone. On the other hand, the increase in  $j(\text{O}^1\text{D})$  accelerates the photolysis of ozone. In addition, the increase in the photolysis frequencies will accelerate the photolysis of OVOC (especially formaldehyde and acetaldehyde), HONO, and  $\text{H}_2\text{O}_2$ , resulting in increases in OH and  $\text{HO}_2$ , which will promote the reaction between OH and VOCs and thus produce more  $\text{RO}_2$ . As a result, more ozone is produced by increasing the reaction rate between  $\text{RO}_2$  (or  $\text{HO}_2$ ) and NO. However, the increase in OH and  $\text{HO}_2$  also consumes ozone and  $\text{NO}_2$ , which con-

tributes to the increase in  $D(\text{O}_3)$ . In brief, the overall effect of changes in photolysis frequencies on the sources and sinks of ozone determines the change in the net ozone production rate.

Ozone production ( $\text{HO}_2 + \text{NO}$ ,  $\text{RO}_2 + \text{NO}$ ), ozone loss ( $\text{O}^1\text{D} + \text{H}_2\text{O}$ ,  $\text{HO}_2 + \text{O}_3$ ,  $\text{O}_3 + \text{OH}$ ,  $\text{NO}_2 + \text{OH}$ , and  $\text{O}_3 + \text{alkenes}$ ), and net ozone production rate during August 2012 were calculated using the box model. We used the observed photolysis frequencies (i.e.  $j_{\text{obs}}$ ), and the calculated photolysis frequencies by parametric equation under the conditions of AOD equal to 0 (i.e.  $j_{\text{AOD}=0}$ ) were used to constrain the box model. The difference of simulated results in the two scenarios can be attributed to the effect of aerosol light extinction. As a result, the presence of aerosols causes a decrease in both ozone production rate and loss rate, as is shown in Fig. 8. Since the decreasing amplitude of the daytime ozone production rate is far larger than that of the daytime ozone loss rate, the mean daytime net production rate of ozone is reduced by 25 %. This reduction is comparable with the results of the study in Mexico City, where aerosols caused a 20 % reduction in the ozone concentrations (Castro et al., 2001). Studies in Houston and Crete have shown that aerosols cause ozone production rates to decrease by about 4 % and 12 %, respectively, which are lower than those found in this study (Flynn et al., 2010; Gerasopoulos et al., 2012).

The ratio of the observed photolysis frequencies to the photolysis frequencies at AOD equal to 0 is defined as JIF (Flynn et al., 2010). A JIF of less than 1 indicates that the aerosols cause a decrease in the photolysis frequencies. Figure 9 shows the relation between  $P(\text{O}_3)_{j_{\text{obs}}}/P(\text{O}_3)_{j_{\text{AOD}=0}}$  (or  $D(\text{O}_3)_{j_{\text{obs}}}/D(\text{O}_3)_{j_{\text{AOD}=0}}$ ) and JIF. The majority of JIF values were less than 1, with an average of 0.72, indicating that aerosols greatly attenuated photolysis frequencies due to high levels of AOD (average of 1.07) during the observation period.  $P(\text{O}_3)_{j_{\text{obs}}}/P(\text{O}_3)_{j_{\text{AOD}=0}}$  and  $D(\text{O}_3)_{j_{\text{obs}}}/D(\text{O}_3)_{j_{\text{AOD}=0}}$  are both linearly positively correlated with JIF, and the scatters are mostly above the 1 : 1 line. As can be seen from the Fig. 9, a 30 % reduction in photolysis frequencies (JIF = 0.7) due to the presence of aerosols results in a decrease in ozone production rate and loss rate by about 26 % and 15 %, respectively. The decreasing amplitude in the ozone production rate is greater than the decrease in the ozone loss rate because the corresponding processes of ozone production are all light-driven, but the corresponding processes of ozone loss are not all light-driven because the reaction of  $\text{O}_3$  with alkenes does not depend on solar radiation. According to the simulated results, the reac-

