

Authors' Responses

We are grateful to the thoughtful comments and suggestions from both reviewers, which greatly improved the quality of our manuscript. The point-by-point responses to these comments are listed below with referees' comments in black and our responses in blue.

Responses to Reviewer #1

Reviewer #1 (Formal Review for Author (shown to author)):

The manuscript by Xu et al. investigated molecular markers of primary biomass burning and biological aerosols during different seasons in Beijing, with focuses on size distribution and seasonal variation. Four sets of ambient aerosol samples were collected for each season using a nine-stage cascade impactor sampler, leading to a total of sixteen sets of samples for the entire measurement period. The samples were analyzed for anhydrosugars, sugar alcohols and sugars. Based on the measurement results, the authors discussed the abundances, seasonal variations and size distributions of these compounds, then estimated the contributions of biomass burning, plant debris and fungal spores to OC. In principle, the topic of this manuscript falls within the scope of Atmospheric Chemistry and Physics. However, I could not support its publication due to the following concerns.

Response:

We appreciated the valuable comments from the reviewer. Organic molecular characterization of urban aerosols has been conducted comprehensively during the past decade. However, very limited studies have been conducted for size-segregated aerosol samples. Thus, we believe that our detailed characterization of size distributions of saccharides in urban Beijing provides useful information on the biomass burning and fungal spore tracers and their patterns of size distributions and GMDs for the first time, which is worth publication in ACP.

1、 There have been many previous studies investigating the concentrations of saccharides in Beijing aerosol (e.g., Liang et al., Chemosphere, 2016, 150, 365-377). Although these studies typically relied on PM_{2.5} and/or PM₁₀ rather than size resolved samples, they generally covered much more sampling days than the present study, and therefore much more representative when discussing the abundances and seasonal variations of saccharides as well as when estimating the contributions of biomass burning, plant debris and fungal spores to OC.

Response:

We appreciated the valuable comments from the reviewer. We know that there are excellent studies focusing on the concentrations of saccharides in Beijing aerosol, while there is still a lack of knowledge on the size distribution of these organic species. In fact, most of the previous studies use high performance anion-exchange chromatography (HPAEC) (e.g. Liang et al., 2016). Here, we measured anhydrosugars, primary saccharides and sugar alcohols using GC/MS in this study. Generally, many studies were carried out based on dozens of samples by GC/MS (Fu et al., 2008; Li et al., 2018; Wan et al., 2019; Wang et al., 2006). Though we could not take into full consideration the sampling days, each set of our samples analyzed in our study are representative and adequate when discussing the abundances and seasonal variations of saccharides as well as when estimating the contributions of biomass burning, plant debris and fungal spores to OC. Each sample set corresponded to specific meteorological condition, which are listed in Table S1.

Compared to the results from previous studies, are there any new findings in Sections 3.1, 3.2 and 3.4? Maybe the authors should focus on the size distributions of saccharides, which may be able to differ the present study from previous ones.

Response:

In Section 3.1, we give a detailed description about the L/M, M/G, L/OC, and L/EC ratios according to particle size. New findings were as followed:

- (1) Higher L/M and M/G values were observed in the fine mode, which ascribed to the difference of burning substrates. Hardwood was potentially the burning substrates in the fine mode while mixture impact of hardwood and softwood burning accounted for the relatively lower L/M ratios in the coarse mode. Higher M/G ratios in the fine mode implied the increasing contributions from crop straws burning, especially in haze days.
- (2) Dust storms could induce a high L /EC ratio in the coarse mode because of coarse particles brought by dust storms and/or road dust resuspension. While decreased concentrations of EC in the coarse mode in dust storms implying that EC may derived of local emissions rather than long distance transportation of dust.

In Section 3.4, we calculated the contributions of OC from BB, plant debris and fungal spores in terms of particle size. The contributions of BB-OC were different in the fine and coarse mode. BB-OC dominated in the fine mode (>90%) and the contribution of BB-OC in the size range of 2.1–9.0 μm were with a proportion over 60%. While in a larger size range, the relative contribution were below 60% in most periods. Plant debris-derived OC and fungal

spores-derived OC mostly existed in the coarse mode. However, both of them were present in the fine mode, especially in spring and summer. Though the contribution of plant debris and fungal spores in the whole range were insignificant in cold seasons, their relative contribution in the coarse mode were comparatively high.

2、 It is completely unclear how the haze, non-haze and dust-storm periods (which were frequently mentioned throughout the manuscript) were identified.

Response:

Thanks for the reviewer for pointing out the missing data. Such information on the meteorological parameters during each sampling period is added in Table S1. The two sets (11–19 April and 4–5 May) were collected in dust storm days, the following sets (30 June–2 July, 12–14 July, 25–27 October, 6–8 November, 27–29 December and 25–27 January) were affected by haze. And the rest sets were for non-haze days.

3、 Considering the formation and evolution processes of haze events in Beijing (which could be fast; e.g., Sun et al., Sci. Rep., 2016, 6, 27151), it is questionable whether the so-called haze samples were representative (recalling that only four sets of samples were collected for each season).

Response:

In many previous studies, total suspended particles (TSP) samples were collected by a high-volume sampler, with an operating flow rate of 1.00 m³/min, approximately (Chen et al., 2013; Li et al., 2018; Wan et al., 2019). While in this study, all samples were collected using a nine-stage cascade impactor sampler (Andersen, U.S.A.) at a flow rate of 25.8 L/min from April 2017 to January 2018. Compared to the high-volume sampler, the flow rate of nine-stage cascade impactor sampler is much slower. If the sampling duration was too short, the circumstance of the concentrations of size-resolved samples below the detection line will occur. As a result, we had to prolong the sampling time to guarantee the validity of samples, especially for the non-haze days. Previous studies found that the formation and evolution processes of haze events could be fast, sometimes happened even less in one day (Sun et al., 2014; Yang et al., 2015). To completely encompass the durations of the rapid formation of haze events and the evolution of secondary organic aerosols (which not discussed in this manuscript), we considered 2 to 3 days as a reasonable sampling period. In addition, such sampling period is necessary to collect enough particles for organic analysis.

4、 Please clarify why dust storm is a major source of OC in coarse particles. This point was presented as a conclusion but was not clearly explained in the manuscript.

Response:

Thanks for the suggestion. In this manuscript, we presented “Dust storm is a major source of organic compounds in the coarse particles, which induce a remarkable size shift to the coarse mode”. This description may be a little inappropriate. We corrected the conclusion in the revised manuscript as “Dust storm greatly enhance organic aerosol concentrations and induce a remarkable size shift towards coarse sizes (see Page 16, Lines 15–16). There are several reasons for this conclusion. Firstly, in general, the concentrations of most primary saccharides sugar alcohols in each impactor stage during dust storms (17–19 April and 4–5 May) were higher than those of non-haze days (19–21 April and 5–6 May), especially for the coarse particle fraction (Figure 6–7). As for anhydrosugars and related sugars, their concentrations in the coarse mode in dust storm were higher, too. Such phenomenon could be probably attributed to strongly windblown mass coarse dust derived from large scale resuspension of dust from crustal, soil, roads or other unpaved areas, along with long-range transport of particles from north and northwest desert regions. Previous studies found that elevated concentrations of trehalose, mannitol and arabitol are generally related to resuspended soil and the outflow of dust storms (Liang et al., 2013; Rogge et al., 2007). Secondly, the GMDs of the total size range and the coarse mode particles in dust storm were larger than non-haze and haze days (Table 4–S5). Some species, such as arabitol, mannitol and inositol, their GMDs associated with coarse particles in dust storm presented a significantly increase, again suggesting the effect of dust storms on the aerosol particle size. Wang et al. (2013) also found that dust storms could act as a major source of coarse particulate matter.

5、 A minor point. Page 6, Line 28. Please check the two ratios cited here.

Response:

Thanks. We have corrected the mistake in the revised manuscript (see Page 7, Line 8–9). The revised content is as followed:

“The M/G ratios during all the periods were in a range of 1.35–2.08 with an average 1.70 (Fig. 2b). The M/G ratios maximized in autumn (1.68–1.97, 1.88) and minimized in summer (1.35–1.82, 1.59).”

Table S1. Information on the weather conditions during each of the sampling periods from April 2017 to January 2018.

Year	Season	Sampling period	Duration (min)	T (°C) ^a	RH (%) ^b	WS ^c	PM _{2.5} (µg m ⁻³) ^d	PM ₁₀ (µg m ⁻³) ^d	Weather conditions

Responses to Reviewer #2

Reviewer #2 (Formal Review for Author (shown to author)):

This paper identified and quantified the Molecular markers of biomass burning and primary biological aerosols. Atmospheric concentrations, seasonal variations and size distributions of anhydrosugars and sugar alcohols were investigated, the analysis and interpretation of the results are overall fair. The paper presents useful information about the organic aerosols. However, some additional information is still necessary for the readers to better understand this work.

