Dr. P. Zieger  
Editor, Atmospheric Chemistry and Physics

Dear Editor,

I am pleased to submit the revised version of our manuscript entitled “Seawater Analysis by Ambient Mass Spectrometry-Based Seaomics” for its publication as an article in the Atmospheric Chemistry and Physics Special Issue entitled “Marine organic matter: from biological production in the ocean to organic aerosol particles and marine clouds” (ACP/OS inter-journal SI).

We acknowledge the reviewer’s comments as well as your suggestions regarding the changes that still needed to be made in the manuscript to be considered for publication in ACP. Accordingly, we have thoroughly followed all recommendations. We have changed the title as suggested and addressed all comments and suggestions made by reviewer #3 to properly tone down the link between the seawater composition measurements and SOA formation.

A highlighted version of the manuscript has been prepared using track changes. Please, find at the bottom of this letter a point-by-point response to the reviewer’s comments and the marked-up manuscript version showing the changes made.

We believe that this work can be of interest to the atmospheric chemistry community, since we present a new approach to bridge different fields of science studying the air/sea interface.

I hope that this modified version of the manuscript can be finally accepted for publication in ACP.

Sincerely,

María Eugenia Monge, Ph.D.

### *Responses to Reviewer #3:*

This manuscript looks almost identical to the one I reviewed previously, and the main strengths and weaknesses largely remain. It is a highly descriptive account of a novel method of characterizing sea surface microlayer (SML) and bulk seawater composition with the aim of ultimately connecting surface ocean composition with marine volatile organic compound and aerosol formation. Attached to this, with limited analysis and synthesis (but large weighting in the study conclusions), is an experiment that tested secondary organic aerosol (SOA) generation by irradiation of a subset of the SML samples.

The authors seem not to have taken to heart the criticism of the reviewers that the connections between the composition measurements and the SOA formation experiments are very tenuous. Put simply, there is nothing that shows that the detected compounds enhanced in the SML are contributing to SOA formation. I proposed in my original review that the authors either dramatically expand the discussion/analysis, or temper their conclusions. The authors seem not to have been persuaded that there was much of a need for either. They have held back from meaningfully editing the manuscript to make their arguments clearer or more convincing to the reader.

I see three possible paths to publication for this manuscript:

1. Change the conclusions in the Conclusions and Abstract to things clearly supported by the manuscript without other major changes (suggestions below). It's not clear if the manuscript in that form would be suitable for publication in ACP or not, as little could be concluded about the relationship between the seawater composition measurements and SOA formation.
2. Dramatically expand the analysis and interpretation and synthesis of the SOA-related section to draw a compelling link to the "seaomics" work. This may or may not be doable given the available data, but it could lead to material support for the conclusions as currently stated.
3. Remove the SOA-focused experiments from the paper and submit the detailed, useful description of the SML and bulk seawater composition method and results to a more appropriate journal.

*We acknowledge the reviewer's comments and constructive suggestions regarding the changes that still needed to be made in the manuscript. We understand the concerns pointed out by the reviewer and have accordingly followed all recommendations thoroughly and toned down the link between the seawater composition measurements and SOA formation experiments. We have changed the title of the manuscript to "Seawater Analysis by Ambient Mass Spectrometry-Based Seaomics", and we have tempered the conclusions in the Conclusions and Abstract sections.*

*We believe that the revised version of the manuscript will be of interest to the atmospheric chemistry community, since this work presents a new approach to bridge different fields of science studying the air/sea interface.*

Specific major Issues with claims in the manuscript by section:

Abstract:

"Tentative identification of these species suggest that saturated fatty acids, peptides, fatty alcohols, halogenated compounds, and oxygenated boron-containing organic compounds may be involved in water-air transfer processes and in photochemical reactions at the water- air interface of the ocean."

I would revise to "...boron-containing organic compounds are available at the surface for water-air transfer processes..." There's no evidence here that these things are specifically participating- they are simply present.

"Results from these experiments and the analytical seaomics strategy provide a proof of concept that organic compounds may play a key role in aerosol formation processes at the water/air interface."

I would revise to "These results provide a proof on concept for an approach to identifying organic molecules involved in aerosol formation processes at the water/air interface." Writing "proof of concept" isn't a license to state a desired conclusion that isn't supported by the present data.

*We have thoroughly modified the abstract following the reviewer's advice as follows (changes indicated in italics):*

*"A transmission mode-direct analysis in real time-quadrupole time of flight-mass spectrometry (TM-DART-QTOF-MS)-based analytical method coupled to multivariate statistical analysis was developed to interrogate lipophilic compounds in seawater samples without the need of desalinization. An untargeted metabolomics approach addressed here as seaomics was successfully implemented to discriminate sea surface*

microlayer (SML) from underlying water (ULW) samples (n=22, 10 paired samples) collected during a field campaign at the Cape Verde islands in September-October 2017. A panel of 11 ionic species detected in all samples allowed sample class discrimination by means of supervised multivariate statistical models. Tentative identification of species *enriched at SML samples* suggests that fatty alcohols, halogenated compounds, and oxygenated boron-containing organic compounds *are available at the surface for water-air transfer processes*. A subset of SML samples (n=5) were subject to on-site experiments during the campaign using a lab-to-the-field approach to test their secondary organic aerosol (SOA) formation potency. Results from these experiments and the analytical seaomics strategy provide a proof of concept *for an approach to identifying organic molecules involved in aerosol formation processes at the water/air interface*.

Line 425:

I am repeating myself from my previous review, but the compounds present in SML particles (“endometabolome”) may not be available to participate in the sea surface SOA-forming chemistry in the real environment. That should be pointed out to the reader with at least a single sentence. It is highly relevant to the question of how relevant these results may be to the ambient environment, and glossing over it (i.e. merely pointing out in review that those components are included in the analysis) does a disservice to the reader.