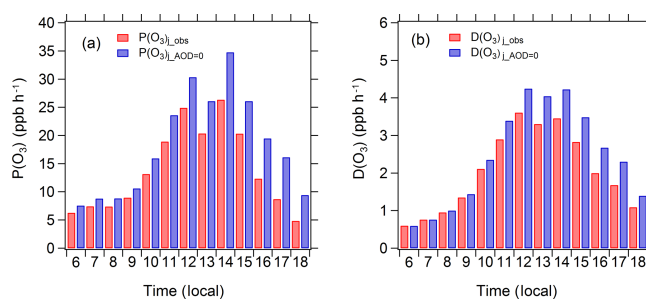

**Figure 8.** Mean daytime ozone production and loss terms in August 2012.  $P(\text{O}_3)_{j_{\text{obs}}}$ ,  $D(\text{O}_3)_{j_{\text{obs}}}$ , and net  $P(\text{O}_3)_{j_{\text{obs}}}$  represent ozone production rate, ozone loss rate, and net ozone production rate under observed photolysis frequencies;  $P(\text{O}_3)_{j_{\text{AOD}=0}}$ ,  $D(\text{O}_3)_{j_{\text{AOD}=0}}$ , and net  $P(\text{O}_3)_{j_{\text{AOD}=0}}$  represent ozone production rate, ozone loss rate, and net ozone production rate under calculated photolysis frequencies when AOD is equal to 0.

**Figure 9.** Correlation between  $P(\text{O}_3)_{j_{\text{obs}}}/P(\text{O}_3)_{j_{\text{AOD}=0}}$  (or  $D(\text{O}_3)_{j_{\text{obs}}}/D(\text{O}_3)_{j_{\text{AOD}=0}}$ ) and JIF of  $j(\text{NO}_2)$ . Single data points represent daytime hourly mean values.

tion of ozone with alkenes during this campaign accounts for 17 % of total ozone loss.

The diurnal profile of the mean ozone production and loss rate is shown in Fig. 10.  $P(\text{O}_3)$  peaks midday between 12:00 and 14:00 local time at 31 ppb h<sup>-1</sup> without aerosol impact and 23 ppb h<sup>-1</sup> with aerosol impact. The maximum  $D(\text{O}_3)$  also occurs between 12:00 and 14:00 at 4.2 ppb h<sup>-1</sup> without aerosol impact and 3.5 ppb h<sup>-1</sup> with aerosol impact. There is little difference between aerosol-impact and aerosol-free  $P(\text{O}_3)$  (or  $D(\text{O}_3)$ ) in the hours of 06:00–11:00, but the

**Figure 10.** Diurnal profiles of mean  $P(\text{O}_3)_{j_{\text{obs}}}$ ,  $P(\text{O}_3)_{j_{\text{AOD}=0}}$ ,  $D(\text{O}_3)_{j_{\text{obs}}}$ , and  $D(\text{O}_3)_{j_{\text{AOD}=0}}$  in August 2012 under clear-sky conditions.

difference in the afternoon (12:00–18:00) is large, indicating that the reduction effect of aerosol on ozone production mainly occurs during the afternoon.

The above analysis focuses on the effect of aerosol on the ozone production due to aerosol light extinction. However, it does not consider the close relationship between aerosol and ozone's gaseous precursors in the actual atmosphere. To explain this problem, we chose two adjacent days (small SZA effect) with obviously different AOD levels: a clean day (A day: August 21, 2012; AOD = 0.21, PM<sub>2.5</sub> = 21.6 μg m<sup>-3</sup>) and a day with high aerosol pollution (B day; 26 August 2012; AOD = 3.2, PM<sub>2.5</sub> = 125.0 μg m<sup>-3</sup>) (Table 7). The difference in AOD between the two days can be taken to represent the maximum daytime gap of AOD for this month. The ozone column concentrations for these two days were 302 and 301 DU, respectively, of which the effect on  $j(\text{O}^1\text{D})$  is negligible. Under these conditions, the  $j(\text{O}^1\text{D})$  value at noon decreases from  $3.23 \times 10^5 \text{ s}^{-1}$  on A day to  $1.29 \times 10^5 \text{ s}^{-1}$  on B day (i.e., a 60 % reduction), and the  $j(\text{NO}_2)$  value at noon decreases from  $8.26 \times 10^{-3} \text{ s}^{-1}$  on A day to  $4.19 \times 10^{-3} \text{ s}^{-1}$  on B day (i.e., a 49.2 % reduction). As shown in Table 7, B day has higher AOD and higher concentrations of gaseous pollutants. The concentrations of CO, NO<sub>2</sub>, HCHO and the OH reactivity of VOCs in B day are much higher than in A day, with ratios of 3.6, 2.3, and 2.0, respectively. The simultaneous increases of gaseous pollutants and AOD are due to the fact that gaseous pollutants (NO<sub>x</sub>, SO<sub>2</sub>, and VOCs) emitted by major pollution sources in Beijing, including traffic and industry, have undergone the processes of gas-phase oxidation and nucleation to generate secondary particulate matter that contributes to aerosol light extinction. Previous studies have reported that secondary particulate matter has accounted for more than 60 % of total particulate matter during severe smog pollution in Beijing summers (T. Han et al., 2015; Guo et al., 2014). In addition, several studies have shown that secondary components in particulate matter (especially secondary organics and ammonium sulfate) have dominated the aerosol light extinction (Han et al., 2014, 2017; Wang et al., 2015). Observations made in Beijing during the summer of 2006 showed