Comments:

1. Three anhydrosugars, six primary saccharides and four sugar alcohols should be introduced clear in the section 1, such as the sources, property.

Response:

Thanks for the reviewer's suggestions. Before analysis, we have gave an introduction about all anhydrosugars, primary saccharides and sugar alcohols in Sections 3.1 and 3.2. Hence, we added the following sentences in the revised manuscript as a supplemental description in Section 1.

“Amongst sugar alcohols, mannitol and arabitol are the primary ones” (see Page 2, Line 22).

“Sparse data about erythritol and inositol can be found in the literature. Recently, these two species were reported as having similar sources as other sugar alcohols, such as arabitol and mannitol” (see Page 2, Line 24).

“On the basis of difference of burning materials (e.g. deciduous leaves and grass), BB is classified as open-field burning in forests, savannas, croplands and residential heating and cooking (Akagi et al., 2011; Yan et al., 2006)” (see Page 3, Line 2).

“Because levoglucosan is chemically stable in the air” (see Page 3, Line 5).

“The levoglucosan to mannosan (L/M) ratio varies with aerosols generated by burning of hardwood, softwood and agricultural waste, with a ratio of 13–27, 2.5–5.8 and 25–55.7, respectively” (see Page 3, Line 6–7).

2. In the section 2.1, a brief introduction to the surrounding environment of sampling sites should be provided, and the details about the sampling time should be described, including start time, end time, and duration.

Response:

We have added the following paragraph in the revised manuscript (see Page 3, Line 18). “Institute of Atmospheric Physics (IAP), Chinese Academy of Sciences locate on the north side of Beijing city, which is considered be a representative urban area for a mixed district of teaching, residential and commercial areas. Urban aerosol samples collected here are influenced by anthropogenic (transport emissions, cooking operations etc.) and natural sources (e.g. soil dust, plant debris and microorganisms).”

The details about the sampling time (start time, end time, and duration) are listed in Table S1.

3. There are only four cases (less than 10 days) in each season, more field measurement estimation could decrease the influence produced by accidental elements, making the results more convincing.

Response:

Thanks for the reviewer for pointing this deficiency. Offline experiments allow investigators to repeat the process under controlled conditions to analyze the emission process, influencing factors and mechanisms (Chen et al., 2012; Zhang et al., 2011). The concentrations of organic tracers, such as compounds analyzed in our study were measured offline using GC/MS and OC/EC were also determined offline using a thermal/optical carbon analyzer (model RT-4, Sunset Laboratory Inc., USA). While field measurements are preferable and realistic since the field studies can reflect the real process at random conditions (Roden et al., 2006). It is realized that more online studies are required in our study. During sampling, we documented basic information about meteorological data, such as relative humidity, wind scale and so on simultaneously (see Table S1). These field measurements do support our conclusion. For example, information about $PM_{2.5}$ and PM_{10} defined the weather conditions precisely; higher relative humidity found in haze days do prefer hygroscopic growth, coagulation and/or condensation fine particle, resulting larger GMDs in the fine mode.

4. Lots of ratios of individual anhydrosugars were showed in section 3.1.2, the result was almost consistent with previous results, and the conclusion should be summarized and classified, so that the author can better understand.

Response:

Thanks for the reviewer's suggestion. We adjusted the order of the paragraphs and some sentences in Section 3.1.2 to arrange a clear and logical order. The first three paragraphs described the features of ratios of individual anhydrosugars and OC/EC, respectively. A new paragraph was added (the fourth paragraph) to give some comparison with other studies. The rest paragraphs were about ratios according to particle size.

The fourth paragraph is as followed:

“The L/M, L/OC and L/EC ratios calculated in this study were compared with those reported for other Asian cities in recent studies. The L/M ratios showed different seasonal and spatial distributions among different cities. Those reported in Nepal (16.3 ± 5.96) were much higher than our study (Wan et al., 2019). Study in Okinawa found a L/M ratio of 10.7 ± 6.1 and exhibited a similar seasonal trend to our study (Zhu et al., 2015a). Lower ratios of L/M suggested that more burning substrates were softwood in Beijing. While in previous studies in Beijing, lower ratios L/M in winter were observed (Cheng et al., 2013). Higher ratio of L/M in our study may ascribe to the reduced use of coal in recent years in Northern China. Coal combustion is also a potential source of levoglucosan, leading to a lower ratio of L/M (Yan et al., 2018). In comparison to annual mean L/OC ratios in Guangzhou and Zhaoqing in the PRD region (10.8×10^{-3} and 27.5×10^{-3} , respectively) (Ho et al., 2014), the lower values of L/OC in Beijing were potentially associated with the less extensive burning activities under the prohibition of open agricultural residue burning. Though indicating a similar seasonal trend to Okinawa, the L/EC ratios in Beijing were much higher than those in Okinawa. Besides the more release of levoglucosan in Beijing, such result may also imply that EC was associated with other sources, such local transport emission and coal combustion, while EC in Okinawa might represent a regional background level (Zhu et al., 2015a).” (see Page 7, Line 22 to Page 8, Line 7).

5. The size distribution of Anhydrosugars, Primary saccharides and Sugar alcohols was analyzed in Section 3.3, a size shift towards large particles and large GMDs in the fine fraction ($< 2.1 \mu\text{m}$) was detected during the hazy days. The author ascribes them to higher

humidity but did not analyze the impact of RH on size distribution. Please give more discussion.

Response:

Thanks. Herner et al (2006) found that the particle size can be modified by chemical reactions, condensation/evaporation, coagulation with other particles, and activation during high humidity, wet and dry deposition. Anhydrosugars, primary saccharides and sugar alcohols are important parts of atmospheric primary organic aerosols (POA), which are highly water-soluble compared with fossil fuel derived particles (Reid et al., 2005). Larger GMDs of primary carbonaceous particles in the fine mode in haze days than in non-haze days have been observed in previous and our studies. One reason for that is enhanced hygroscopic growth of the airborne particles under relatively higher humidity. As exhibited in Table S1, haze days were characterized by higher relative humidity in our study. Wang et al (2011) found that all fine mode of WSOC showed a larger GMD in the hazy days. Kang et al (2016) also discovered that the fine mode GMDs of aliphatic hydrocarbons generally larger in haze samples due to higher relative humidity. In addition, the increase concentrations of airborne aerosols could increase the overall coagulation rate, resulting in faster rate of collisions between particles and formation of larger particles (Herner et al., 2006). Table 2 shows that the concentrations of anhydrosugars, primary saccharides and sugar alcohols were much higher in haze days, which were responsible for the larger GMDs in the fine mode and a size shift towards large particles. (see Page 14, Lines 12-19).

A list of all relevant changes made in the manuscript

1. Information on the meteorological parameters during each of the sampling periods in detail are added and presented in Table S1 in supplementary information.
2. Extra description are provided about anhydrosugars, primary saccharides and sugar alcohols in Section 1 in the revised manuscript.
3. Some missing introductions and information are added in the section 2.1.
4. Ratios of individual anhydrosugars and OC/EC are summarized and classified in Section 3.1. Errors about L/M ratio are corrected in the revised manuscript.
5. Explanation about “Dust storm greatly enhance organic aerosol concentrations and induce a remarkable size shift towards coarse sizes” are added in the revision.

