15 **Abstract**

16 An Aerodyne high-resolution time-of-flight aerosol mass spectrometer (HR-ToF-AMS) was
17 deployed along with other online instruments to study the highly time-resolved chemistry and
18 sources of submicron aerosols (PM₁) at Waliguan (WLG) Baseline Observatory, a high-altitude
19 (3816 m a.s.l.) background station located at the northeast edge of Qinghai-Tibet Plateau (QTP),
20 during 1–31 July 2017. The average PM₁ mass concentration during this study was 9.1 μg m⁻³
21 (ranging from 0.3 to 28.1 μg m⁻³), which was distinctly higher than those (2.0–5.7 μg m⁻³)
22 measured with Aerodyne AMS at other high-elevation sites in the southern or central QTP. Sulfate
23 showed dominant contribution (38.1%) to PM₁ at WLG following by organics (34.5%),
24 ammonium (15.2%), nitrate (8.1%), BC (3.0%) and chloride (1.1%). Accordingly, bulk aerosols
25 appeared to be slightly acidic throughout this study mainly related to the enhanced sulfate
26 contribution. All chemical species peaked at the accumulation mode, indicating the well mixed
27 and highly aged aerosol particles at WLG from long-range transport. Positive matrix factorization
28 (PMF) on the high-resolution organic mass spectra resolved four distinct organic aerosol (OA)
29 components, including a traffic-related hydrocarbon-like OA (HOA), a relatively fresh biomass
30 burning OA (BBOA), an aged biomass burning OA (agBBOA) and a more-oxidized oxygenated
31 OA (OOA). On average, the two relatively oxidized OAs, OOA and agBBOA, contributed 34.4%
32 and 40.4% of organics, respectively, while the rest were 18.4% for BBOA and 6.8% for HOA.
33 Source analysis for air masses displayed that higher mass concentrations of PM₁ and enhanced
34 contributions of sulfate and biomass burning related OA components (agBBOA + BBOA) were
35 from northeast of the WLG with shorter transport distance, whereas lower PM₁ mass
36 concentrations with enhanced OOA contribution were from west after long-range transport,
37 suggesting their distinct aerosol sources and significant impacts of regional transport on aerosol
38 mass loadings and chemistry at WLG.

39 **1 Introduction**

40 The Qinghai-Tibet Plateau (QTP) is one of the most remote and pristine region in the world. Its
41 huge surface area ($\sim 2,500,000 \text{ km}^2$) and high elevation (with a mean elevation of more than 4000
42 m above sea level (a.s.l.)) make it especially important in earth sciences and therefore the QTP is
43 generally called as the "third pole" (Yao et al., 2012). According to its high elevation, sparse
44 population and minor local anthropogenic activities, the QTP is regarded as an ideal area for
45 observing the natural background aerosol and long-range transported aerosol. In recent decades, a
46 certain number of studies have presented convincing evidence for the long-range transport of air
47 pollutants from the surrounding areas to the QTP (Engling et al., 2011; Xia et al., 2011; Lüthi et al.,
48 2015; Zhang et al., 2017). Particularly, air pollutants from the southern and southeastern Asia, two
49 of the major regions with enhanced biomass burning emissions in the world, would stack up in the
50 southern foothills of the Himalayas during the pre-monsoon season, then climbed over Himalayas
51 by the topographic lifting and the mountain-valley breeze circulation, and finally moved upward
52 to QTP (Lüthi et al., 2015). These long-range transport following by deposition of polluted air
53 masses, especially for the two important light-absorbing substances of black carbon (BC) and
54 brown carbon (BrC), have significant impacts on climate, environment and hydrology in the QTP
55 (Xu et al., 2009; Kang et al., 2010; Qian et al., 2011; Yang et al., 2014).

56 In contrast, aerosol particles in the northern QTP showed quite different behaviors comparing with
57 those in the southern QTP due to the different aerosol sources and climate for these two regions.
58 For example, Li et al. (2016) found equal important contributions from fossil fuel (46%) and
59 biomass (54%) aerosol sources to BC in the Himalayas, nevertheless, it was dominated by fossil
60 fuel combustion (66%) in the northern QTP. Correspondingly, the chemical composition of
61 ambient aerosol in the northern QTP was also distinctly different with that in the southern QTP.
62 Xu et al. (2014a, 2015) conducted aerosol composition studies from filter measurements of $\text{PM}_{2.5}$
63 (particulate matter with aerodynamic diameter less than $2.5 \mu\text{m}$) at the Qilian Shan Station
64 observatory at the northeast edge of QTP, and found sulfate was the dominant component during
65 summer season due to the influence of anthropogenic emissions from industrial areas in the
66 northwestern China. Similar results were also found by Li et al. (2013) and Zhang et al. (2014)
67 which conducted field studies in the northeast part of QTP. Nitrate, oxidized from the nitrogen
68 oxides (NO_x), was also an important component in the northern QTP which could interact with
69 mineral dust during transport (Xu et al., 2014a). Due to the relatively lower elevation comparing
70 with the southern QTP (< 4000 vs. > 5000 m a.s.l.), the polluted air masses are easily transported
71 to the mountain areas in the northern QTP forced by the strong mountain-valley breeze during
72 summer (Xu et al., 2013). Besides the significant impacts by anthropogenic emissions from the
73 northwestern China or Indian subcontinent, air pollutants to the northeastern QTP could also come
74 from the central Eurasian continent (Xue et al., 2013). However, most of the previous studies for
75 characterizing the chemical properties and sources of aerosol particles in the northeastern QTP
76 were heavily based on the filter or snow/ice samples with low time resolution ranging from days
77 to weeks, mainly because of the absent deployment of real-time instruments at the remote region
78 with harsh environments, challenging weather conditions and logistical difficulties. Studies
79 focusing on the atmospheric aerosol chemical compositions in the northeastern QTP using the
80 high-time-resolution real-time measurements are still relatively rare until now.