*We have clarified the point raised by the reviewer as follows:*

*“It is worth noting that organic compounds identified in the discriminant panel may have derived both from the secreted (exometabolome) and/or intracellular metabolites (endometabolome) of biological organisms such as algal species and microorganisms present in seawater, since samples were not filtered. Therefore, in a real environment some of these compounds may be present in lower levels than those detected in the present work or may not be available to participate in the sea surface SOA-chemistry.”*

Conclusions:

I disagree with the conclusion that the results here “suggest that organic compounds enriched at the water/air interface may play a key role in aerosol formation processes.” It seems likely to be true based on previous work, but I don’t see how these results support that claim. If the experiment had included OFR oxidation runs using the underlying water and showed that those samples showed no SOA formation, such a

conclusion could be supported. Lacking such data, the authors would need to be able to say something about which compounds may be contributing to the differential SOA forming ability of the different SML samples, and then argue that those compounds are enhanced in the SML.

*Following the reviewer's advice, we have modified the Conclusions section as follows:*

“An untargeted TM-DART-QTOF-MS-based analytical method coupled to multivariate statistical analysis allowed analyzing organic compounds present in SML and ULW seawater samples collected during a field campaign at the Cape Verde islands, without the need of desalinization. This seomics approach was successfully implemented to discriminate SML from ULW samples. Tentative identification of the discriminant metabolite panel suggests that halogenated compounds, fatty alcohols, and oxygenated boron-containing organic compounds *are available for* water-air transfer processes and photochemical reactions at the water-air interface of the ocean. Combined results from TM-DART-QTOF-MS and on-site SOA formation testing experiments on SML samples, suggest that organic compounds enriched at the water/air interface *may be contributing to the differential SOA forming ability of SML samples*. This strategy, implemented for the first time in this collaborative study, provides new opportunities for improving the characterization of seawater OM content, and discovering compounds involved in aerosol formation processes.”

**Abstract.** A transmission mode-direct analysis in real time-quadrupole time of flight-mass spectrometry (TM-DART-QTOF-MS)-based analytical method coupled to multivariate statistical analysis was developed to interrogate lipophilic compounds in seawater samples without the need of desalination. An  
40 untargeted metabolomics approach addressed here as seaomics was successfully implemented to discriminate sea surface microlayer (SML) from underlying water (ULW) samples (n=22, 10 paired samples) collected during a field campaign at the Cape Verde islands in September-October 2017. A panel of 11 ionic species detected in all samples allowed sample class discrimination by means of supervised multivariate statistical models. Tentative identification of ~~these~~ species enriched at SML  
45 samples suggests that ~~saturated fatty acids, peptides,~~ fatty alcohols, halogenated compounds, and oxygenated boron-containing organic compounds are available at the surface for water-air transfer processes ~~may be involved in water air transfer processes and in photochemical reactions at the water air interface of the ocean~~. A subset of SML samples (n=5) were subject to on-site experiments during the campaign using a lab-to-the-field approach to test their secondary organic aerosol (SOA) formation  
50 potency. Results from these experiments and the analytical seaomics strategy provide a proof of concept for an approach to identifying organic molecules involved ~~that organic compounds may play a key role~~ in aerosol formation processes at the water/air interface.

## 1 Introduction

60 Oceans act as sinks and sources for gases and aerosol particles. The ocean surface chemical composition influences physicochemical processes occurring at the air-water interface by connecting the ocean biogeochemistry with the atmospheric chemistry in the marine boundary layer (MBL) (Donaldson and George, 2012). Therefore, understanding how organic compounds of marine origin are influencing the formation of aerosols in the MBL with potential impacts on the radiative fluxes, aerosol hygroscopicity and subsequent cloud condensation nuclei properties is important. It has been suggested that complex photoactive compounds are enhanced at the air-sea interface (Reeser et al., 2009a; Reeser et al., 2009b), inducing abiotic production of volatile organic compounds. For instance, experimental photosensitized reactions at the air-water interface using humic acids as a proxy of dissolved organic matter (DOM), have led to the chemical conversion of linear saturated fatty acids into unsaturated functionalized gas phase products (Ciuraru et al., 2015). Atmospheric photochemistry can even take place in the absence of photosensitizers if the air-water interface is coated with a fatty acid (Rossignol et al., 2016). On a global scale, interfacial photochemistry has recently been suggested to serve as an abiotic source of volatile organic compounds comparable to marine biological emissions (Brüggemann et al., 2018).

The sea surface microlayer (SML) covers up to 70 % of the Earth's surface and is enriched in DOM, including organic compounds such as fatty acids, fatty alcohols, sterols, amines, amino acids, proteins, lipids, phenolic compounds, and UV-absorbing humic-like substances derived from oceanic biota; particulate matter; microorganisms (Liss and Duce, 2009; Donaldson and George, 2012); colloids and phytoplankton-exuded aggregates, mainly constituted by lipopolysaccharides (Liss and Duce, 1997; Hunter and Liss, 1977; Bayliss and Bucat, 1975; Liss, 1986; Hardy, 1982; Garabetian et al., 1993; Williams et al., 1986; Schneider and Gagosian, 1985; Gershly, 1983; Guitart et al., 2004; Facchini et al., 2008; Kovac et al., 2002). While the identification of these classes of compounds has been achieved in the past, an improved chemical characterization of the SML and its chemical processing is highly desirable to understand its contribution into atmospheric composition, air quality and climate change (Liss and Duce, 2009).

85 Metabolomics is the comprehensive analysis and characterization of all small molecules (MW < 1500) in a biological system, (Fiehn et al., 2000; Nicholson and Lindon, 2008) such as the marine metabolome. Mass spectrometry (MS) is one of the primary analytical techniques used to explore the metabolome, as it is highly sensitive and versatile for chemical analyses in targeted and untargeted studies (Clendinen et al., 2017; Weckwerth and Morgenthal, 2005). Targeted metabolomics focuses on detecting and quantifying a pre-selected set of metabolites. Conversely, untargeted metabolomics attempts to cover the broadest range of detectable compounds in a biological system (Viant et al., 2019), to subsequently extract chemical patterns or class fingerprints that can allow sample classification based on metabolite panels without any a priori hypotheses. Multivariate statistical techniques compute all compound features (variables) simultaneously with the aim of reducing data dimensionality, finding underlying trends, and isolating feature/metabolite panels relevant to class discrimination (Saccenti et al., 2014). Following compound identification, relative changes of abundances can be analyzed for biological interpretation.