Molecular markers of biomass burning and primary biological aerosols in urban Beijing: Size distribution and seasonal variation

Abstract. Biomass burning and primary biological aerosol particles account for an important part of urban aerosols. Floods of studies have been conducted on the chemical compositions of fine aerosols (PM_{2.5}) in megacities where the haze pollution is one of the severe environmental issues in China. However, little is known about their size distributions in atmospheric aerosols in the urban boundary layer. Here, size-segregated aerosol samples were collected in Beijing during haze and clear days from April 2017 to January 2018. Three anhydrosugars, six primary saccharides and four sugar alcohols in these samples were identified and quantified by gas chromatography/mass spectrometry (GC/MS). Higher concentrations of a biomass burning tracer, levoglucosan, were detected in autumn and winter than other seasons. Sucrose, glucose, fructose, mannitol and arabitol were more abundant in the bloom and glowing seasons. Particularly high level of trehalose was found in spring, which was largely associated with the Asian dust outflows. Anhydrosugars, xylose, maltose, inositol and erythritol are mainly existed in the fine mode (<2.1 μm), while the others showed the coarse mode privilege. The concentrations of measured tracers of biomass burning particles and primary biological particles in the haze events were higher than those in the non-hazy days, with an enrichment factor of 2–10. Geometric mean diameters (GMD) of molecular markers of biomass burning and primary biological aerosols showed that there was no significant difference in the coarse mode (>2.1 μm) between the haze and non-haze samples, while a size shift towards large particles and large GMDs in the fine fraction (<2.1 μm) was detected during the hazy days, which highlights that the stable meteorological conditions with high relative humidity in urban Beijing may favor the condensation of organics onto coarse particles. The contributions of reconstructed primary organic carbon (POC) by tracer-based methods from plant debris, fungal spores, and biomass burning to aerosol OC in the total mode particles were in the ranges of 0.09–0.30% (on average 0.21%), 0.13–

1.0% (0.38%) and 1.2–7.5% (4.5%), respectively. This study demonstrates that the contribution of biomass burning was significant in Beijing throughout the whole year with the predominance in the fine mode, while the contributions of plant debris and fungal spores dominated in spring and summer in the coarse mode, especially in the size of $>5.8\ \mu\text{m}$. Our observations demonstrate that the sources, abundance, and chemical composition of urban aerosol particles are strongly size dependant in Beijing, which are important to better understand their environmental and health effects of urban aerosols and should be considered in air quality and climate models.

1 Introduction

Organic aerosols (OAs), one of the primary contributors of atmospheric aerosol, account for 20–90% of submicron aerosols. Numerous studies found that OAs have significant impact on the hydrological cycle and global climate (Jimenez et al., 2009; Kanakidou et al., 2005; Ng et al., 2010; Pöschl, 2005), as well as human health (Nel, 2005). Concentration, composition and size of OAs are vital factors for such adverse impact (Tremblay et al., 2007). Fine particles are more detrimental to human health due to the ability to deposit into deep parts of lungs (Nemmar et al., 2002). In addition, due to distinct sources of fine and coarse particles, particle size of organic species existing in could act as a tool to identify OA sources and to assess health hazard.

Primary biological aerosol particles (PBAP) and biomass burning (BB) are two major source of atmospheric primary organic aerosols (POA). PBAPs those are directly emitted into the atmosphere include bacteria, plant debris, fungal spores, fragments of plants and animals (Després et al., 2012; Fang et al., 2018; Fu et al., 2012; O'dowd et al., 2004; Samaké et al., 2019). These PBAPs not only affect the hydrological cycle and climate change by means of acting as cloud and ice nuclei but also jeopardize human health (Fröhlich-Nowoisky et al., 2012; Fröhlich-Nowoisky et al., 2016; Humbal et al., 2018; Rajput et al., 2018). Although recent studies have revealed the abundance and size distributions of PBAPs, quantitate studies regarding their emission sources and relative contributions remained poorly known (China et al., 2018; Di Filippo et al., 2013; Huffman et al., 2010; Jia et al., 2010; Tobo et al., 2013). Primary saccharides have been used as tracers for PBAP (Fu et al., 2013; Medeiros et al., 2006; Wan et al., 2007). Sucrose, glucose and fructose are predominantly derived from plant materials, such as pollen, fruit, and leaves (Pacini, 2000; Puxbaum and Tenze-Kunit, 2003). Amongst sugar alcohols, mannitol and arabitol are the primary ones. Mannitol, arabitol, and trehalose have been recognized as tracers of airborne fungi (Bauer et al., 2008a; Fu et al., 2016; Samaké et al., 2019; Verma et al., 2018). Sparse data about erythritol and inositol can be found in the literature. Recently, these two species were reported as having similar sources as other sugar alcohols, such as arabitol and mannitol (Chen et al., 2013).

Biomass burning (BB), as a substantial source of particles in the atmosphere, generate plenty of POA (Andreae and Merlet, 2001;Wan et al., 2019;Yan et al., 2015). On the basis of difference of burning materials (e.g. deciduous leaves and grass), BB is classified as open-field burning in forests, savannas, croplands and residential heating and cooking (Akagi et al., 2011). Levoglucosan, generated by the thermal decomposition of cellulose (Simoneit, 2002;Simoneit et al., 1999), is regarded as the most typical tracer for BB because levoglucosan is chemically stable in the air (Simoneit et al., 2004;Simoneit et al., 1999). Isomeric ratios of individual anhydrosugars has been applied to distinguish biofuel sources (Engling et al., 2006;Fine et al., 2004a;Sheesley et al., 2003). The levoglucosan to mannosan (L/M) ratio varies with aerosols generated by burning of hardwood, softwood and agricultural waste with a ratio range of 13–27, 2.5–5.8 and 25–55.7, respectively (Engling et al., 2006;Fu et al., 2012;Sang et al., 2013;Sheesley et al., 2003).

As a highly developed economic zone, Beijing has been facing serious air pollution. Though the government have made great efforts to improve the air quality in Beijing, haze events still appear frequently, especially in winter (Cheng et al., 2016;Zheng et al., 2015). Moreover, air pollution, accompanied with high abundances of fine particles, has become a serious environment problem in China's cities and adjacent areas. There have been many studies on the composition and sources of aerosols in Beijing (Yang et al., 2016). However, few studies have been conducted regarding the size distribution, contribution and processes of POAs in different seasons in Beijing. Thus, research on chemical compositions and size distributions of PBAP and BB in Beijing are vital in terms of regional air quality.

In this study, size-segregated aerosols were sampled in Beijing from April 2017 to January 2018. Molecular characteristics, size distributions, and seasonal trends of anhydrosugars and other saccharides were investigated. Concentrations and contributions of plant debris, fungal spores and biomass burning derived OC were estimated according to the tracer methods. The variations in size distributions of organic species in aerosols in different seasons were also assessed.

2 Experimental methods

2.1. Sample collection

All samples were collected using a nine-stage cascade impactor sampler (Andersen, U.S.A.) at a flow rate of 25.8 L/min from April 2017 to January 2018. The sampler was put on a second-story building rooftop in the Institute of Atmospheric Physics, Chinese Academy of Sciences in Beijing, China (39°58'28"N, 116°22'16"E). The institute of Atmospheric Physics (IAP), Chinese Academy of Sciences is located on the north side of Beijing city, which is considered to be a representative urban area for a mixed district of traffic, residential and commercial areas. Urban aerosol samples collected here are influenced by both anthropogenic (e.g. traffic and cooking emissions) and natural sources (e.g. soil dust, plant debris, and

5 **microorganisms**). Before sampling, the quartz fiber filters were combusted at 450°C for 6 h. The cutoff sizes are in the following sequence: >9.0, 9.0–5.8, 5.8–4.7, 4.7–3.3, 3.3–2.1, 2.1–1.1, 1.1–0.7, 0.7–0.4, and <0.4 µm. Four sets of size-segregated aerosol samples per season and thus sixteen sets (i.e., 144 samples) were obtained throughout the year. Blank filters were obtained for each season for quality control. Specific information including weather conditions, sampling periods and sample numbers was summarized in Table S1. All samples were stored at a –20 °C in freezer prior to analysis.

2.2. Sample extraction and derivatization

10 Using a disinfected scissor, each filter aliquot (~6.4 cm²) was cut and extracted three times with dichloromethane/methanol mixture (2:1, v/v) under ultrasonic agitation for 10 minute. After filtering, the solvent extracts were concentrated with a rotary evaporator and a stream of filtered dry nitrogen gas. The extracts were converted to their trimethylsilyl derivatives using mixture of 25 µL of N,O-bis-(trimethylsilyl) trifluoroacetamide (BSTFA) with 1% trimethylsilyl chloride and 5 µL of pyridine for 3 h at 70°C (Fu et al., 2008). The derivatives were diluted through adding 30 µL internal standard (C₁₃ *n*-alkane, 1.43 ng µL⁻¹), and then were stored in a freezer before GC/MS analysis.

2.3. Gas chromatography/mass spectrometry measurement

15 An Agilent model 7890 GC coupled to Agilent model 5975C mass-selective detector (MSD) was used to analyze organic compounds of these samples. **Two** µL of pretreatment sample was injected and separated in a fused silica capillary column. The column temperature program were optimized with a serial of procedures: start and hold for 2 min at 50 °C, increase to 120 °C with a pace at 15 °C min⁻¹, then raise to 300 °C at 5 °C min⁻¹, and keep isothermal at 300 °C for 16 min. The mass spectrometer was operated on Electron Ionization (EI) mode at 70 eV and scanned from 50 to 650. Mass spectral data were acquired and processed with the Chemstation software. Individual compound was identified by comparing mass spectra with those of authentic standards. The data reported here were corrected for the field blanks.