81 The Aerodyne aerosol mass spectrometer (AMS) is a unique instrument which can provide
82 chemical composition and/or size distribution information of non-refractory submicron aerosol
83 (NR-PM₁) with high time resolution and sensitivity (Jayne et al., 2000; Jimenez et al., 2003;
84 Canagaratna et al., 2007). AMS has been widely implemented worldwide in recent decades,
85 especially in China since 2006 due to the great concern of atmospheric environment (Li et al.,
86 2017, and references therein). Besides the typical applications for studying air pollution in these
87 urban/rural sites, e.g. megacities with severe haze pollution in eastern China, AMS has also been
88 successfully deployed at many remote sites due to its low detection limit (see details in Table 1 of
89 Xu et al. (2018) and Table S1 of Zhang et al. (2018)). In recent years, the deployments of AMS in
90 the highland areas of QTP have been conducted in a few field studies (Fig. S1), including a
91 high-resolution time-of-flight AMS (HR-ToF-AMS) and a soot particle AMS (SP-AMS) at Nam
92 Co in the central QTP (Wang et al., 2017; Xu et al., 2018), a HR-ToF-AMS at QOMS in the
93 southern QTP (Zhang et al., 2018) and a HR-ToF-AMS at Mt. Yulong in the southeastern QTP
94 (Zheng et al., 2017). In addition to the low PM₁ (NR-PM₁ + BC) mass loadings, the dominant
95 contribution from organic aerosol (OA) (54–68%) was found in the southern and central QTP
96 (Zheng et al., 2017; Xu et al., 2018; Zhang et al., 2018). OA was composed by oxygenated OA
97 (OOA) and biomass burning related OA (BBOA) components in those high-altitude background
98 sites. The OOA component was associated with the intense oxidation processes that converted the
99 fresh OA to secondary OA, while BBOA was related to the direct emissions from the biomass
100 burning activities in the highland areas. However, relatively few studies have been conducted in
101 the northern QTP except a study reporting measurement using Aerodyne aerosol chemical
102 speciation monitor (ACSM) at Menyuan (Du et al., 2015).

103 In this study, a HR-ToF-AMS with other real-time collocated instruments were first deployed at
104 the Waliguan (WLG) Baseline Observatory, which was one of the World Meteorological
105 Organization's (WMO) Global Atmospheric Watch (GAW) baseline observatories, located in the
106 northeastern QTP, to characterize the submicron aerosol chemical compositions and sources
107 during summer season. The real-time characterizations of submicron aerosols including mass
108 concentrations, chemical composition, size distribution as well as temporal and diurnal variations
109 were presented in details in this study. Source apportionment using positive matrix factorization
110 (PMF) analysis on the high-resolution OA mass spectrum was conducted to investigate the sources
111 and chemical evolution of OA during long-range transport. Finally, back trajectories of air masses
112 were then performed to present the possible sources and pathway of ambient aerosols during the
113 sampling period.

114 **2 Experimental methods**

115 **2.1 Site and measurements**

116 The field study was carried out during 1–31 July 2017 within the typical warm and rainy season at
117 the Waliguan (WLG) Baseline Observatory (36°17' N, 100°54' E, 3816 m a.s.l.), which is located
118 at the top of Mt. Waliguan at the northeast edge of QTP in western China with an ~ 600 m
119 elevation difference from the surrounding ground (Fig. 1a and b). Mt. Waliguan is a relatively
120 remote area and generally covered by typical highland vegetation, e.g., highland grassland and

121 tundra, and constructed as an in-land baseline station of Global Atmosphere Watch (GAW) since
122 1994 (http://www.wmo.int/pages/prog/arep/gaw/gaw_home_en.html). The closest town, Gonghe
123 County, is located ~ 30 km to the west of Mt. Waliguan and with a population of ~ 30,000, while
124 Xining, the capital city of Qinghai province, China, is the closest concentrated population center
125 located about 90 km to the northeast and with a population of 2.35 millions. A national road is
126 about 9 km to the north of Mt. Waliguan, yet with relative light vehicle traffic. Therefore, there are
127 no strong anthropogenic source emissions around Mt. Waliguan. The date and time used in this
128 study are reported in local time, i.e., Beijing Time (BJT: UTC + 8 h).

129 **2.2 Instrumentation**

130 Aerosol measurements were performed at the top floor of the main two-story building at WLG
131 observatory from 1 to 31 July 2017 with a suit of real-time instruments, including a HR-ToF-AMS
132 (Aerodyne Research Inc., Billerica, MA, USA) for size-resolved chemical compositions (organics,
133 sulfate, nitrate, ammonium and chloride) of NR-PM₁, a photoacoustic extinciometer (PAX, DMT
134 Inc., Boulder, CO, USA) for particle light absorption and scattering coefficients (b_{abs} and b_{scat}) at
135 405 nm and the black carbon (BC) mass concentration through a constant mass absorption
136 efficient (MAE) value of $10.18 \text{ m}^2 \text{ g}^{-1}$, and a cloud condensation nuclei counter (CCN-100, DMT
137 Inc., Boulder, CO, USA) for the number concentration of cloud condensation nuclei (CCN) that
138 can form into cloud droplets. Simultaneously, other synchronous data were also acquired at the
139 WLG baseline observatory during the sampling period, including the mass concentrations of PM_{2.5}
140 and PM₁₀ (particulate matter with aerodynamic diameter less than 10 μm) measured by a TEOM
141 1405-DF dichotomous ambient particulate monitor with a filter dynamics measurement system
142 (Thermo Scientific, Franklin, MA, USA) and gaseous pollutants of carbon monoxide (CO) and
143 ozone (O₃) measured using the Thermo gas analyzers (Model 48i and 49i, respectively, Thermo
144 Scientific, Franklin, MA, USA). The setup of instruments in this study was shown in Fig. 1d.
145 Ambient particles were sampled through an inlet system, including a PM_{2.5} cyclone (model
146 URG-2000-30EH, URG Corp., Chapel Hill, NC, USA) for removing coarse particles with size
147 cutoffs of 2.5 μm , a nafion dryer following the cyclone to dry the ambient air and eliminate the
148 potential humidity effect on particles, and 0.5 inch stainless steel tubes. The inlet stepped out of
149 the building rooftop about 1.5 m, and the total air flow of the inlet was about 12.5 L min^{-1} ,
150 maintained by a vacuum pump with a flow rate of 10 L min^{-1} for the PM_{2.5} size cut, and the other
151 part of flow rate by the instruments. The room temperature was maintained at ~ 18 °C by two air
152 conditioners. In addition, a Vantage Pro2 weather station (Davis Instruments Corp., Hayward, CA,
153 USA) was set up on the building rooftop to obtain the real-time meteorology data, including
154 ambient temperature (T), relative humidity (RH), wind speed (WS), wind direction (WD), solar
155 radiation (SR), and precipitation (Precip.).