Advancements in new, soft ambient ion generation techniques offer alternative MS-based applications for surface analysis with little to no sample preparation, addressing high-throughput analytical challenges in

untargeted metabolomics workflows (Monge et al., 2013; Harris et al., 2011; Clendinen et al., 2017). In particular, direct analysis in real time (DART), (Cody et al., 2005; Gross, 2014; Jones et al., 2014; Monge and Fernández, 2014) which is a plasma-based ambient ion source, has been successfully applied in untargeted metabolomics studies in different scientific fields (Salter et al., 2011; Ifa et al., 2009; Steiner and Larson, 2009; Fernández et al., 2006; Chernetsova et al., 2010; Hajslova et al., 2011; Cajka et al., 2011; Dove et al., 2012; Jones and Fernández, 2013; Zang et al., 2017), though no studies have been reported up to date exploring oceanic biological systems. In DART-MS, a stream of metastable atomic or molecular species generated within the discharge heated He or N<sub>2</sub>, is directed at the sample, and ions are suctioned into the mass spectrometer (Cody et al., 2005). Thermally-desorbed analytes having typically MW < 1000, are ionized following atmospheric pressure chemical ionization-like pathways (Cody et al., 2005; Song et al., 2009a; Song et al., 2009b; McEwen and Larsen, 2009). Therefore, a major limitation is that it requires analytes to be volatile or semi-volatile, reducing the metabolome coverage. An important advantage of DART compared to electrospray ionization for seawater analysis is that it is less affected by high salt levels (Kaylor et al., 2014; Tang et al., 2004), avoiding desalination processes that may lead to sample alteration. Conversely, ESI sources allow the coupling of MS to chromatographic systems that provide an additional parameter to improve confidence in compound identification when compared to an authentic chemical standard.

In the present work, a transmission mode (TM)-DART-quadrupole time-of-flight (QTOF)-MS-based analytical method was developed to interrogate seawater DOM composition in SML and underlying water (ULW) samples collected during a field campaign at the Cape Verde islands in September-October 2017. An untargeted metabolomics approach, addressed here as seaomics, was implemented to successfully discriminate SML from ULW samples based on a selected panel of 11 ionic species. Tentative identification of the discriminant panel provided insight into the family of compounds that may be involved in water-air transfer processes and photochemical reactions at the water-air interface of the ocean surface. In addition, secondary organic aerosol formation potency from SML interfacial photochemical products was explored during the field campaign using a lab-to-the-field approach. To our knowledge, this is the first study applying an untargeted TM-DART-QTOF-MS-based seaomics analytical strategy coupled to multivariate statistical analysis to investigate DOM seawater composition.

## 2 Experimental

### 2.1 Chemicals

LC-MS grade acetonitrile was purchased from Fisher Chemical (NC, USA). Ultrapure water with 18.2 MΩ·cm resistivity (Thermo Scientific Barnstead Micropure UV ultrapure water system, USA) was used to prepare standard solutions. Commercial seawater (S9883), glucose, xylose, fructose, galactosamine, mannitol, L-glycine, L-alanine, GABA (γ-Aminobutyric acid), L-serine, L-proline, L-valine, L-threonine, L-isoleucine, L-leucine, L-asparagine, L-aspartic acid, L-glutamine, L-glutamic acid, L-methionine, L-histidine, L-phenylalanine, L-arginine, L-tryptophan, 2-amino-4,5-dimethoxybenzoic acid, 2-cyanoguanidine, flecainide acetate, lacosamide, enalapril maleate, 4-bromo-phenol, and mercaptosuccinic acid were purchased from Sigma-Aldrich (St. Louis, MO, USA). Decanoic acid, docosanoic acid,

dodecanoic acid, eicosanoic acid, and octadecanoic acid were purchased from Loradan AB, Inc. (Solna, Sweden). KBr was purchased from Biopack (CABA, Argentina), and phenol was purchased from CARLO ERBA Reagents S.A (Sabadell, Spain).

## 140 **2.2 Sample Collection at the Cape Verde Field Campaign**

Sea Surface Microlayer (SML) samples were manually collected by the traditional glass plate (GP) method (van Pinxteren et al., 2012) and with an automatic catamaran using the same sampling principle as GP, named MarParCat (CAT). The MarParCat is an autonomous catamaran for sampling the SML on rotating glass plates. Larger quantities of SML samples can be collected with this method in a shorter  
145 time. Underlying water (ULW) samples were collected from 1.0 m sea subsurface during the same time window as SML samples, using both strategies; i.e., manual sampling addressed as GP, and MarParCat (Supplementary Table S1). SML and ULW samples that were collected in the same site are addressed as paired samples (Supplementary Information, Table S1). The samples analyzed in the present study (n=22) were collected between 18/09/2017 and 10/10/2017 and stored at -20 °C until processing. Information  
150 related to sampling conditions, sample salinity, pH, and temperature, is provided in Table S1. Dissolved organic carbon (DOC) levels varied between 1.8 and 3.2 mg L<sup>-1</sup> in the SML and between 0.9 and 2.8 mg L<sup>-1</sup> in the ULW water (van Pinxteren et al., 2019).