**Table 6.** The fitting parameters  $a_1$ – $a_6$  and determination coefficients of Eq. (6) for  $j(\text{O}^1\text{D})$  in the ozone column range of 300–330 DU.

$a_1$	$a_2$	$a_3$ $\times 10^{-3}$	$a_4$	$a_5$	$a_6$	$r^2$
$1.1 \pm 0.3$	$0.58 \pm 0.17$	$-8.7 \pm 0.9$	$0.63 \pm 0.05$	$-7.5 \pm 0.3$	$43 \pm 1$	0.96

that ammonium sulfate and ammonium nitrate contributed 44.6 % and 22.3 %, respectively, to the total extinction coefficient during a severe period of smog (Han et al., 2014); in the summer of 2014 in Beijing, ammonium sulfate, secondary organic aerosols, and ammonium nitrate contributed 30 %, 22 %, and 18 %, respectively, to the total extinction coefficient (Han et al., 2017).

As shown in Fig. 11, the simulation results indicate that the net  $P(\text{O}_3)$  of B day is 36.2 % higher than that of A day due to higher concentrations of ozone precursors on B day. This result is consistent with the observed ozone concentrations, of which the observed ozone concentration in B day is 2.2 times higher than that of A day. If we adjust the photolysis frequencies level of B day to the level of A day, the net  $P(\text{O}_3)$  increases by 70.0 %, which indicates that the high level of particulate matter in B day greatly inhibits ozone production. This result means that the system is under negative feedback, thus keeping  $\text{O}_3$  at a relatively stable level. Table 8 summarizes the average levels of gaseous pollutants and photolysis frequencies for AOD less than 1 and greater than 1, as measured during August 2012. It shows that the concentrations of ozone's precursors are higher and the photolysis frequencies are lower at high AOD levels ( $\text{AOD} > 1$ ) than those at a low AOD level ( $\text{AOD} < 1$ ). This result means that the negative feedback mechanism is prevalent throughout the whole campaign period. Therefore, the prevention and control measures of air pollution in Beijing need to incorporate this coupling mechanism between particulate matter and ozone to achieve effective control of these two main pollutants.

#### 4 Conclusions

Photolysis reactions are important driving forces for tropospheric photochemical oxidation processes and ozone production. In this study, we explored in detail the effects of aerosols on photolysis frequencies and ozone production in Beijing, based on a long observation period of 4 years. We have found the following:

1. There is a strong correlation between  $\text{PM}_{2.5}$  and AOD, and the slope in summer is significantly smaller than in winter, which indicates that aerosols in summer have a more efficient extinction capacity than in winter.
2. As AOD increased, the extinction effect of aerosol on photolysis frequencies was decreased; this result was probably related to a higher proportion of scat-

**Figure 11.** Diurnal profile of net  $P(\text{O}_3)$  simulated by the box model. Three cases are displayed: (1) A day (red circles), 21 August 2012, with a low AOD level and high photolysis frequencies; (2) B day (blue circles), 26 August 2012, with a high AOD level and low photolysis frequencies; and (3) the photolysis frequencies of B day adjusted to the level of A day with other conditions unchanged (green circles). The specific conditions of A day and B day are listed in Table 7.

tering aerosols under high AOD conditions than under low AOD conditions. The slope of the correlation between photolysis frequencies and AOD indicates that the aerosols in Beijing have a stronger extinction on actinic flux than absorptive dust aerosols in the Mediterranean.