156 The details of the Aerodyne HR-ToF-AMS has been described elsewhere (DeCarlo et al., 2006).
157 Briefly, a 120 μm critical orifice (replaced the typical 100 μm for enhancing the transmission
158 efficiency at high-altitude area) and an aerodynamic lens were settled in the front inlet system to
159 sample and focus the ambient particles into a concentrated and narrow beam. The focused particle
160 beam exiting the lens was accelerated into the particle-sizing vacuum chamber to obtain the
161 aerodynamic size of particles by a rotating wheel chopper. Then, particles were vaporized

162 thermally at ~ 600 °C by a resistively heated surface and ionized by a 70 eV electron impact, and
163 finally, detected by a high-resolution mass spectrometer. The chopper generally worked at three
164 positions alternately, i.e., open, close, and chopping positions, for measuring the bulk and
165 background signals as well as the size-resolved spectral signals of airborne particles, respectively.
166 Similar to most of the previous AMS field measurements, the mass spectrometer was toggled
167 under the high sensitive V-mode (detection limits ~ 10 ng m⁻³) and the high resolution W-mode
168 (~ 6000 m/ Δ m) every 5 min in this study. Under the V-mode operation, the instrument also
169 switched between the mass spectrum (MS) mode and the particle P-ToF mode every 15 s to obtain
170 the mass concentrations and size distributions of NR-PM₁ species, respectively, whereas the high
171 resolution W-mode was used to obtain high resolution mass spectral data. However, the data and
172 error matrices inputted into the PMF analysis were finally generated from the V-mode data rather
173 than the W-mode data in this study due to the low aerosol mass loading at WLG. Hence, all the
174 data used in this study are from V-mode with 10 min time resolution.

175 **2.3 Data processing**

176 The HR-ToF-AMS data were processed using the standard AMS analysis software of SQUIRREL
177 (v1.56) to determine the mass concentrations and size distributions of NR-PM₁ species and the
178 high resolution data analysis software of PIKA (v1.15c) to analyze the ion-speciated mass spectra,
179 components and elemental compositions (e.g., oxygen-to-carbon (O/C), hydrogen-to-carbon (H/C),
180 nitrogen-to-carbon (N/C) and organic mass-to-organic carbon (OM/OC) ratios using the
181 “improved-ambient” method (Canagaratna et al., 2015)) of organics in this study. A collection
182 efficiency (CE) was introduced to compensate for the incomplete transmission and detection of
183 particles due to particle bouncing at the vaporizer and partial transmission through the
184 aerodynamic lens. Middlebrook et al. (2012) had evaluated the dependency of CE on several
185 ambient properties and concluded a composition-dependent CE parameterization according to the
186 sampling line RH, aerosol acidity, and mass fraction of ammonium nitrate (ANMF). High RH,
187 high aerosol acidity or high ANMF values would all increase the CE obviously. However, in this
188 study, (1) aerosol particles were dried totally through a nafion dryer in the inlet system and made
189 sure that RH in the sampling line were below 40%; (2) aerosol particles were just slightly acidic as
190 indicated by the average ratio (0.86) of measured ammonium to predicted ammonium (see Sect.
191 3.1 and Fig. 3a for details); (3) ANMF values were normally below 0.4 during the entire sampling
192 period as shown in Fig. S2. Therefore, these three parameters were all expected to have negligible
193 effects on the quantification of aerosol species from our AMS data set and thus a constant CE of
194 0.5, which has been widely used in previous field AMS studies, was finally employed in this
195 study.

196 The source apportionment of organics in this study was conducted by PMF analysis using the
197 PMF2.exe algorithm (v4.2) (Paatero and Tapper, 1994) and PMF Evaluation Tool (PET, v2.03)
198 (Ulbrich et al., 2009) in robust mode on the high resolution organic mass spectrum. The PMF
199 analysis was thoroughly evaluated following the procedures summarized in Table 1 of Zhang et al.
200 (2011), including modifying the error matrix, down-weighting or removing the low signal-to-noise
201 (S/N) ions, etc. For example, the signals of H₂O⁺ and CO⁺ for organics were scaled to that of
202 CO₂⁺ as CO⁺ = CO₂⁺ and H₂O⁺ = 0.225 × CO₂⁺, while signals of HO⁺ and O⁺ were set as

203 $\text{HO}^+ = 0.25 \times \text{H}_2\text{O}^+$ and $\text{O}^+ = 0.04 \times \text{H}_2\text{O}^+$ according to Aiken et al. (2008). Then the above
204 four ions were further down-weighted by increasing their errors by a factor of 2 in PMF analysis.
205 Isotopic ions were generally excluded because their signals are not directly measured. The “bad”
206 ions with $S/N < 0.2$ were removed from the data and error matrices, while the “weak” ions with
207 $0.2 < S/N < 2$ were downweighted by increasing their errors. In addition, some runs with huge
208 residual spikes, e.g., data with much too low mass loadings related with the heavy rain on 27 July
209 2017, were also removed from the data and error matrices. A summary of the key diagnostic plots
210 of PMF results for this study is presented in Fig. S3. Overall, the PMF solutions were investigated
211 from one to six factors with the rotational parameter (f_{Peak}) varying from -1 to 1 with a step of
212 0.1 . Finally, a four-factor solution with $f_{\text{Peak}} = 0$ was chosen in this study by examining the model
213 residuals, scaled residuals and Q/Q_{exp} contributions for each m/z and time, as well as comparing the
214 mass spectra of individual factor with reference spectra and the time series of individual factor
215 with external tracers. The mass spectra, time series, and diurnal variations of PMF results from
216 three-factor and five-factor solutions were also shown in Fig. S4 and S5 for comparison,
217 respectively. The three-factor solution did not separate the two biomass burning factors whereas
218 the five-factor solution showed a splitting factor.