## **2.3 Aerosol Particle Formation Experiments at the Cape Verde Islands**

155 A subset of collected SML seawater samples were subject to on-site experiments using a lab-to-the-field approach to test whether they were photochemically active (Ciuraru et al., 2015). Before each experiment, 100 mL SML sample was conditioned to room temperature and divided into 12 aliquots. These were centrifuged at 3500 rpm and 4 °C for 25 min to exclude colloids and aggregates (particulate matter), using a 5702R centrifuge (Eppendorf Inc.). Subsequently, 2 mL of surface solution was collected from each  
160 centrifugal vessel to isolate closer representations of SML samples considering the dilution factor inherent to the collection process, i.e., SML diluted with ULW contribution, and leading to a total sample volume of 24 mL for subsequent experiments. Centrifugation was aimed at concentrating SML samples as a condition for aerosol formation.

Sample irradiation was conducted using a cylindrical quartz cell reactor (2 cm diameter, 10 cm length,  
165 and 30 mL volume), half filled with 14 mL of SML solution, thereby recreating an air/water interface with a maximum area of 20 cm<sup>2</sup>. Experimental details of the reactor can be found elsewhere (Ciuraru et al., 2015). This quartz reactor was surrounded with UV lamps in a ventilated box, maintaining the system at a relatively constant room temperature. The interface was irradiated by means of 210W actinic UV irradiation peaking at 350 nm (the spectrum is displayed in Fig. S1, Supporting Text 1) that was supplied  
170 by 7 low pressure mercury UV lamps (Philips) and one extra UV pen ray (UVP, Philips).

This experimental approach allowed reproducing the air-sea exchanges under quiescent conditions and investigating particle formation potentially arising from the reaction between photochemically emitted gaseous products and OH radicals. For this purpose, the quartz cell was continuously flushed with 600

sccm purified air, entraining the air-water interfacial exchanged gaseous products to a Potential Aerosol Mass (PAM) oxidation flow reactor with 254 nm light supply, addressed as OFR254. Particle formation via OH radical photochemistry in the OFR254 was monitored using a scanning mobility particle sizer (SMPS, model 3976, TSI) and one extra ultrafine condensation particle counter (UCPC, TSI 3776,  $d_{50} > 2.5$  nm). A description of the OFR254 operation and a scheme of the experimental setup are detailed in the Supplementary Information section (Fig. S2 and S3). Blank experiments were routinely conducted using ultrapure water (18.2 M $\Omega$ -cm resistivity).

#### 2.4 Sample Preparation for DART-MS Analysis

Samples were thawed at 4 °C for 5 h; neither desalination nor filtration was performed. Samples were split in 8 mL aliquots using 15 mL conical tubes and were subsequently frozen at -20 °C until lyophilization. Quality control (QC) samples were prepared by mixing equal volumes of all samples including both collection methods before sample lyophilization (QCALL) and after metabolite extraction and reconstitution in acetonitrile (QCMIX22). Chemical standard mixtures used for analytical method development and as system suitability samples (SSS) were prepared in ultrapure water for sugars, and amino acids, in methanol/water mixtures for lipids and by combining all standards from the three families of compounds (Supplementary Information, Table S2). The sample preparation blank was prepared with ultrapure water as follows: fresh ultrapure water was stored for 2 days at -20 °C in a new plastic bottle equivalent to those used for sample collection; subsequently thawed, split in 8 mL aliquots and stored in 15 mL conical tubes at -20 °C until lyophilization. This protocol was also implemented to prepare commercial seawater samples (CSW) that were used for analytical method development. Blanks, QCs, SSS, and samples were lyophilized at 0.280 mBar during 48 h using a Christ Alpha 1-4 Freeze dryer. SML samples, ULW samples, QCs, and SSS were lyophilized with sample blanks in different batches to evaluate possible cross-contamination. Lyophilized samples were shipped from TROPOS (Germany) to CIBION-CONICET (Argentina), where they were stored at -80 °C until TM-DART-QTOF-MS analysis. Lyophilized residues were reconstituted in 1200  $\mu$ L of acetonitrile, yielding a concentration factor of 6.67. Reconstituted samples were vortex-mixed during 5 min for metabolite extraction, and centrifuged during 10 min at 4861  $\times$  g and 20 °C to favor the formation of a salt pellet. For each sample, 500  $\mu$ L of supernatant was collected for further analysis.

#### 2.5 DART-MS Analysis

A DART® SVP ionization source (IonSense Inc., MA, USA) was coupled to a Xevo G2S QTOF mass spectrometer (Waters Corporation, Manchester, UK) by means of a VAPUR® interface flange (IonSense Inc., MA, USA). The DART source was operated with He as the discharge gas heated at 300 °C, and data were acquired in negative ionization mode. A transmission mode (TM)-DART geometry was implemented for sample analysis, setting a distance of 2.5 cm in the rail holding the source. This allowed using the minimum possible DART-to-sample distance to provide the greatest sensitivity (Zang et al., 2017; Jones and Fernández, 2013). Samples were deposited in a stainless-steel mesh that was subsequently