2.4. Measurements of OC and EC

20 Organic carbon (OC) and elemental carbon (EC) were measured using a thermal/optical carbon analyzer (model RT-4, Sunset Laboratory Inc., USA). A punch (17-mm diameter) of each aliquot or blank filter was used for the determination. The concentrations of OC and EC here were all corrected for field blanks.

2.5. Backward trajectories and fire counts

To better characterize the features and origins of air masses in Beijing, **three-day** backward trajectory analyses were conducted using the HYSPLIT4 model (Draxler and Rolph, 2013) for all the dust storm and haze periods in our study. Backward trajectories were calculated at an altitude of 500m above ground level. Influence of BB in urban Beijing are demonstrated by fire spots acquired from the MODIS website (<https://earthdata.nasa.gov/earth-observation-data/near-real-time/firms>). The crowding level of the fire spots here represented the scales and intensity of BB. Cluster analyses were applied for typical dust storm and haze events in the present study (Fig.S1).

3 Results and discussion

3.1. Abundances and seasonal variations in anhydrosugars

3.1.1 Anhydrosugars

Levoglucosan, a typical tracer of biomass burning, is formed from the thermal decomposition of cellulose during vegetation burning activities, which has been detected in many urban as well as rural areas (Cheng et al., 2013; Chowdhury et al., 2007; Fu et al., 2010; Wang et al., 2006; Yttri et al., 2007). As another important type of anhydrosugars, isomers of levoglucosan, including mannosan and galactosan, are exclusively derived from the pyrolysis of hemicellulose (Fraser and Lakshmanan, 2000; Simoneit et al., 1999; Simoneit, 2002). The concentrations of and temporal variations in anhydrosugars (i.e., Levoglucosan, mannosan and galactosan) are shown in Table 1 and Fig. 1. Among the three anhydrosugars, levoglucosan was the predominant compounds ($80.1\text{--}1230\text{ ng m}^{-3}$, 365 ng m^{-3}), which was one order of magnitude higher than mannosan ($8.41\text{--}168\text{ ng m}^{-3}$, 46.8 ng m^{-3}) and galactosan ($5.09\text{--}108\text{ ng m}^{-3}$, 27.6 ng m^{-3}). The concentration of levoglucosan was the highest in winter, followed by autumn, spring, and summer. Similar seasonality has been documented in several studies in Beijing (Chen et al., 2013; Liang et al., 2016). The abundances in summer and winter was comparable with previous studies (Cheng et al., 2013; Zhang et al., 2008). Mannosan and galactosan displayed a similar seasonal trend. Resemble to levoglucosan, total anhydrosugars peaked in winter ($250\text{--}1503\text{ ng m}^{-3}$, 678 ng m^{-3}) and bottomed in summer ($87.8\text{--}246\text{ ng m}^{-3}$, 137 ng m^{-3}). The most abundant anhydrosugars in winter is possibly due to the enhanced sources from open-field biomass and domestic burning, together with frequent development of inversion layers in winter. Interestingly, the concentrations of levoglucosan in autumn ($224\text{--}759\text{ ng m}^{-3}$, 501 ng m^{-3}) and winter ($131\text{--}1230\text{ ng m}^{-3}$, 559 ng m^{-3}) were much higher than those in summer ($80.1\text{--}203\text{ ng m}^{-3}$, 114 ng m^{-3}). Except for the decrease of biomass burning activities, a higher level of OH radical in summer on account of high temperature and intensive ultraviolet light (Stone et al., 2012) may lead to the photochemical degradation of levoglucosan (Arangio et al., 2015b; Hennigan et al., 2010; Lai et al., 2014; Mochida et al., 2010).

Concentrations of individual anhydrosugars in haze days were much higher than those in non-haze days in each season (Table 2). Moreover, the level of anhydrosugars (2310 ng m⁻³, average) in winter was one order of magnitude higher than the other seasons (302 ng m⁻³, 171 ng m⁻³, 798 ng m⁻³ for spring, summer and autumn, respectively). Such trends indicated that the haze samples were largely influenced by biomass burning emissions in Beijing, consistent with previous studies in Beijing (Zhang et al., 2017) and other regions such as New Delhi (India), Tasmania (Australia) and Kathmandu (Nepal) (Fu et al., 2010; Reisen et al., 2013; Wan et al., 2019).

During spring dust storm periods, air masses primarily originated from the middle-to-north Asia (MNA) (Fig. S1a–1b). Specifically, 71–75% of air masses originated from the west-to-central Russia and passed through Mongolia, and finally arrived in Beijing. Such phenomenon likely attributed to the influence of Asian outflow. Compared to April 17 to 19, fewer fire spots were found in the movement route of air mass in May 4 to 5, that can explain the lower levels of anhydrosugars in the aerosols. As seasons came to summer, the influence of air mass from central China was strengthened. In the meantime, frequent straw burning events are found in these regions due to the harvest season (Fig. S1c–1d). However, this emission had an insignificant impact on the anhydrosugars considering the relatively low concentrations. In winter haze periods, 53–100% of the air masses originated from the north China, and the rest fraction are originating from the Mongolia. Interestingly, much fewer fire spots could be observed (Fig. S1g–1h) compared to summer and autumn. In winter, domestic burning and small-scale open-field burning are much intensive than other seasons. However, these two burning activities are hardly detectable by satellite, which could account for the much higher abundances of anhydrosugars.

Pearson correlations among anhydrosugars and OC, EC were also studied (Table S2). Levoglucosan displayed a positive correlation with mannosan ($r = 0.99$, $p < 0.001$) and galactosan ($r = 0.98$, $p < 0.001$). Such consistent trends suggested that the anhydrosugars were emitted from similar sources. EC is considered to be closely related with BB (Akagi et al., 2011). Positive correlations between EC and levoglucosan ($r = 0.45$, $p < 0.001$), mannosan ($r = 0.43$, $p < 0.001$) and galactosan ($r = 0.43$, $p < 0.001$) indicate that BB was a major source of the anhydrosugars in urban Beijing aerosols.

3.1.2 Ratios of L/M, M/G, L/OC, and L/EC

Previous surveys found that levoglucosan/mannosan (L/M) ratios vary with biofuel burning sources, those from hardwood, softwood and crop residues are often in ranges of 13–27, 2.5–5.8 and 25–55.7, respectively (Engling et al., 2006; Fine et al., 2004b; Krůmal et al., 2010; Sheesley et al., 2003). The L/M values are exhibited in Table1 and Fig.2. The annual L/M ratios varied within a narrow range over the sampling periods (7.62–8.64, 8.27), indicating a mixture contribution of softwood burning and hardwood burning. The L/M ratios were relatively higher in winter (7.30–11.8, average 8.64) and spring (6.34–11.8, 8.49), consistent with those obtained in previous studies (Zhu et al., 2015a). This probably associated with

open-field biomass burning, e.g. agricultural residues and deciduous leaves. The L/M ratios were smaller in summer and autumn, along with a higher level of M/G ratios than those in winter and spring. These results were likely attributed to the higher proportion of softwood burnings and the degradation of levoglucosan (Arangio et al., 2015a; Lai et al., 2014; Mochida et al., 2010).

The ratio of mannosan to galactosan (M/G) is used as an auxiliary means to distinguish the burning substrates because galactosan is more abundant than mannosan in combustion smokes of crop straws, grasses, and briquettes (Fabbri et al., 2009; Oros et al., 2006; Vicente et al., 2018). The M/G ratios during all the periods were in a range of 1.35–2.08 with an average 1.70 (Fig. 2b). The M/G ratios maximized in autumn (1.68–1.97, 1.88) and minimized in summer (1.35–1.83, 1.59). The lower ratios in summer haze days (June 30 to July 2) were in agreement with the former studies during summer BB periods (Engling et al., 2006). The higher ratios in typical summer time in July (July 14 to July 16 and July 21 to July 23) were consistent with previous results in North China Plain and Western United States (Fine et al., 2004b; Fu et al., 2008). The M/G ratios ranged from 1.49 to 1.89 (average 1.62) in winter, consistent with the higher abundance of galactosan over mannosan associated with the BB products from crop wastes in the North China Plain (Fu et al., 2008).