219 **3 Results and discussion**

220 **3.1 Size-resolved chemical characteristics of PM_{10}**

221 An overview of temporal variations of mass concentrations and fractions of PM_{10} chemical species
222 (organics, sulfate, nitrate, ammonium, chloride and BC) as well as meteorological conditions (T ,
223 RH, WS, WD, and Precip.), mass concentrations of relevant particulate matters ($\text{PM}_{2.5}$ and PM_{10})
224 and gaseous pollutants (O_3 and CO), and mass fractions of organic components are shown in Fig.
225 2, respectively. The missing data are due to hardware or software malfunction, maintenance of the
226 instrument, or removing large spikes and unique burning event (a local Tibetan festival event
227 occurred during 5–6 July 2017 with extremely high aerosol mass loadings) in data processing. Air
228 temperature (T) ranged from 8.5 to 14.5 °C for the averaged diurnal variation during the study,
229 with an average ($\pm 1\sigma$) of 11.0 ± 2.0 °C, while relative humidity (RH) ranged from 55.9 to 73.5%
230 with an average of $66.6 \pm 5.7\%$ (Fig. S6). The wind directions (WD) at WLG were predominantly
231 by eastern, southeastern and northeastern during this study, with an average wind speed (WS) of
232 4.4 ± 2.8 m s^{-1} (Fig. 1c and 2b). In addition, WD generally changed from eastern to southeastern
233 during the nighttime with WS higher than 4 m s^{-1} , whereas from northwestern to northeastern
234 during the daytime with relatively lower WS (Fig. S6). Two moderate rain events occurred during
235 2–9 and 22–28 July 2017, with daily mean precipitation of 2.6 and 7.4 mm d^{-1} , respectively (Fig.
236 2a).

237 The total PM_{10} mass varied dynamically throughout this study with mass concentration ranging
238 from 0.3 to 28.1 $\mu\text{g m}^{-3}$. This dynamic variation pattern could also be found for the mass
239 concentrations of $\text{PM}_{2.5}$, PM_{10} and CO , with their correlation coefficients (R^2) versus PM_{10} varying
240 reasonably from 0.39 to 0.63 (Fig. 2 and S7). In addition, PM_{10} accounted 66% of $\text{PM}_{2.5}$ mass in
241 this study (Fig. S7), reflecting essentially contribution of submicron aerosols at WLG. Overall, the
242 average mass concentration of total PM_{10} ($\pm 1\sigma$) at WLG for the entire study was $9.1 (\pm 5.3)$ $\mu\text{g m}^{-3}$,

243 which was much higher than those at other high-elevation sites in the QTP measured with
244 Aerodyne AMS, such as $2.0 \mu\text{g m}^{-3}$ between 31 May and 1 July 2015 at Nam Co Station (4730 m
245 a.s.l.) in the central QTP (Xu et al., 2018), $4.4 \mu\text{g m}^{-3}$ between 12 April and 12 May 2016 at
246 QOMS (4276 m a.s.l.) at the south edge of QTP (Zhang et al., 2018), and $5.7 \mu\text{g m}^{-3}$ between 22
247 March and 14 April 2015 at Mt. Yulong (3410 m a.s.l.) at the southeastern QTP (Zheng et al.,
248 2017), whereas this value was comparable with that ($11.4 \mu\text{g m}^{-3}$) measured with an Aerodyne
249 ACSM between 5 September and 15 October 2013 at Menyuan (3295 m a.s.l.) at the northeastern
250 QTP (Du et al., 2015). The higher PM_{10} mass concentration at WLG in the northeastern QTP
251 comparing with those at other sites in the central or southern QTP was likely due to the relatively
252 shorter distance from the industrial areas (e.g., Xining city) in the northwestern China and strong
253 mountain-valley breeze during summer. This conclusion could be supported by the comparisons of
254 air mass back-trajectories between WLG in this study (see Sect. 3.4 for details) and those at Nam
255 Co Station in Xu et al. (2018) and QOMS in Zhang et al. (2018). Sulfate and organics were the
256 two dominant PM_{10} species at WLG, accounting for 38.1% and 34.5% on average, respectively,
257 followed by ammonium (15.2%), nitrate (8.1%), BC (3.0%) and chloride (1.1%). This chemical
258 composition of PM_{10} at WLG was quite different with those at Nam Co, QOMS and Mt. Yulong
259 sites in the central or southern QTP (Zheng et al., 2017; Xu et al., 2018; Zhang et al., 2018), where
260 organics was the dominant species accounting for 54–68% of total PM_{10} mass due to the significant
261 contribution of biomass burning emissions, whereas sulfate only contributed 9–15% of total PM_{10} .
262 The consistent high contribution of sulfate was also observed at Menyuan (28%) in the
263 northeastern QTP and other rural and remote sites (19–64%) in East Asia which were far away
264 from urban areas, as that summarized in Fig. 1 in Du et al. (2015). Moreover, as displayed in Fig.
265 3b, mass contribution of sulfate increased significantly with the increase of total PM_{10} mass (lower
266 than 15% for PM_{10} mass equal to $1.0 \mu\text{g m}^{-3}$ and increased to more than 45% for PM_{10} mass of 20.0
267 $\mu\text{g m}^{-3}$), suggesting important contribution of sulfate to submicron aerosols at WLG.

268 Bulk acidity of PM_{10} at WLG was also evaluated according to the method in Zhang et al. (2007).
269 The predicted ammonium was calculated based on the mass concentrations of sulfate, nitrate and
270 chloride and assumed full neutralization of these anions by ammonium. The PM_{10} appeared to be
271 slightly acidic throughout this study, as indicated by the scatter plot between the measured and
272 predicted ammonium in Fig. 3a (Slope = 0.86, $R^2 = 0.98$). The acidic feature of aerosol particles at
273 WLG was consistent with those results at Menyuan (Du et al., 2015) and Qilian Shan Mountain
274 (Xu et al., 2015) that both located in the northeastern QTP, but different with those at Nam Co (Xu
275 et al., 2018) and QOMS (Zhang et al., 2018) in the central or southern QTP where bulk aerosol
276 particles were generally neutralized or excesses of ammonium. The enriched sulfate in the
277 northeastern QTP might be related tightly with the enhanced coal consumption in the northwest of
278 China and aqueous processing by cloud at the mountains. This conclusion could be further
279 demonstrated by the emission distribution of sulfur dioxide (SO_2) in China observed by the Ozone
280 Monitoring Instrument (OMI) satellite data in previous studies (Lu et al., 2011; van der A et al.,
281 2017), where SO_2 showed considerable concentrations in the northwest of China, especially in
282 urban areas like Xining and Lanzhou cities, whereas extremely low concentrations occurred in the
283 southern QTP.