placed in a linear rail-based sampler, which was digitally controlled to minimize variance in sample position. Fig. S4 illustrates the experimental design for depositing samples in different spots of the mesh to avoid cross-contamination. A protocol for calibrating the mass spectrometer across the range of  $m/z$  50-850 using the DART source operated in TM was developed using a mixture of standards prepared in a water-methanol solution (1:1 v/v) that would provide almost equidistant  $m/z$  peaks. Signals of different adduct ions from 2-cyanoguanidine, enalapril maleate, mercaptosuccinic acid, 2-amino-4,5-dimethoxybenzoic acid, flecainide acetate, and lacosamide were used for the TOF calibration (Supplementary Information, Table S3). Drift correction was performed after data acquisition using stearic acid present as an ambient contaminant. The  $[M-H]^-$  adduct ion with  $m/z$  283.2643 was chosen as a lock mass to have a high degree of accuracy in exact mass measurement. Data were acquired in continuum mode in the range of  $m/z$  50-850, and the scan time was set to 1 s. A standard solution of enalapril 3.7  $\mu$ M was used as an additional SSS and added to each mesh in spot # 3 (Fig. S4) to evaluate mass accuracy of the  $[M-H]^-$  ion at  $m/z$  375.1925. The resolving power and mass accuracy of the TM-DART-QTOF-MS system were 23000 fwhm and 0.2 mDa at  $m/z$  375.1925, respectively. Twelve spots per mesh were utilized for analysis. Each spot contained 3 droplets of 20  $\mu$ L of sample, which were dried at room temperature before analysis. The mesh holder was moved at a speed of 0.2 mm s<sup>-1</sup> for data acquisition. Mesh # 1-11 included a solvent (SV) blank (acetonitrile); a commercial seawater control; a sample preparation blank (using ultrapure water); a QCMIX22 (pooled QC sample from all reconstituted samples: 10 SML + 12 ULW), and technical triplicates of all samples (Fig. S4). As indicated in Fig. S4, mesh # 12 included QCALL samples (pooled QC sample from all samples before lyophilization: 10 SML + 12 ULW samples). For TM-DART-QTOF-MS/MS experiments, the product ion mass spectra were acquired with collision cell voltages between 10 and 40 V, depending on the analyte. Ultra-high-purity argon ( $\geq 99.999$  %) was used as the collision gas. Data acquisition and processing were carried out using MassLynx version 4.1 (Waters Corp., Milford, MA, USA). Data were acquired for each spot, and acquisition over each mesh was automatically performed through synchronization between the DART software (IonSense Inc.) and MassLynx (Waters Corp.). System suitability procedures were performed to verify that the method and associated instrumentation were fully functioning before and during the analysis of experimental samples.

## 2.6 Seaomics Data Analysis

Progenesis Bridge (Waters Corp., Milford, MA, USA) was used for data pre-processing. This software allowed defining the lock mass for drift correction after acquisition; and merged the original data into a Gaussian profile. Spectral features ( $m/z$  values) were further extracted from TM-DART-QTOF-MS data using Progenesis QI version 2.1 (Nonlinear Dynamics, Waters Corp., Milford, MA, USA). An absolute ion intensity filter was applied in the peak picking process for integration, defining a threshold for the aggregate run. Only SML and ULW samples were considered for peak picking. This process yielded 889 features ( $m/z$ ) detected within samples. Subsequently, six features were removed due to high mass defect (potential salts clusters). For correction of inter-mesh effects, a quality control sample-based robust locally estimated scatterplot smoothing (LOESS) signal correction method (Dunn et al., 2011) was

250 applied using QCMIX22 samples. This strategy allowed correcting for temporal signal fluctuation of each feature along the total acquisition time. Subsequently, features with relative standard deviation (RSD) >30 % in QCMIX22 were discarded, and only those with 5-fold average intensity in samples compared to blanks (i.e., sample preparation blanks and solvent blanks) were retained. Manual curation of features was also performed to eliminate redundancy (isotopic peaks from the same feature), to retain signals with a detected isotopic pattern, and to account for resolution limitations in the peak picking process. Moreover, only those monoisotopic peaks with intensity  $>10^3$  in the continuum spectra were retained. The final curated matrix comprised of 51 features ( $m/z$  values) was normalized by total ion area. Abundance values from technical triplicates were averaged, except for SML GP2 sample, for which only two replicates were considered. The matrices obtained before and after averaging technical replicates (Data Set S1 in the Supplementary Information) were utilized to build unsupervised and supervised multivariate statistical analysis models using MATLAB R2015a (The MathWorks, Natick, MA, USA) with the PLS Toolbox version 8.1 (Eigenvector Research, Inc., Manson, WA, USA). Principal component analysis (PCA) (Richard A. Johnson) and t-distributed stochastic neighbor embedding (t-SNE) (Van Der Maaten and Hinton, 2008) techniques were used to track data quality, reduce the data dimensionality, identify potential outliers in the dataset, as well as to identify sample clusters and evaluate the analytical method reproducibility. Orthogonal projection to latent structures-discriminant analysis (oPLS-DA) (Trygg et al., 2007; Bylesjö et al., 2006; Trygg and Wold, 2002; Shrestha and Vertes, 2010) coupled with a genetic algorithm (GA) variable selection method was applied to find a feature panel that maximized classification accuracy for the binary comparison of SML and ULW samples. The selected group of discriminant features had the lowest root-mean-square error of cross-validation (RMSECV) at the conclusion of the GA variable selection process. This process was performed five different times and the selected panel yielded the lowest RMSECV and exhibited largest feature overlap with the other four panels. The parameters for GA were as follows: population size: 64, variable window width: 1, % initial terms (variables): 15, target minimum # of variables: 5, target maximum # of variables: 15, penalty slope: 0.03, maximum generations: 100, % at convergence: 50, mutation rate: 0.005, crossover: double, regression choice: PLS, # of latent variables: 5, cross-validation: contiguous, # of splits: 10, # of iterations: 10, replicate runs: 10. The oPLS-DA model was cross-validated using venetian blinds with 4 data splits, and 1 sample per blind to account for overfitting. Data were preprocessed by autoscaling prior to PCA or oPLS-DA analysis. PCA was also performed to inspect data before and after GA variable selection (i.e., on the curated spectral feature matrix and on the discriminant feature panel). Fold changes were calculated for paired samples for each discriminant feature by comparing sample replicate average values for SML and ULW samples. Wilcoxon Paired Signed Rank Test was used to compare SML with ULW samples ( $p < 0.05$ ). Median fold changes were calculated for each discriminant feature (Supplementary Information, Table S4).

## 2.7 Metabolite Identification Procedure

Metabolite identification was attempted for the discriminant features resulting from the GA variable selection process. Elemental formulae were generated based on accurate masses and isotopic patterns,

taking into account stringent conditions for isotope ratios. For those cases in which there was overlap  
290 between isotopic peaks of different features, the isotopic pattern was not considered for molecular  
formula generation. In addition, fragmentation patterns obtained from TM-DART-QTOF-MS/MS  
experiments were used for tentative identification.