The ratios of levoglucosan to OC (L/OC) and EC (L/EC) are applied to evaluate the impact of BB to airborne particles and the possible photochemical aging of levoglucosan (Feng et al., 2007; Mkoma et al., 2013; Zhang et al., 2008). The ratios of L/OC showed a clear temporal trend (annual mean 3.67×10^{-3} , Fig. 2c) with the highest values in winter ($2.79\text{--}9.15 \times 10^{-3}$), followed by autumn ($3.46\text{--}5.21 \times 10^{-3}$), spring ($0.69\text{--}6.89 \times 10^{-3}$) and summer ($0.73\text{--}1.14 \times 10^{-3}$). Similar seasonal trends have been reported in previous studies (Feng et al., 2007; Ho et al., 2014). EC is highly related to the activities of coal combustion, vehicle exhaust and biomass burning (Akagi et al., 2011; Lu et al., 2011; Waked et al., 2014). The L/EC ratios showed a similar variation pattern to the L/OC ratios. The L/EC ratios exhibited maxima in autumn ($45\text{--}107 \times 10^{-3}$, 83×10^{-3}), followed by winter ($34\text{--}118 \times 10^{-3}$, 73×10^{-3}), spring ($20\text{--}53 \times 10^{-3}$, 36×10^{-3}) and summer ($12\text{--}25 \times 10^{-3}$, 17×10^{-3}), indicating more contribution of BB to aerosols in cold seasons.

The L/M, L/OC and L/EC ratios in this study were compared with those reported for other Asian cities in recent studies. The L/M ratios showed different seasonal and spatial distributions among different cities. Those reported in Nepal (16.3 ± 5.96) were much higher than our study (Wan et al., 2019). A previous study in Okinawa found a L/M ratio of 10.7 ± 6.1 and exhibited a similar seasonal trend to our study (Zhu et al., 2015a). Lower ratios of L/M suggested that more burning substrates were softwood in Beijing. While in previous studies in Beijing, lower L/M ratios in winter were observed (Cheng et al., 2013). Higher ratios of L/M in our study may ascribe to the reduced use of coal in recent years in North China. Coal combustion is also a potential source of levoglucosan, leading to a lower ratio of L/M (Yan et al., 2017). In comparison to annual mean L/OC ratios in Guangzhou and Zhaoqing in the PRD region (10.8×10^{-3} and 27.5×10^{-3} , respectively) (Ho et al.,

2014), the lower values of L/OC in Beijing were potentially associated with the less extensive burning activities under the prohibition of open agricultural residue burning. Although the seasonal trend is similar to that of Okinawa, the L/EC ratios in Beijing were much higher than those in Okinawa. Besides the high abundance of levoglucosan in Beijing, these results may also imply that EC was associated with other sources, such as local transport emission and coal combustion, while EC in Okinawa might represent a regional background level (Zhu et al., 2015a).

The L/M, M/G, L/OC, and L/EC ratios according to particle size are presented in Fig. 3. Higher L/M values were observed in fine particles during non-haze days, which were 1.02–1.71 times higher than those in coarse modes. In contrast, the L/M ratios did not vary significantly according to particle size in the haze days. The L/M values in fine modes during haze periods were slightly higher than those in coarse modes. The ratios between fine and coarse modes were close to unity. The elevated L/M ratios in fine modes suggested that hardwood was potentially the burning substrates, while the relatively lower L/M ratios in coarse modes indicated the mixture impact of hardwood and softwood burning. The M/G ratios were also higher in fine modes than coarse modes with a factor of 1.0–2.5, suggesting large impact of biomass burning from crop straws and grasses in fine modes. Moreover, such activities were more pronounced in haze days than non-haze days, implying the increasing contributions from crop straws burning in haze days.

The L/OC ratios showed a uniform dependence on particle size of much higher in fine modes during all sampling periods. The average ratios of L/OC (fine modes) to L/OC (coarse modes) for four seasons were 6.31, 4.49, 11.3 and 9.47, respectively. Such a pattern was consistent with the finding that levoglucosan mostly exists in fine modes (Simoneit and Elias, 2001). The L/OC ratios in summer were a magnitude lower than other seasons that likely attributed to the less biomass burning emissions in Beijing urban areas.

The L/EC ratios also exhibited a clear pattern with high values in fine modes and low values in coarse modes, similar to the L/OC ratios. Cao et al (2005) found that the EC in PM₁₀ was more abundant than in PM_{2.5}, while most levoglucosan was in fine modes, resulting in low L/EC ratios in coarse modes. Nevertheless, a high L /EC ratio was observed in the coarse modes during 4–5 May when Beijing encountered the most severe dust storm in that spring. Unlike the other samples, levoglucosan accounted for an unexpectedly high proportion in the coarse modes (discussed in 3.3.1). Meanwhile, the concentrations ($23\text{--}57\times10^{-3}\text{ }\mu\text{g m}^{-3}$) of EC in coarse modes were much lower in the dust period than in non-haze periods ($30\text{--}211\times10^{-3}\text{ }\mu\text{g m}^{-3}$) during spring. As a consequence, low level of EC and high level of levoglucosan lead to the high L/EC ratio in the coarse mode.

3.2. Abundances and seasonal variations in primary saccharides and sugar alcohols

3.2.1 Primary saccharides

The concentrations of primary saccharides and sugar alcohols in four seasons are exhibited in Table 1 and Fig. 4. The concentrations of primary saccharides and sugar alcohols averaged 620 ng m^{-3} and 139 ng m^{-3} , respectively. Except maltose and xylose, other primary saccharides exhibited higher abundance in spring and summer compared to autumn and winter. Among these compounds, sucrose ($30.8\text{--}1590 \text{ ng m}^{-3}$, 267 ng m^{-3}) was the most abundant one, followed by glucose ($38.9\text{--}502 \text{ ng m}^{-3}$, 162 ng m^{-3}) and fructose ($7.97\text{--}72.5 \text{ ng m}^{-3}$, 30.1 ng m^{-3}).

Fructose and glucose are mainly derived from plant fragments (e.g. bark, leaves), pollen, lichen and soil dust (Dahlman et al., 2003;Fu et al., 2012;Pacini, 2000;Vesprini et al., 2002;Zhu et al., 2015b). Glucose maximized in spring ($107\text{--}502 \text{ ng m}^{-3}$, 255 ng m^{-3}), followed by summer ($184\text{--}279 \text{ ng m}^{-3}$, 234 ng m^{-3}), winter ($60.0\text{--}139 \text{ ng m}^{-3}$, 86.4 ng m^{-3}) and autumn ($38.9\text{--}93.3 \text{ ng m}^{-3}$, 71.2 ng m^{-3}). Fructose varied with a similar trend. High concentrations in spring is likely coincided with agricultural tilling activities (Simoneit et al., 2004) and comparably active vegetation in warmer season. The significant correlation between glucose and fructose ($r = 0.81$, $p < 0.001$) further indicated that these two compounds originated from common sources (Table S3), in consistence with the results of previous studies in East Asian areas (Chen et al., 2013;Fu et al., 2012;Zhu et al., 2015b). Studies found good correlations between fructose, glucose with OC in biomass burning aerosols over Amazonia pasture site (Graham, 2002), different with this study (Table S3), which suggested that biomass burning made minor contribution to glucose and fructose in Beijing.

Sucrose, a major constituent of pollen, peaked in spring as the blossom booming season, coincide well with previous studies(Fu et al., 2012;Pacini, 2000;Yttri et al., 2007;Jia et al., 2010)(Fu et al., 2012;Pacini, 2000;Yttri et al., 2007;Jia et al., 2010)(Fu et al., 2012;Pacini, 2000;Yttri et al., 2007;Jia et al., 2010)(Fu et al., 2012;Pacini, 2000;Yttri et al., 2007;Jia et al., 2010) . A previous study reported that sucrose, like glucose and fructose, could abundantly emit into the air along with the increased biological activities (Rogge et al., 2007). Accordingly, sucrose was much more predominant in spring ($266\text{--}1594 \text{ ng m}^{-3}$, 743 ng m^{-3}), then sharply declined in winter ($87.7\text{--}209 \text{ ng m}^{-3}$, 137 ng m^{-3}) and summer ($30.8\text{--}275 \text{ ng m}^{-3}$, 114 ng m^{-3}). Interestingly, sucrose minimized in autumn ($32.6\text{--}115 \text{ ng m}^{-3}$, 73.3 ng m^{-3}) rather than in summer. This likely attributed to the agricultural activities in summer. In June and July, tilling activities make crop (e.g., wheat) roots expose to the air frequently, conducting to the release of sucrose from the roots into the atmosphere.

Trehalose is present in various microorganisms (e.g., fungi and bacteria), some higher plants and invertebrates (Medeiros et al., 2006). In this study, trehalose exhibited a high abundance in spring ($51.8\text{--}559 \text{ ng m}^{-3}$, 199 ng m^{-3}) and peaked in summer ($101\text{--}378 \text{ ng m}^{-3}$, 232 ng m^{-3}), sharply reduced by nearly 75% in autumn and winter. Trehalose is a useful tracer for soil input to the atmosphere in regions related to agricultural activities

and dust storm (He et al., 2001; Simoneit et al., 2004). Thus, the concentration of trehalose was considerably high in a dust period during 4-5 May (559 ng m⁻³) and haze days during 30 June to 2 July and 12-14 July (Fig. 4h).