284 The average chemically-resolved size distributions of mass concentrations of NR- PM_{10} species are

285 shown in Fig. 3c. Overall, all chemical species peaked at the accumulation mode with different
286 peaking sizes, e.g. ~ 400 nm in aerodynamic diameter (D_{va}) for organics, ~ 450 nm for chloride,
287 and ~ 500 nm for the rest three secondary inorganic species (sulfate, nitrate and ammonium),
288 indicating the well mixed and highly aged aerosol particles at WLG during the sampling period.
289 Moreover, organics presented relatively wider distribution than the three secondary inorganic
290 species in the small sizes (< 300 nm). This could also be clearly revealed by the variations of mass
291 contribution of chemical species as a function of particle sizes in Fig. 3d. The contribution of
292 organics decreased apparently with the increasing sizes whereas those of three inorganic species,
293 especially sulfate, increased correspondingly. Specifically, organics could contribute more than
294 half of the ultrafine NR-PM₁ ($D_{va} < 100$ nm) that maybe associated with the existing of relatively
295 fresh sources of organic particles, while the three inorganic species dominated (more than 60%) at
296 the accumulation mode due to their highly aged properties.

297 **3.2 Bulk characteristics and elemental composition of OA**

298 The average high-resolution mass spectrum (HRMS) and elemental compositions of OA during
299 the study were shown in Fig. 4a. Note that the elemental ratios of O/C, H/C, N/C and OM/OC in
300 this study were all determined using the “improved-ambient” method (Canagaratna et al., 2015),
301 which increased O/C by 29%, H/C by 14% and OM/OC by 15% on average, respectively,
302 comparing with those determined from the “Aiken ambient” method (Aiken et al., 2008) (Fig. S8).
303 The average HRMS of OA was quite similar with those at other locations, e.g., Menyuan (Du et al.,
304 2015), Nam Co (Xu et al., 2018) and QOMS (Zhang et al., 2018) in the QTP, with significantly
305 high contribution at m/z 44 (17.9%; composed totally by CO_2^+ in this study and similarly
306 hereinafter). On average, $\text{C}_x\text{H}_y\text{O}_1^+$ dominated the total OA (44.0%) followed by C_xH_y^+ (27.9%),
307 $\text{C}_x\text{H}_y\text{O}_2^+$ (21.7%), H_yO_1^+ (5.1%), $\text{C}_x\text{H}_y\text{N}_p^+$ (1.0%) and $\text{C}_x\text{H}_y\text{O}_z\text{N}_p^+$ (0.2%), as shown in pie chart
308 in Fig. 4a. The total contributions of the two major oxygenated ion fragments ($\text{C}_x\text{H}_y\text{O}_z^+$) was 65.7%
309 at WLG, which was comparable to those values at Nam Co during 31 May–1 July 2015 (57.9%;
310 Xu et al., 2018) and QOMS during 12 April–12 May 2016 (66.2%; Zhang et al., 2018), whereas
311 much higher than that (38.0%) measured during 11 July–7 August 2012 at Lanzhou (Xu et al.,
312 2014b). In addition, the average O/C ratio of 0.99 in this study was also comparable with those at
313 Nam Co (0.88; determined by “improved-ambient” method and similarly hereinafter; Xu et al.,
314 2018) and QOMS (1.07; Zhang et al., 2018), but quite higher than those observed at various urban
315 and rural sites in China during summertime, e.g., 0.53 and 0.56 in Beijing, 0.40 in Shanghai, 0.41
316 in Shenzhen and 0.36 in Jiaxing (Hu et al., 2017). As either the contributions of CO_2^+ and
317 $\text{C}_x\text{H}_y\text{O}_z^+$ or element ratio of O/C are generally considered as good indicators for the aging degree
318 of OA, the relatively higher values at WLG as well as at other sites in the QTP together indicated
319 that OA in the QTP was highly oxidized due to the absence of local emissions and long-range
320 transport.

321 Diurnal cycles of O/C and OM/OC ratios in this study varied shallowly within 0.96–1.05 and
322 2.40–2.52, respectively, suggesting an overall OA source from regional transport at WLG (Fig.
323 4b). The relatively higher O/C and OM/OC ratios during afternoon potentially related with the
324 photochemical oxidation processes in the daytime, while lower values in the late morning mainly
325 associated with the transport of relatively fresh OA from nearby areas to WLG site, which could

326 be further revealed by the corresponding higher H/C and N/C ratios in the late morning as well as
327 the diurnal variations of the two primary OA components (see Sect. 3.3 for details).
328 Correspondingly, the H/C ratio presented an opposite diurnal pattern comparing with O/C. The
329 elemental ratios in the Van Krevelen diagram (H/C versus O/C), which had been used widely to
330 probe the oxidation reaction mechanisms for bulk OA, were calculated following a slope of -0.64
331 in this study (Fig. S8), which suggested that the OA oxidation mechanism at WLG was a
332 combination of carboxylic acid groups with fragmentation and alcohol/peroxide functional groups
333 without fragmentation (Heald et al., 2010).

334 3.3 Source apportionment of OA

335 PMF analysis on the OA HRMS identified four distinct components, i.e., a traffic-related
336 hydrocarbon-like OA (HOA), a relatively fresh biomass burning OA (BBOA), an aged biomass
337 burning OA (agBBOA) and a more-oxidized oxygenated OA (OOA) in this study. Each of OA
338 components had unique characteristics on mass spectral profile, average element ratios, diurnal
339 pattern, and temporary variation as well as tight correlations with corresponding tracers. The
340 details on the source apportionment results of OA are given as follows.