### 3 Results and Discussion

#### 3.1 TM-DART-QTOF-MS-based Method Optimization

295 Figure 1 illustrates the untargeted TM-DART-QTOF-MS seaomics analytical workflow implemented for  
the analysis of seawater samples collected during the Cape Verde field campaign. A TM geometry was  
implemented to analyze samples in a flow-through fashion to increase reproducibility with lower risk of  
cross contamination (Zhou et al., 2010a;Zhou et al., 2010b;Jones and Fernández, 2013;Perez et al.,  
2010;Zang et al., 2017;Jones et al., 2014). The analytical method development involved optimization of  
300 the ion source stabilization time, accomplished in 60 seconds; the synchronization between data  
acquisition and the linear rail control; the selection of He over N<sub>2</sub> to generate the plasma, based on higher  
sensitivity obtained with the former; the optimization of He temperature set at 300 °C; the selection of  
acetonitrile for metabolite extraction; the optimization of the solvent volume required for extraction to  
allow i) maximum metabolite concentration considering that the seawater metabolome is comprised of  
305 organic compounds with a wide range of physicochemical properties and levels; and ii) enough sample  
volume for technical replicates, QCs and tandem MS analysis; and the sample volume deposited on the  
mesh to maximize signal-to-noise ratio (number of sample droplets and droplet volume). The selected  
OM extraction method with acetonitrile as extracting solvent favored the analysis of lipophilic  
compounds. In addition, to enhance the detection of organic acids, the analytical method was optimized  
310 operating the DART ion source in negative ionization mode, since it follows negative ionization APCI-  
like mechanisms including electron capture, dissociative electron capture, proton abstraction, and anion  
adduction (McEwen and Larsen, 2009;Cody and Dane, 2013;Gross, 2014) .

#### 3.2 Seawater Sample Fingerprinting

315 The curated data matrix, comprised of 51 features i.e., m/z values, and all sample replicates (Data Set S1  
in the Supplementary Information), was used to build a PCA model that accumulated 62.29 % of the total  
variance in the first two principal components (PCs) (Fig. 2). The 2D scores plot illustrated in Fig. 2A  
shows distinguishable separation between acetonitrile blanks, sample preparation blanks, commercial  
seawater samples and seawater samples collected during the field campaign. Since the maximum data  
320 variance in a PCA model is in the direction of the base of eigenvectors of the covariance matrix, the  
largest differences are given by seawater samples compared to blanks. However, seawater samples from  
the Cape Verde islands were discriminated from commercial seawater samples. In addition, QCMIX22  
replicates clustered together, indicating reproducibility in the sample preparation method, high data  
quality, and adequate performance of the analytical platform. Moreover, overlapping of both type of QC

325 samples (QCMIX22 and QCALL) suggested reproducibility in the sample extraction protocol. Solvent  
blanks from different mesh and different positions (spots) were clustered together, suggesting negligible  
cross-contamination in the analysis. Results provided by the t-SNE model (Fig. 2B), which is a nonlinear  
dimensionality reduction technique, were in agreement with those provided by the linear transformation-  
based technique of PCA and emphasize the reproducibility of the developed analytical method for  
330 seawater sample analysis. This was further evidenced by the visualization of sample replicate clusters in a  
t-SNE model that only included SML and ULW samples (Fig. S5).

To investigate the possibility of seawater sample clustering, a PCA model was built with the 51 extracted  
and curated features for averaged technical replicates of SML and ULW samples. Fig. 3A shows the PCA  
scores plot including the first three principal components that accounted for 43.93 %, 25.08 %, and 8.40  
335 % variance, respectively. No outliers were detected by this analysis and no sample clustering was  
visualized in the score plot. Thus, sample discrimination was further attempted by means of oPLS-DA  
coupled to a GA variable selection method to find a reduced set of features that would allow sample  
classification and class membership prediction. A panel of 11 features with the lowest RMSECV was  
selected through the GA process. Fig. 3B shows the cross-validated prediction plot using the selected  
340 feature panel by means of a model that consisted of 5 latent variables that interpreted 82.19 % and 95.41  
% variance from the X- (feature abundances) and Y- (class membership) blocks, respectively. This oPLS-  
DA model resulted in 100 % cross-validated accuracy, sensitivity, and specificity; therefore, there was no  
sample misclassification. Sample classification was further evaluated by means of a non-supervised  
method using the 11 discriminant features to discard possible overfitting by the supervised multivariate  
345 model. Fig. 3C shows certain degree of sample separation into clusters in the PC3 dimension according to  
the seawater sample collection depth, i.e., SML or ULW.

### 3.3 SOA formation potency from SML samples

A subset of SML samples (CAT 8, GP 10, CAT 6, CAT 3 and CAT 4) that were analyzed by the TM-  
350 DART-QTOF-MS seaomics strategy were also subject to on-site experiments during the field campaign  
using a lab-to-the-field approach to test their SOA formation potency. The outcome of a typical SML  
irradiation experiment is illustrated for sample CAT 8 in Fig. 4. Different time periods (P) during which  
experimental parameters were modified along the experiment are indicated in the figure. In the absence of  
light (before P1), no particle formation was detected downstream of the preconditioned OFR (5.0 ppmv  
355 initial O<sub>3</sub> and half-power UV light supply). However, when SML samples were exposed to actinic  
irradiation (periods P1-P4), particle formation was detected in the OFR254. Moreover, the particle  
number concentration exhibited OH exposure (OH<sub>exp</sub>)-dependent trends (P2-P3). Gaseous products were  
probably generated from photosensitized reactions at the SML interface, and subsequently reacted with  
OH radicals in the OFR254, leading to particle formation.

360 Because of the difficulty associated to on-site measuring total OHR (OH radical reactivity) from the cell  
reactor or tracing OH<sub>exp</sub> in the OFR, we only qualitatively tested the particle generation rates with  
respect to various oxidation degrees by changing the UV light intensity or O<sub>3</sub> concentration in the OFR.