Xylose and maltose exhibited a totally different seasonal trend from other primary saccharides. Xylose showed high levels in autumn (10.2–29.7 ng m⁻³, 22.2 ng m⁻³) and winter (11.0–32.7 ng m⁻³, 20.7 ng m⁻³). Xylose exists in most woods and straw as a major constituent of hemicellulose (Chen et al., 2013; Sullivan et al., 2011). The biomass burning activities in Beijing likely caused the elevated abundance of xylose, given the positive correlation between xylose and levoglucosan ($r = 0.86$, $p < 0.001$). Maltose, a microbial degradation product of starch, showed a similar seasonal pattern with xylose (Medeiros et al., 2006) and positively correlated with levoglucosan ($r = 0.89$, $p < 0.001$). These results suggest that biomass burning was a major source of xylose and maltose.

3.2.2 Sugar alcohols

The sum of sugar alcohols (29.8–418 ng m⁻³, 139 ng m⁻³) was much lower than primary saccharides and anhydrosugars (Table 1). In the detected compounds, mannitol showed the highest level (3.64–259 ng m⁻³, 58.4 ng m⁻³), followed by arabitol (5.35–149 ng m⁻³, 36.7 ng m⁻³), inositol (5.05–69.2 ng m⁻³, 21.8 ng m⁻³) and erythritol (3.16–44.1 ng m⁻³, 21.8 ng m⁻³). Both mannitol and arabitol exhibited maxima in summer (65.1–259 ng m⁻³, 151 ng m⁻³ and 43.4–149 ng m⁻³, 79.6 ng m⁻³, respectively). Mannitol minimized (3.64–37.7 ng m⁻³, 20.4 ng m⁻³) in autumn and arabitol minimized in winter (5.52–33.8 ng m⁻³, 14.1 ng m⁻³). Mannitol significantly correlated with arabitol during the whole sample period ($r = 0.83$, $p < 0.001$), indicating they are generally related to common sources. Mannitol and arabitol primarily derive from airborne fungal spores (Fu et al., 2010; Medeiros et al., 2006; Zhang et al., 2010) and detritus of mature leaves (Pashynska et al., 2002). In summertime, fungal spores can be derived from multiple sources (e.g., plants, vegetation decomposition and agricultural activities); while in autumn and winter, fungal spores are mainly suspended from exposed surfaces (Liang et al., 2013). Moreover, a previous study point out higher leaf area index and atmospheric water vapor would facilitate the emission of mannitol (Heald and Spracklen, 2009). Together with that study, mannitol and arabitol in our study may closely related to the activities of the terrestrial biosphere.

Erythritol and inositol was less abundant of the calculated sugar alcohols. The abundance of erythritol was the lowest in spring (3.16–15.8 ng m⁻³, 9.92 ng m⁻³) and the highest in summer (13.8–44.1 ng m⁻³, 30.2 ng m⁻³), and maintained at a relative high level in autumn and winter (11.1–33.0 ng m⁻³, 22.3 ng m⁻³ and 10.7–41.6 ng m⁻³, 24.9 ng m⁻³, respectively). Temporally, erythritol correlated well with levoglucosan ($r = 0.50$, $p < 0.001$), indicating a potential contribution from BB (Table S3). Results on inositol in aerosols was seldom reported (Chen et al., 2013). In this study, inositol showed maxima (20.7–69.2 ng m⁻³, 41.5 ng m⁻³) in spring and minima (5.05–26.0 ng m⁻³, 12.4 ng m⁻³) in winter. Inositol was positively correlated

with trehalose ($r = 0.65$, $p < 0.001$) and exhibited a similar temporal variation with other sugar alcohols, suggesting developing leaves and plant debris may be a potential source.

3.3. Size distribution

3.3.1 Anhydrosugars

The size distributions of anhydrosugars for each sampling period are exhibited in Fig. 5. The concentrations of anhydrosugars in fine ($< 2.1 \mu\text{m}$) and coarse ($\geq 2.1 \mu\text{m}$) mode and whole size ranges are listed in Table 3. Among the class of anhydrosugars, levoglucosan was approximately an order of magnitude higher than other compounds in the fine and coarse particles. Levoglucosan is initially emitted from the flame, subsequently condenses onto preexisting particles as temperature decrease, and thus exists mostly in fine particles (Simoneit and Elias, 2001). In this study, levoglucosan showed a unimodal size distribution with a peak at the ranges of $0.4\text{--}2.1 \mu\text{m}$ during most sampling periods (Figs. 5a–5d). The concentrations of levoglucosan in the fine mode were 1.8–9.3 times of those in the coarse mode. Mannosan and galactosan also showed a size distribution pattern similar to levoglucosan during all sampling periods.

Interestingly, all three anhydrosugars exhibited a unimodal size distribution in the coarse mode during the most serious dust storm period (4 to 5 May). Such distribution behaviors highlighted the significant contribution of dust storm to the loading of organic aerosols (OA) in Beijing. In a dust storm, strongly windblown coarse particles from a large-scale resuspension from crustal, soil, roads or other unpaved areas, along with long-range transport of particles from north and northwest desert regions could induce a remarkable size shift of OA from the fine to the coarse mode. Similar result has reported such phenomenon (Herner et al., 2006). The total mode GMDs (geometric mean diameters) of these species, corresponding to the dust storm periods in spring, showed larger value ($1.12\text{--}1.47 \mu\text{m}$) than those in the non-haze periods ($0.62\text{--}1.04 \mu\text{m}$). The typical summer haze period (June 30 to July 2) with a minor peak at $3.3\text{--}5.8 \mu\text{m}$ in the coarse mode was likely due to the meteorological conditions with higher humidity and lower wind speed. Previous studies found that the size of ambient particle can be modified by chemical reactions, condensation/evaporation, coagulation with other particles, and activation during high humidity, wet and dry deposition (Herner et al., 2006). Anhydrosugars are highly water-soluble compared with fossil fuel derived particles, whose sizes increase with increasing relative humidity (Reid et al., 2005). During the haze period, the concentrations of all species was comparatively higher, especially in autumn and winter. As mention above, larger scale of BB in cold seasons could lead to massive emission of these species. Moreover, autumn/winter were characterized by low mixing layer and stagnant conditions in haze days, which benefit the accumulation of the pollutants (Balducci and Cecinato, 2010; Bigi and Ghermandi, 2011; Carbone et al., 2010; Perrone et al., 2012; Pietrogrande et al., 2013). The total and coarse mode GMDs of anhydrosugars in spring and summer were larger than in autumn and winter,

while the fine mode GMDs showed smaller values (Table 4, S4 and S5). Such altering of particle size has been observed in other places (Herner et al., 2006; Wang et al., 2011).

3.3.2 Primary saccharides

The size distributions of all primary sugars are exhibited in Figs. 6–7. Both glucose and fructose existed mostly in coarse modes. Though the concentrations of glucose were much higher than fructose, these two compounds showed similar trends with a bimodal size distribution, peaking at 0.7–1.1 and >5.8 μm for spring, 0.4–1.1 and 3.3–5.8 μm for summer and autumn, 0.4–1.1 and 4.7–9 μm for winter. Compared to the smaller contribution in the fine mode in spring and summer (5.9–8.5%, 14.5–26.7% for glucose and fructose, respectively), the fractions of these two compounds were more abundant in fine aerosols during autumn and winter (15.0–24.4%, 32.6–45.8% for glucose and fructose, respectively). However, the origins of glucose and related sugars in fine particles remained unclear. Former studies suggested that fragmented pollen grains, either in cytoplasmic vesicles or dissolved in the cytosol, could be sources of sugars in the fine aerosol (Pacini, 2000; Yttri et al., 2007).

The size distribution of sucrose was exhibited in Figs. 6i–6l. Sucrose showed a bimodal size distribution with high concentrations in the coarse mode during the sampling periods. A minor peak was found in the size ranges of 0.4–1.1 μm and a major peak was in >5.8 μm . Compared to other three seasons (approximate 14.9%, 18.8%, 19.1% for summer, autumn and winter, respectively), sucrose existed much less in the fine mode (3.3%) in spring. Such phenomenon could be ascribed to the prevailing of pollen grain emission during the spring bloom season (Xu et al., 2012). Previous studies reported that most pollens of grasses actually remain in the anthers, and the cycle of wetting/drying cause the pollens to rupture from the anthers, with the pollen in the size ranges of 120 nm to 4.67 μm (Taylor et al., 2002). Meanwhile, furious windblown coarse aerosols from resuspension of dust in spring could further lead to higher abundance. Glucose, fructose and sucrose exhibited the largest total and coarse mode GMDs in dust storm aerosols, suggesting the effect of dust storms on particles which could contribute a large number of sugars (Table 4, Table S5).