341 Figure 5 shows the average HRMS and temporal variation of each OA component, respectively. A
342 traffic-related hydrocarbon-like OA (HOA), with the lowest O/C ratio (0.33) and the highest H/C
343 ratio (1.83) among the four factors, was identified in this study. Similar to several HOA mass
344 spectra reported in previous studies (Zhang et al., 2005; Ng et al., 2011), HRMS of HOA in this
345 study was also dominated by hydrocarbon ion series of $C_nH_{2n\pm 1}^+$, especially $C_3H_5^+$ ($m/z = 41$),
346 $C_3H_7^+$ ($m/z = 43$), $C_4H_7^+$ ($m/z = 55$), $C_4H_9^+$ ($m/z = 57$), $C_5H_9^+$ ($m/z = 69$), and $C_5H_{11}^+$ ($m/z = 71$),
347 as shown in Fig. 5a. Consequently, the dominant contribution of ion fragment was $C_xH_y^+$ (62.8%)
348 follow by $C_xH_yO_1^+$ (29.3%) and $C_xH_yO_2^+$ (6.1%) (Fig. S9), suggesting the primary feature of
349 HOA compared with other OA components. The two dominant ions, $m/z 57$ (mainly $C_4H_9^+$ and
350 $C_3H_5O^+$) and $m/z 55$ (mainly $C_4H_7^+$ and $C_3H_3O^+$), which are generally associated with primary
351 organics from combustion sources, are commonly considered as tracers for HOA in previous
352 studies (Zhang et al., 2005). In our study, HOA contributed 71 and 27% to $C_4H_7^+$ and $C_3H_3O^+$,
353 respectively, at $m/z 55$ while 89 and 29% to $C_4H_9^+$ and $C_3H_5O^+$ at $m/z 57$. The time series of
354 HOA correlated closely with those of $C_4H_9^+$ ($R^2 = 0.68$, Fig. 5e) and other alkyl fragments, like
355 $C_3H_7^+$, $C_4H_7^+$, $C_5H_9^+$ ($R^2 = 0.52-0.65$, Fig. S10). Besides, the high-resolution mass spectrum of
356 HOA was highly similar to those from other locations around the world (Aiken et al., 2009; Elser
357 et al., 2016; Hu et al., 2016), with correlation coefficients (R^2) varying from 0.62 to 0.94 (Fig.
358 S11). Diurnal variation of HOA (Fig. 6c and d) in this study presented two slight peaks in the late
359 morning (around 10:00 BJT) and evening (around 20:00 BJT), respectively. Although there was
360 not traffic rush hour in the high-elevation site, the increasing vehicles on the national road
361 combined with the valley breeze together lead to the slightly higher HOA concentrations in the
362 late morning, then HOA decreased continuously with the increasing planetary boundary layer
363 (PBL) height in the afternoon and elevated again to a stable high level during the nighttime due to
364 the low PBL height and mountain breeze. Note that the O/C ratio of HOA in this study was
365 obviously higher than those (generally lower than 0.2) observed in either urban sites or laboratory
366 studies where have intense local traffic emissions (He et al., 2010; Sun et al., 2011; Xu et al.,

367 2016). The reason is mainly due to the regional transport of traffic emission to WLG. As
368 mentioned in Sect. 2.1, one national road is about 9 km to the north of Mt. Waliguan yet with
369 relative light vehicle traffic. Hence, the traffic related aerosols from either the national road or
370 nearby towns and cities would undergo certain oxidation processes during transportation to WLG
371 site.

372 Two biomass burning related OA factors, a relatively fresh biomass burning OA (BBOA) and an
373 aged biomass burning OA (agBBOA), with distinctly different oxidation degrees were also found
374 in this study. Although the m/z 44 signals were still the highest peaks for both the two factors, the
375 m/z 60 signals, which were generally regarded as well-known tracers for biomass burning
376 emissions (Alfarra et al., 2007), were also obvious in both HRMS. The fractions of the signals at
377 m/z 60 (f_{60}) in their HRMS were 0.51 and 0.46%, respectively, which were significantly higher
378 than the typical value of 0.3% that has been widely used as a background level in air masses not
379 impacted by active open biomass burning in previous studies (Cubison et al., 2011; Zhou et al.,
380 2017), demonstrating the presence of biomass burning related OA factors at WLG site. As shown
381 in the Fig. 5, the time series of agBBOA correlated tightly with $C_2H_4O_2^+$ ($R^2 = 0.79$) and sulfate
382 ($R^2 = 0.47$), while BBOA correlated slightly with $C_2H_4O_2^+$ ($R^2 = 0.47$) and potassium ($R^2 = 0.30$),
383 respectively. The time series of agBBOA also correlated well with $C_xH_yO_1^+$ and $C_xH_yO_2^+$ ions,
384 while BBOA correlated well with $C_xH_y^+$ and $C_xH_yO_1^+$ (Fig. S10). In addition, both the mass
385 spectra of the two biomass burning related OA factors resembled well with that of BBOA at
386 QOMS (R^2 of 0.886 and 0.954, respectively; Fig. S11; Zhang et al., 2018), whereas correlated
387 moderately ($R^2 = 0.39$ – 0.59) with other standard BBOA mass spectra at other sites around the
388 world (Aiken et al., 2009; Mohr et al., 2012). The agBBOA mass spectrum in this study correlated
389 tightly ($R^2 = 0.914$) with the less oxidized oxygenated OA (LOOOA) identified at Nam Co station
390 (Fig. S11; Xu et al., 2018). All these comparisons and correlation analysis further verified the
391 reasonable source apportionment of OA in this study, namely there were two biomass burning
392 related OAs at WLG, as a result of the different oxidation degrees of biomass burning emissions
393 transported from surrounding areas to WLG site (see Sect. 3.4 for details). Similar OA source
394 apportionment of two BBOA components with different oxidation degrees have also been resolved
395 in previous studies, e.g., an additional oxygenated biomass-burning-influenced organic aerosol
396 (OOA₂-BBOA or OOA-BB) in the Paris metropolitan area (Crippa et al., 2013), urban Nanjing
397 (Zhang et al., 2015) and Mt. Yulong (Zheng et al., 2017), respectively, besides the relatively fresh
398 BBOA component. The O/C and OM/OC ratios for the relatively fresh biomass burning OA
399 (BBOA) were 0.69 and 2.06, respectively, while much higher values of 1.02 and 2.49 for the aged
400 biomass burning OA (agBBOA). Correspondingly, the $C_xH_yO_z^+$ fragment also showed higher
401 contribution for agBBOA than that for BBOA (67.8% vs. 56.6%; Fig. S9). Moreover, the O/C
402 ratio of BBOA in this study was also obviously higher than those in other urban or rural sites in
403 China where had direct or local biomass burning sources, e.g., 0.24 in Lanzhou (Xu et al., 2016),
404 0.36 in Beijing (Sun et al., 2016) and 0.26 in Kaiping (Huang et al., 2011). The diurnal patterns of
405 the two biomass burning related OAs presented nearly opposite trends in this study (Fig. 6c and d),
406 with high values during the nighttime and decreased trend in the afternoon for BBOA whereas
407 increased obviously during the daytime for agBBOA, mainly associated with the possible aging
408 evolution from BBOA to agBBOA via photochemical oxidation during the daytime.