Assuming that photochemistry occurring at the SML interface was at steady-state, air-water exchanged gaseous products were constantly entrained into the OFR, and the estimated particle generation rates/OHexp for each period followed the trend: P1<P4<P2<P3. During P1, particle concentration gradually increased with SML illumination, and final number concentration exceeded  $8 \times 10^3 \text{ cm}^{-3}$ . These particles exhibited a median diameter of several nanometers at the edge of the lower 10 nm size limit of the SMPS detection system, thus measuring the particle size distribution was not possible. During P2, UV light intensity was doubled in the OFR by turning all lamps on. A particle burst was detected with the UCPC, with a shift towards larger particle sizes. The oxidation capacity in the OFR was further enhanced by supplying additional external O<sub>3</sub> (initial mixing ratio of 7.0 ppmv). Total particle concentration decreased while larger particles were formed. During P4, one UV lamp in the OFR was turned off, and a sharp decrease in particle concentration was observed, but the final concentration was still higher than during P1 (Fig. 4). Particle formation was observed for CAT 8 and GP 10 SML samples. Results from the atmospheric simulation experiments conducted on SML samples were in agreement with previous laboratory studies that demonstrated air-sea interfacial driven chemistry as a source of marine secondary aerosol (Roveretto et al., 2019; Ciuraru et al., 2015; Fu et al., 2015).

### 3.4 Discriminant Compound Identification & Role in Aerosol Particle Formation

Compound identification was attempted for the 11 features of the discriminant panel. The coupling of the DART source to a high-resolution mass spectrometer allowed generating elemental formulae for unknown compounds, which together with tandem MS capability contributed to their identification. Figure S6 shows the high resolution continuum mass spectra obtained for each of the discriminant features detected in all samples and obtained from the GA selection process. The analysis of fragment ions detected in tandem MS experiments together with neutral loss analysis provided information regarding functional groups and contributed to filter molecular formulae obtained by accurate mass and isotopic pattern analysis. Table 1 describes the ionic species associated to the discriminant features and their corresponding molecular formulae, and provides information of product ions, and neutral and/or radical losses identified in TM-DART-QTOF-MS/MS experiments. In addition, the table includes the family of compounds identified with a certain confidence level. In general, discriminant features comprised saturated fatty acids, fatty alcohols, peptides, brominated compounds and boron-containing organic compounds.

An expected limitation of TM-DART-QTOF-MS analysis was associated to spectral overlap; thus, in some cases the isotopic pattern was not considered for compound identification. However, two different quadrupole mass windows of 6 and 1 Da were used in tandem MS experiments to mitigate this problem. The mass window of 6 Da allowed investigating the complete isotopic profile with high sensitivity at expense of lower selectivity than the narrower mass window. In contrast, the mass window of 1 Da provided more confidence in the identification of product ions with higher selectivity at the expense of lower sensitivity than the broader mass window. In cases of low precursor ion intensity or quadrupole co-selection, MS/MS spectra were not collected (Table 1).

Different types of species were generated for desorbed and ionized analytes (M) by the plasma-based source operated in negative mode, including  $[M-H]^-$ ,  $[M]^-$  and  $[M]^{*\cdot}$  ionic species. The generation of a radical anion,  $[M]^{*\cdot}$ , was suggested for feature # 4 based on the product ions detected in tandem MS experiments and the generated molecular formulae. Based on the tentative identification of feature # 4,  
405 additional experiments were performed with chemical standards including a dicarboxylic acid (succinic acid) and saturated fatty acids under the same experimental conditions as for seawater sample analysis. Different ionic species were detected in these experiments except for radical anions. However, literature evidence suggests the production of radical anions based on electron capture mechanisms occurring in He-based plasma sources (Cody and Dane, 2016;Bridoux and Machuron-Mandard, 2013;Jorabchi et al.,  
410 2013).

Based on the analysis of the isotopic patterns and tandem MS results, several features were identified as oxygenated boron-containing organic compounds. In these compounds, the boron atom is speculated to be functionalized with saturated fatty acids yielding tetra coordinated boron esters that would generate  $[M]^-$  anions. Boron-containing compounds are known to be ubiquitous in vascular plants, marine algal species,  
415 and microorganisms (Dembitsky et al., 2002). Four out of five features identified as boron-containing organic compounds functionalized with saturated fatty acids as well as features identified as fatty alcohols were enriched in SML samples compared to ULW samples (Table S4).

Compounds having a bromine atom in their molecular formula were also tentatively identified in the discriminant panel and are suggested to be halogenated compounds rather than bromine adduct ions. This  
420 hypothesis is based on the results yielded by the comparative analysis of a saturated acetonitrile solution with KBr and 2 mM phenol and the analysis of an acetonitrile solution of 4-bromo-phenol (Fig. S7), used as model compounds. The  $[M-H]^-$  ion was detected in the analysis of 4-bromo-phenol, but the  $[M+Br]^-$  adduct ion was not observed for the KBr saturated solution containing phenol. The two features (# 21 and 34) that were identified as halogenated compounds were enriched in SML samples (Table S4). Possible  
425 sources of halogenated compounds in SML samples are photochemical reactions occurring at the water/air interface (Roveretto et al., 2019;Donaldson and George, 2012). It is worth noting that organic compounds identified in the discriminant panel may have derived both from the secreted (exometabolome) and/or intracellular metabolites (endometabolome) of biological organisms such as algal species and microorganisms present in seawater, since samples were not filtered. Therefore, in a real  
430 environment some of these compounds may be present in lower levels than those detected in the present work or may not be available to participate in the sea surface SOA-chemistry.