Trehalose resembles more closely arabitol and mannitol, which existed mostly in the coarse mode with a proportion of over 90% and showed a nearly unimodal size distribution during the whole sampling periods (Figs. 7a–7d). This result indicates that trehalose originated from fungal spores, consisting with former studies (Lewis and Smith, 1967; Medeiros et al., 2006). The same as sucrose, trehalose was greatly influenced by the dust storm in spring. The concentrations of trehalose in dust storm were 4–10 times higher than in non-haze periods (Fig. 7a), indicating the essential impact of dust storm. Also, trehalose showed the largest total, fine and coarse GMDs in dust storm periods (Table 4, Table S4–5). This phenomenon was in good agreement with the observation in Seoul (Jeon et al., 2013). Noticeably, the total and coarse mode GMDs of trehalose in winter non-haze days were much larger than those in haze days. We assumed that soil resuspension by wind input substantial large particles into the air, while the mechanism needs to be further discussed.

Differ from other sugar and sugar alcohols, xylose and maltose showed a bimodal size distribution (Fig. 7). Except for summer, xylose and maltose were observed with a major peak at 0.4–1.1 μm and a minor peak at 3.3–5.8 μm in another three seasons. In summer, xylose and maltose existed more in coarse aerosols and even peaked at 3.3–9 μm during 30 June to 2 July. The distribution patterns of xylose and maltose were similar to those of anhydrosugars, suggesting biomass burning may be a dominant sugar source in the fine mode. Xylose and glucose were positively correlated well with each other ($r = 0.83$, $p < 0.001$) in coarse modes. Whereas, the origin of maltose in coarse modes remained unclear in this study. The correlations between maltose and glucose and sucrose were poor ($r = -0.04$ and $r = 0.01$, respectively), which was contrary to the former studies that maltose is particularly important in developing flower buds (Bielecki, 1995), indicating that maltose may be derived from other sources.

3.3.3 Sugar alcohols

The size distributions of sugar alcohols were illustrated in Figs. 6–7. Mannitol and arabitol showed similar trends while erythritol and inositol exhibited a different distribution pattern. Both mannitol and arabitol showed a unimodal size distribution in spring and summer while bimodal size distributions in autumn and winter. Mannitol and arabitol peaked at $>9.0 \mu\text{m}$ and 3.3–9.0 μm in spring and summer, respectively, while they exhibited more in fine aerosols in winter. Such a phenomenon was attributed to various sources of mannitol and arabitol. In summer and autumn, fungal spores in the atmosphere can be derived from complex sources (e.g., plant leaves, agricultural activities), which may contribute more to coarse particles than those in winter (Yttri et al., 2007). While in winter, there are less plant cover and agricultural activities, resulting in a more fraction in the fine mode. Former studies suggested that mannitol was present in aerosols sampled influenced by wildfire smoke, and mannitol and arabitol might be emitted by thermal stripping during wildfires (Medeiros and Simoneit, 2007; Simoneit et al., 2004). These sources can also effectively elevate the abundance of mannitol and arabitol in the fine mode in winter. Compared to other sampling periods, mannitol and arabitol in the dust storm exhibited the largest GMD values, which was ascribed to large emissions from the re-suspension of fungal spores from the surface soil. Previous studies also found that elevated concentrations of trehalose, mannitol and arabitol were generally related to resuspended soil and the outflow of dust storms (Liang et al., 2013; Rogge et al., 2007). In summer, autumn and winter haze days, the total and coarse mode GMDs of mannitol and arabitol were generally larger than those in non-haze (Table 4 and S4).

Inositol showed a bimodal size distribution in four seasons, while the pattern varied with season. In spring, the concentrations of inositol were high in the coarse mode with a peak at $>9.0 \mu\text{m}$. While in other seasons, the concentrations of inositol peaked at 0.4–1.1 μm . The total mode GMDs of inositol in the dust storm samples were much larger than those in other non-haze and haze samples, indicating the substantial influence of dust. The size pattern of inositol was similar to those of arabitol and mannitol, potentially responding to fungal spores in local terrestrial biosphere. In this

study, inositol was positively related to levoglucosan in the fine mode ($r = 0.77$, $p < 0.001$), which could explained the fine mode preference in cold seasons. Such a correlation was further ascertained by the total and fine mode GMDs of inositol, for its similarity with that of anhydrosugars.

Erythritol presented a bimodal size distribution for all sampling periods. In summer, erythritol exhibited more in the coarse mode with a major peak at 3.3–5.8 μm and a minor peak at 0.4–1.1 μm . While in other seasons, the distribution patterns reversed with the prevailing of the fine mode and peaked at 0.4–1.1 μm . The source of erythritol in the fine mode was different from that in the coarse mode. The positive relationship between erythritol and levoglucosan ($r = 0.90$, $p < 0.001$) in the fine mode, suggests the dominant contribution from biomass burning to erythritol. However, erythritol co-varied with arabitol ($r = 0.59$, $p < 0.001$) in the coarse mode, suggesting that erythritol is partly of local origin.

Larger GMDs of primary carbonaceous particles in the fine mode in haze days than in non-haze days have been observed in both previous and the present studies. One reason is the enhanced hygroscopic growth of airborne particles under relatively high humidity. As exhibited in Table S1, haze days were characterized by high relative humidity. Previous studies found that all the fine modes of WSOC showed a larger GMD in hazy days, and the fine mode GMDs of aliphatic hydrocarbons generally larger in haze samples due to higher relative humidity (Kang et al., 2016; Wang et al., 2011). In addition, the increased concentrations of airborne aerosols could increase the overall coagulation rate, resulting in faster rate of collisions between particles and formation of larger particles (Herner et al., 2006). Table 2 shows that the concentrations of anhydrosugars, primary saccharides and sugar alcohols were much higher in haze days, which were responsible for the larger GMDs in the fine mode and a size shift towards large particles.

3.4. Abundance and contributions of OC from biomass burning, plant debris and fungal spores

Based on the tracer methods, the quantitative estimates of OC from biomass burning (BB), plant debris and fungal spores are shown in Table 5 and Fig. 8. In a combustion test in fireplaces conducted by Fine et al. (2004b), the emission ratio of OC/levoglucosan mass was 7.35 on average, and high ratios of 8.0–8.2% are probably typical for open fires of burning grasses, woods and agricultural residues (Andreae and Merlet, 2001; Zhang et al., 2007). Considering the several burning of agricultural wastes, an L/OC ratio of 8.2% was applied in this study. Except for summer, BB-OC was the most dominant and showed an order of magnitude higher than the other two OC contributors. The level of BB-OC maximized in cold seasons (6.81 $\mu\text{g m}^{-3}$ for winter, 6.11 $\mu\text{g m}^{-3}$ for autumn) and minimized in summer (1.39 $\mu\text{g m}^{-3}$). The contributions of BB-OC reached the highest level (7.52%) in winter, followed by autumn (5.51%) and the lowest (1.21%) in summer (Table 5 and Fig. 8b). Apart from the elevated abundance of levoglucosan, stable meteorological conditions would also lead to the accumulation of BB-OC in cold seasons (He et al., 2001).

Compared to BB-OC, the contributions of plant debris and fungal spores exhibited totally different patterns. Based on the relationship between glucose and plant debris (Puxbaum and Tenze-Kunit, 2003), the plant debris-derived OC was estimated. The plant debris-derived OC showed a

seasonal trend with higher concentrations in spring ($0.34 \mu\text{g m}^{-3}$) and summer ($0.31 \mu\text{g m}^{-3}$), but lower in autumn ($0.09 \mu\text{g m}^{-3}$) and winter ($0.11 \mu\text{g m}^{-3}$). Likewise, the contributions of plant debris to OC were relative larger in spring and summer (both 0.30%), but it only accounted for 0.01% in autumn and 0.16% in winter. Mannitol, a tracer for fungal spores, was applied to estimate the contribution of fungal spores to OC using an experimentally derived factors of 1.7 pg mannitol and 13 pg OC per fungal spore (Bauer et al., 2008b; Carvalho et al., 2003; Graham et al., 2003). In general, the abundance of fungal spores-derived OC exhibited a similar trend with plant debris derived-OC, which maximized in summer ($1.15 \mu\text{g m}^{-3}$) and reduced in autumn and winter ($0.16 \mu\text{g m}^{-3}$). The contributions of fungal spores to OC maximized in summer (1.00%) and minimized in autumn (0.13%).