409 Another OA component, characterized by the highest peak at m/z 44 (contributed $\sim 28\%$ of total
410 signal), the highest average O/C (1.42) and OM/OC (3.00), and the highest contribution of
411 $C_xH_yO_z^+$ fragment (44.5% of $C_xH_yO_1^+$ and 30.6% of $C_xH_yO_2^+$; Fig. S9) among the four factors,
412 was identified as an oxygenated OA (OOA) in this study. The OOA HRMS in this study was quite
413 similar with those more-oxidized oxygenated OA (MO-OOA) or low-volatility oxygenated OA
414 (LV-OOA) factors identified frequently in previous AMS studies, especially resembled tightly to
415 those MO-OOA identified in other QTP locations (Fig. S11), e.g. Nam Co ($R^2 = 0.995$; Xu et al.,
416 2018) and QOMS ($R^2 = 0.997$; Zhang et al., 2018), suggesting that this factor mainly represented a
417 typical regional oxygenated OA. The time series of OOA in this study correlated closely with the
418 main secondary inorganic species, sulfate ($R^2 = 0.51$), indicating their commonly regional and
419 aged properties. In addition, the time series of OOA also correlated well with $C_xH_yO_2^+$ ions,
420 especially with CO_2^+ ($R^2 = 0.62$) as shown in Fig. S10. Although OOA showed relatively stable
421 contributions throughout the whole day, the OOA mass concentrations also presented distinct
422 diurnal variation at WLG site, namely relatively low values in the late morning, continuously
423 increasing trend during the afternoon and moderate values at the nighttime (Fig. 6c and d), which
424 tightly associated with the photochemical activities in the daytime, aqueous-processing of OA at
425 nighttime as well as the diurnal variation of PBL height.

426 Overall, the average mass concentration of organics was $3.14 \mu\text{g m}^{-3}$ for the entire study and
427 composed by 34.4% of OOA, 40.4% of agBBOA, 18.4% of BBOA and 6.8% of HOA on average
428 (Fig. 6a). The biomass burning related OA components together contributed more than half of the
429 total organics. In addition, obviously enhanced contributions were found for the two biomass
430 burning related OA components, particular for agBBOA, with the increasing organics mass,
431 whereas OOA decreased correspondingly (Fig. 6b). For example, BBOA and agBBOA contributed
432 only $\sim 10\%$ to total organics when OA was less than $1.0 \mu\text{g m}^{-3}$, whereas the contribution reached
433 up to 70% with the mass concentration of OA increased to $7 \mu\text{g m}^{-3}$. Moreover, the important
434 contribution of agBBOA could also be clearly seen in the temporal variations in Fig. 2f, where
435 agBBOA dominated organics during the relatively polluted periods. All of these suggested that
436 biomass burning emissions from regional transport was the important source for OA at WLG. The
437 triangle plot (f_{44} vs. f_{43} or $f_{CO_2^+}$ vs. $f_{C_3H_3O^+}$), which has been widely used in AMS studies, was
438 an useful method to characterize the possible evolution mechanism of organic components upon
439 aging in the ambient atmosphere (Ng et al., 2010). As shown in Fig. 4c and d, the majority of data
440 are distributed within the two dash lines that defined as the general triangular space where ambient
441 organic components fall by Ng et al. (2010). HOA presented relatively primary nature among four
442 organic components and located in the bottom of triangle plots, while two biomass burning related
443 components in the middle part and OOA in the upper-left corner of the triangle plots, suggesting
444 an obvious oxidation evolution from relatively primary components to secondary components.

445 3.4 Source analysis

446 In order to study the dominant sources and explore the influence of regional transport to PM_{10} mass
447 loading and chemical composition at WLG during summer season, the 72 h backward air mass
448 trajectories and average clusters at 500 m above ground level were calculated at 1 h intervals using
449 the Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Draxler and

450 Rolph, 2003) and meteorological data from the NOAA Global Data Assimilation System (GDAS).
451 Finally, six air mass clusters were adopted in this study as presented in Fig. 7a.

452 Air masses from northeast (C1) with the shortest transport distance and lowest height among all
453 the clusters, dominated the air mass contribution (57%) and had the highest average PM_{10} mass
454 concentration ($10.8 \mu\text{g m}^{-3}$) during the sampling period, whereas the rest five clusters (C2–C6)
455 were generally from the west or northwest and showed apparently longer transport distances,
456 higher heights and relatively lower mass concentrations ($5.8\text{--}7.8 \mu\text{g m}^{-3}$) than C1. As shown in
457 Fig. 1b, three towns (Haiyan, Huangyuan and Huangzhong) as well as the capital city (Xining) of
458 Qinghai Province were located to the northeast of WLG within 100 km, leading to relatively dense
459 population and intense industrial activities in these areas compared with those areas to the west of
460 WLG. Therefore, the prevailing air masses with low transport height for C1 could bring large
461 amount of surface anthropogenic and industrial pollutants to WLG. This conclusion could further
462 be supported by the significantly different contributions of chemical species during each cluster
463 (Fig. 7a). Specifically, C1 showed higher contribution of sulfate compared to other clusters (39.5
464 vs. 32.0–35.5%), which was mainly related with the intense industrial emissions. In addition, OA
465 components for C1 showed higher contributions from BBOA (19.5%) and agBBOA (43.3%)
466 compared with those for C4 and C5 (12.3 and 11.2% for BBOA and 35.4 and 36.7% for agBBOA,
467 respectively), whereas much lower contribution of oxidized OOA was found for C1 than those for
468 C4 and C5 (31.0 vs. 43.9 and 44.0%), suggesting the relatively fresh of OOA for C1. This
469 phenomenon was more clear for the two distinct periods, P1 and P2, as shown in Fig. 7b and 8. Air
470 masses for P2 was mainly from the northeast (C1; 79.0%) and resulted higher contributions from
471 sulfate (39.9% to total PM_{10}) and the two biomass burning related OA components (BBOA and
472 agBBOA, 63.2% to total organics), however, three clusters (C4–C6) from the west with long
473 transport distances dominated P1 and led to significant enhancement of OOA contribution.