3. The influence of AOD on photolysis frequencies was evaluated quantitatively by establishing parametric equations. According to the parametric equation, aerosols lead to a decrease in seasonal mean  $j(\text{NO}_2)$  by 24 % and 30 % for summer and winter, respectively, and a corresponding decrease in seasonal mean  $j(\text{O}^1\text{D})$  by 27 % and 33 % respectively, compared to an aerosol-free atmosphere.
4. In order to evaluate the effects of aerosols on ozone production rate, we carried out an observation campaign in August 2012. The results show that aerosols reduced the net ozone production rate by 25 % by reducing the photolysis frequencies. High concentrations of ozone gaseous precursors were often accompanied by high concentrations of particulate matter, which, to

**Table 7.** Mean and standard deviation of observed data during daytime (06:00–18:00) for A day and B day.

Observed data	A day: 21 August 2012	B day: 26 August 2012
AOD	0.21 ± 0.05	3.2 ± 0.4

HCHO (ppb)	4.0 ± 1.4	46.5 ± 1.9

a large extent, inhibited excessive levels of ozone generation and reflected the negative feedback effect of the atmospheric system. Therefore, the influence of aerosol on photolysis frequencies and thus on the rate of oxidation of VOCs and NO<sub>x</sub> to ozone and secondary aerosol is important for determining the atmospheric effects of controlling the precursor emissions of these two important air pollutants (aerosols and ozone).

## Remarks from the language copy-editor

- CE1** Please note that the word “urban” has been removed before “Beijing” throughout the paper because all cities are urban by definition. Its use is therefore redundant.
- CE2** For your information: although it was indicated that no Oxford (z) spellings were used, they were used throughout the paper. They have therefore not been changed in the interests of consistency. In addition, although it was specified that no Oxford comma has been used, it was used a lot of the time, so this was made consistent and any missing were added throughout the paper.
- CE3** Please define this abbreviation.
- CE4** Please note the slight changes to this section, as edits to this section are not displayed in the track-changes PDF.

## Remarks from the typesetter

- TS1** The composition of Figs. 2, 3, 6–8, 10, and 11 has been adjusted to our standards.
- TS2** Please add reference to reference list.
- TS3** Please add reference to reference list.
- TS4** Please add reference to reference list.
- TS5** Please add reference to reference list.
- TS6** Please add reference to reference list.
- TS7** Please add reference to reference list.
- TS8** Please provide a short running title.
- TS9** Is it Muller as in the reference list or Müller?
- TS10** Please add reference to reference list.
- TS11** Please add reference to reference list.
- TS12** Please provide date of last access.
- TS13** Please provide date of last access.
- TS14** Please add reference to reference list.
- TS15** Please confirm change for Tables 1, 3, 7, and 8 from Du to DU.
- TS16** Please add reference to reference list.
- TS17** Please add reference to reference list.
- TS18** Please confirm.
- TS19** Please note that units have been changed to exponential format. Please check all instances.
- TS20** Please confirm.
- TS21** Please provide a statement on how your underlying research data can be accessed. If the data are not publicly accessible, a detailed explanation of why this is the case is required. The best way to provide access to data is by depositing them (as well as related metadata) in reliable public data repositories, assigning digital object identifiers (DOIs), and properly citing data sets as individual contributions. Please indicate if different data sets are deposited in different repositories or if data from a third party were used. Additionally, please provide a reference list entry including creators, title, and date of last access. If no DOI is available, assets can be linked through persistent URLs to the data set itself (not to the repositories’ home page). This is not seen as best practice and the persistence of the URL must be secured.
- TS22** Declaration of all potential conflicts of interest is required by us as this is an integral aspect of a transparent record of scientific work. If there are possible conflicts of interest, please state what competing interests are relevant to your work.
- TS23** Please note that the funding information has been added to this paper. Please check if it is correct. Please also double-check your acknowledgements to see whether repeated information can be removed or changed accordingly. Thanks.