The contributions of OC from BB, plant debris and fungal spores according to particle size are shown in Fig. 10. BB-OC accounted for more than 85% of the three species in the fine modes. It was more pronounced in autumn and winter as approximately 100%. The contributions of BB-OC in coarse modes were of two patterns. In the size range of $2.1\text{--}9.0 \mu\text{m}$, the relative contributions of OC were higher in spring, autumn and winter with a proportion over 60%, and exhibited smallest fraction in summer. While in the size range larger than $9.0 \mu\text{m}$, the smallest fraction of BB-OC appeared in spring and the relative contribution were below 60% in most periods. Plant debris-derived OC mostly existed in the coarse modes. In the size range larger than $9.0 \mu\text{m}$, the plant debris-derived OC was the dominant one and peaked in spring (Fig. 9). Resemble plant debris-derived OC, fungal spores-derived OC also showed high contribution in the coarse mode. The annual contributions of fungal spores to OC ranged from 0.04–2.73% (0.56%) in the coarse mode, while those in the fine mode were just 0.03–0.14 %, 0.06%. Burege (2002) found that fungal spores in the atmosphere exist predominantly in the size range of $2\text{--}10 \mu\text{m}$. Previous studies also found similar results that mannitol mainly occurs in the coarse size fraction (Carvalho et al., 2003; Graham et al., 2003; Samaké et al., 2019). The relative contribution decreased in the smaller size ranges and presented summer privilege over other seasons. The contributions of fungal spores to OC were particularly high (1.48%) in the coarse fraction in summer, indicating the multiple sources of fungal spores in summertime. Both plant debris OC and fungal spores OC were present in fine modes, especially in spring and summer, which has been observed in several sites (Carvalho et al., 2003; Graham et al., 2003; Yang et al., 2012). It was worth mentioning that though the contribution of plant debris and fungal spores in the whole range were insignificant in cold seasons, their contribution in the coarse mode could not be ignored.

Compared to the contributions of BB, plant debris and fungal spores in non-haze day, the total contribution to OC showed a larger fraction in haze days for each season with enriched factors of 1.2–9.1. However, the reasons for elevated contribution in hazy days varied with season. In summer, the enhanced concentration of fungal spores-derived OC was the primary causation (Fig. 9), especially in the size range of $3.3\text{--}9.0 \mu\text{m}$. The levels of plant debris-derived OC in haze days were about 2.4–4.0 times higher than that in non-haze days, while BB-OC and fungal spores-derived OC showed no significant differences (Figs. 8–9). Hence, the contribution to POC in haze days existed more in the coarse mode than that in non-

haze days. Whereas in autumn and winter, the elevated total contribution attributed to the increased concentration of BB-OC. Figs. 9f–9i showed that BB-OC in the size range of 0.4–2.1 μm of haze samples were much higher than that in non-haze samples. As a result, the prevalence of BB-OC lead to more total contribution in the fine mode and more in haze days.

4 Conclusions

Atmospheric concentrations, seasonal variations and size distributions of anhydrosugars and sugar alcohols were investigated in urban aerosols from Beijing, China. High concentrations of anhydrosugars in the cold seasons were associated with the enhancement of biomass burning activities and adverse meteorological conditions. High levels of primary bioaerosol tracers such as sucrose, fructose, glucose, mannitol and arabitol were found in bloom and glowing seasons. The predominance of trehalose, a known tracer for Asian dust, was found during the most severe dust storm event (4–5 May). Anhydrosugars, xylose, maltose, inositol and erythritol mostly existed in the fine mode, while other primary sugars and sugar alcohols dominated in coarse particles. **Dust storm greatly enhance organic aerosol concentrations and induce a remarkable size shift towards coarse sizes.** Fine mode GMDs of biomass burning aerosols and primary biological aerosol particles were larger in the haze days than in the non-haze days, probably due to the stable meteorological conditions with higher humidity, which favor the condensation of organic matters onto aerosol particles, especially in the coarse mode.

Based on the tracer-based methods, the contributions of biomass burning, plant debris and fungal spores to OC were calculated with a percentage of 1.21–7.52%, 0.09–0.30% and 0.13–1.00%, respectively. The contribution of biomass burning-derived OC predominated in the fine mode throughout the year, although in the size range of 2.1–9.0 μm were not negligible. The contribution of plant debris-derived OC dominated in the coarse mode and decreased with the decreasing size. The contribution of fungal spores-derived OC dominated in the size range of 3.3–5.8 μm in summertime samples. Though the sources of plant debris and fungal spores prevailed in spring and summer, small contributions in the coarse mode were also found during cold seasons due to long-range atmospheric transport from the southern regions. To better characterize sources and formation processes of haze particles and atmospheric chemistry in the North China Plain, further investigations on the size distributions of biogenic and anthropogenic SOA tracers are strongly needed in the future.

Supporting Information Available

Information on sampling parameters from April 2017 to January 2018 (Table S1). Linear correlation coefficients among anhydrosugars and OC, and with EC in Beijing aerosols from April 2017 to January 2018 (Table S2). Linear correlation coefficients among primary saccharides and sugar alcohols, and with levoglucosan in Beijing aerosols from April 2017 to January 2018 (Table S3). Geometric mean diameters (GMDs, nm) of anhydrosugars and other saccharides in the fine ($<2.1\ \mu\text{m}$) and coarse ($\geq 2.1\ \mu\text{m}$) mode particles in the Beijing (Table S4 and Table S5). Clusters of 3-day backward trajectories of air masses arriving at Beijing during dust storm events and haze periods from April 2017 to January 2018 (Fig. S1).

Data availability. The dataset for this paper is available upon request from the corresponding author (fupingqing@tju.edu.cn).

Competing interests. The authors declare that they have no conflict of interest.

Author contributions. PQF designed this research. Field campaigns were organized by PQF, SJH and YCL. Aerosol samples were collected by SJH. Laboratory analyses were performed by SFX, LJR, HR, and SJH. The manuscript was written by SFX and PQF with consultation and editing from all other authors.

Table S4. Geometric mean diameter (GMD, μm) of anhydrosugars and other saccharides in the fine mode particles ($<2.1 \mu\text{m}$) in the Beijing, from April 2017 to January 2018. GMD: $\log\text{GMD} = (\sum C_i \log D_{pi}) / \sum C_i$, where C_i is the concentration of compound in size i and D_{pi} is the geometric mean particle diameter collected on stage i .

Compounds	Fine							
	Spring		Summer		Autumn		Winter	
	dust storm	non-haze	haze	non-haze	haze	non-haze	haze	non-haze
<i>Anhydrosugars</i>								
Galactosan	0.51	0.46	0.48	0.46	0.76	0.67	0.61	0.47
Mannosan	0.55	0.46	0.62	0.55	0.74	0.67	0.61	0.44
Levogluconan	0.57	0.41	0.59	0.56	0.72	0.50	0.55	0.45
<i>Sugar Alcohols</i>								
Arabitol	0.38	0.43	0.69	0.84	0.58	0.75	0.61	0.37
Mannitol	0.46	0.42	0.76	0.49	0.69	0.55	0.53	0.54
Inositol	0.34	0.40	0.54	0.39	0.51	0.46	0.50	0.37
Erythritol	0.39	0.47	0.51	0.60	0.71	0.55	0.61	0.51
<i>Sugars</i>								
Glucose	0.38	0.46	0.72	0.68	0.60	0.48	0.51	0.43
Sucrose	0.33	0.51	0.68	0.48	0.65	0.56	0.48	0.49
Fructose	0.40	0.44	0.46	0.49	0.65	0.43	0.48	0.36
Maltose	0.31	0.36	0.47	0.31	0.57	0.39	0.61	0.34
Xylose	0.43	0.42	0.62	0.66	0.64	0.65	0.66	0.41
Trehalose	1.02	0.69	0.87	0.64	0.80	0.62	0.70	0.55

Table S5. Geometric mean diameter (GMD, μm) of anhydrosugars and other saccharides in the coarse mode particles ($>2.1\ \mu\text{m}$) in the Beijing, from April 2017 to January 2018.

Compounds	Coarse							
	Spring		Summer		Autumn		Winter	
	dust storm	non-haze	haze	non-haze	haze	non-haze	haze	non-haze
<i>Anhydrosugars</i>								
Galactosan	5.10	5.04	5.39	5.97	4.55	4.51	4.25	5.32
Mannosan	4.79	4.85	5.40	5.56	3.90	4.29	3.76	6.01