Putative identification of the discriminant panel capable of differentiating SML from ULW samples provides further evidence to support secondary organic aerosol (SOA) formation detected with the lab-to-the-field approach during the campaign. The PCA scores plot illustrated in Fig. 5 shows that SML  
435 samples were not distinguished based on the collection method, i.e., GP or CAT, and points out those SML samples that were also evaluated for SOA formation during the field campaign. As previously discussed, two of these SML samples (CAT 8 and GP 10) yielded SOA formation (Fig. 4). Since CAT 8 and GP 10 were separated in the bidimensional scores map from the group formed of CAT 3, CAT 4 and CAT 6; a further PCA model was built only with those samples (n=5) that were analyzed by both TM-  
440 DART-QTOF-MS and the lab-to-the-field approach (Fig. S8). Figure S8A shows that PC2 clearly

separates samples according to SOA formation. Four out of 7 features that mainly contribute to sample class separation with largest absolute values in the loadings plot associated to PC2, and illustrated in Fig. S8B, were putatively identified as boron-containing organic compounds (Table S5). Despite the limitations associated with the low number of samples used to perform statistical analysis, results suggest that SML samples that led to particle formation were enriched on boron-containing organic compounds and other unidentified molecules (Table S5). ~~These results provide a proof of concept that organic compounds may play a key role in aerosol formation process at the water/air interface.~~

#### 4 Conclusions

An untargeted TM-DART-QTOF-MS-based analytical method coupled to multivariate statistical analysis allowed analyzing organic compounds present in SML and ULW seawater samples collected during a field campaign at the Cape Verde islands, without the need of desalinization. This seaomics approach was successfully implemented to discriminate SML from ULW samples. Tentative identification of the discriminant metabolite panel suggests that halogenated compounds, fatty alcohols, and oxygenated boron-containing organic compounds ~~are available for~~ ~~may be involved in~~ water-air transfer processes and ~~in~~ photochemical reactions at the water-air interface of the ocean. Combined results from TM-DART-QTOF-MS and on-site SOA formation testing experiments on SML samples, suggest that organic compounds enriched at the water/air interface ~~may be contributing to the differential SOA forming ability of SML samples~~ ~~may play a key role in aerosol formation process~~. This strategy, implemented for the first time in this collaborative study, provides new opportunities for improving the characterization of seawater OM content, and discovering compounds involved in aerosol formation processes.

#### Data availability

The mass spectrometry data have been deposited to the MetaboLights public repository, with the data set identifier MTBLS1198.

#### 465 Author contribution

MEM, MVP, HH, and CG designed the collaborative study. MVP and HH designed sample collection methods. MM processed samples until storage at -80 °C. MEM, MM and NZ developed the TM-DART-MS-based seaomics strategy and analyzed the data. MEM, NZ, MM, AD, NH and CG contributed to optimize the TM-DART-MS-based analytical method. NZ and MM conducted TM-DART-MS and MS/MS experiments. MR, CL and CG conducted on-site aerosol particle formation experiments. MEM, NZ and CG wrote the manuscript. All authors revised the manuscript.

## Competing interests

The authors declare that they have no conflict of interest.

690 **Table 1:** Identification of discriminant features based on accurate mass (a), isotopic pattern (b), and MS/MS experiments (c). Features with  $p < 0.05$  are highlighted in red (Wilcoxon Paired Signed Rank Test). Fold change trends in binary comparisons are indicated with arrows, ( $\uparrow$ ): increased levels, and ( $\downarrow$ ): decreased levels.

ID <sup>1</sup>	$m/z^2$	Ion type	MS	Tandem MS Experiments			Tentative MF for Detected Ionic Species; $\Delta m/mDa$	Criteria to obtain MF: a) exact mass b) isotopic pattern c) MS/MS information	Tentative ID: Main Class (Sub Class)	Fold Change Trend

**Figure 1.** Scheme illustrating the analytical strategy implemented at CIBION-CONICET for the analysis of lyophilized seawater samples using TM-DART-QTOF-MS.

**Figure 2.** (a) PCA scores plot showing the first two principal components, and (b) bi-dimensional t-SNE plot of seawater samples (circles) and solvent blanks (squares). WB: sample preparation blanks using ultrapure water (green), QC<sub>ALL</sub>: Pooled sample from all seawater samples before lyophilization (purple), QC<sub>MIX22</sub>: Pooled sample from all reconstituted seawater samples (pink), SML: Sea surface microlayer water samples (light blue), ACN: Acetonitrile (orange), CSW: Commercial seawater samples (gold), ULW: Underlying water samples (black). PCA and t-SNE models were built using the 51 extracted features and all replicates were included.

**Figure 3.** (a) PCA scores plot showing the first three principal components of sea surface microlayer samples (SML, light blue) and ultralow seawater samples (ULW, black). PCA was done based on 51 extracted features with averaged values from technical replicates. Accounted variance: PC 1, 43.93 %; PC 2, 25.08 %; PC 3, 8.40 %. (b) Cross-validated (CV) prediction plot of orthogonal projection to latent structures-discriminant analysis (oPLS-DA) model of SML samples (light blue) and ULW samples (black). The model consisted of 5 LVs with 82.19 % and 95.41 % total captured X-block and Y-block variances, respectively. The CV accuracy, sensitivity and specificity were 100 %. (c) PCA scores plot showing the first three principal components of SML samples (light blue) and ULW samples (black). PCA was done based on 11 discriminant features selected by the genetic algorithm. Variance accounted for PC 1, 44.22 %; PC 2, 17.44 %; and PC 3, 11.92 %.

**Figure 4.** Irradiation experiment for SML CAT 8 sample in a quartz cell and subsequent particle formation from the SML interfacial gaseous products via OH radical photochemistry in the OFR. (a) O<sub>3</sub> mixing ratio and humidity in the OFR, (b) particle concentration measured by CPC, and (c) particle size distribution profiles scanned by SMPS downstream of the OFR. The yellow shaded area represents the time period in which the quartz cell containing the concentrated SML sample was illuminated. P1-P4 corresponds to different operations to the OFR in varying oxidation degrees to the gaseous products from the quartz cell.

**Figure 5.** Bi-dimensional PCA score plot for SML samples using the matrix with 51 features for averaged technical replicates. Samples that were evaluated for particle formation during the Cape Verde field campaign are indicated with circles (led to SOA formation) and rectangles (did not lead to SOA formation).