474 Besides the back trajectory analysis, bivariate polar plot analysis was another useful method to
475 give insight into the potential source regions of ambient aerosols, which presents the relationships
476 of mass concentrations of PM_{10} chemical species with wind conditions (WS and WD) (Fig. S12).
477 All species showed elevated mass concentrations from east, however, with different hotspots for
478 various species, suggesting their probably distinct sources and impacts from regional transport.
479 The three main inorganic species (sulfate, nitrate and ammonium) and aged OOA generally had
480 hotspots from the northeast in accordance with the predominant air masses from northeast during
481 the daytime where showed more intensive anthropogenic and industrial emissions. Whereas
482 chloride, BC and BBOA had obvious hotspots from southeast with wind speed around 10 m s^{-1} ,
483 which were mainly associated with the possible burning emissions of residents located to the
484 southeast of WLG during the nighttime.

485 **4 Conclusions**

486 In this study, the highly time-resolved physicochemical properties of submicron aerosols were
487 investigated during summer 2017 at a high-altitude background station in the northeastern QTP,
488 using a suit of real-time instruments including HR-ToF-AMS, PAX, etc. The major findings
489 include the following:

490 1. The mass concentration of total PM₁ (NR-PM₁ + BC) varied dynamically between 0.3 and
491 28.1 μg m⁻³ during this study, with an average PM₁ mass loading of 9.1 (± 5.3) μg m⁻³,
492 which was higher than those measured with Aerodyne AMS at other high-elevation sites in
493 the southern or central QTP. Different with the significant impacts of biomass burning
494 emissions in the southern QTP, sulfate showed dominant contribution (38.1%) at WLG. In
495 addition, mass contribution of sulfate increased obviously with the increase of PM₁ mass
496 loading, indicating the apparently regional transport of sulfate from industrial areas in the
497 northwestern China. Correspondingly, PM₁ appeared to be slightly acidic throughout this
498 study related with the enhanced sulfate contribution. All chemical species of NR-PM₁ peaked
499 at the accumulation mode, suggesting the well mixed and highly aged aerosol particles at
500 WLG during the sampling period.

501 2. OA on average was dominated by 65.7% of C_xH_yO_z⁺ ion fragment, with the average O/C
502 ratio of 0.99 and OM/OC ratio of 2.44, indicating its highly aged property at this remote site.
503 PMF analysis performed on the OA HRMS resolved four distinct OA components, including
504 HOA, BBOA, agBBOA and OOA. On average, the two relatively oxidized OAs (OOA and
505 agBBOA) contributed 34.4% and 40.4%, respectively, while the rest were 18.4% for BBOA
506 and 6.8% for HOA. In addition, obvious enhanced contributions were found for the two
507 biomass burning related OA components with the increasing OA mass, demonstrating that
508 biomass burning emissions from regional transport was the dominant OA source at WLG.

509 3. Air masses from northeast (C1) with the shortest transport distance among the six clusters
510 presented dominant contribution (57%) and the highest PM₁ mass concentration (10.8 μg
511 m⁻³), mainly due to the enhanced contributions of sulfate and biomass burning related OA
512 components from the industrial areas in the northwestern China. The rest clusters (C2–C6)
513 from the west or northwest with apparently larger transport distances, however, showed
514 relatively lower mass concentrations and higher OOA contributions than C1. These source
515 analysis together suggested the distinct aerosol sources and significant impacts of regional
516 transport to aerosol mass loadings and chemical compositions at WLG during summer
517 season.

518 *Data availability.* The processed AMS data and meteorological data in this study are available
519 upon request from the corresponding author.

520 *Author contribution.* XHZ analyzed the data and wrote the manuscript. JZX organized the
521 campaign, analyzed data, and wrote the manuscript. SCK and QZ wrote the manuscript.

522 *Acknowledgements.* The authors thank the Waliguan Baseline Observatory for the logistical
523 support with the field campaign and thank the colleagues for continuing support and discussion.

701

702 **Figure 1.** (a) Topography map of the Qinghai-Tibet Plateau (QTP), (b) location map of Mt. Waliguan Base (WLG; 36.283 °N,
 703 100.900 °E, 3816 m), (c) the wind rose plot colored by wind speed during the field study period, and (d) the setup of instruments
 704 in this study.

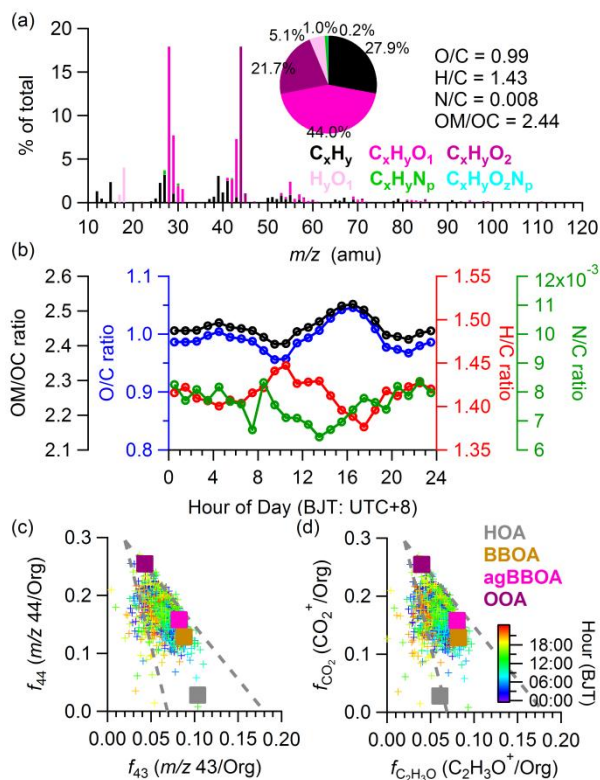

705

706 **Figure 2.** Time series of (a) ambient temperature (T), relative humidity (RH), and precipitation (Precip.), (b) wind speed (WS)
 707 colored by wind direction (WD) and O_3 , (c) mass concentrations of $PM_{2.5}$, PM_{10} , and CO, (d) mass concentrations of PM_1 species,
 708 (e) mass contributions of PM_1 species as well as the total PM_1 mass concentrations, (f) mass contributions of four organic
 709 components. The pie chart shows the average chemical composition of PM_1 for the entire study period, with the average PM_1
 710 mass concentration (unit of $\mu g m^{-3}$) marked in the central.

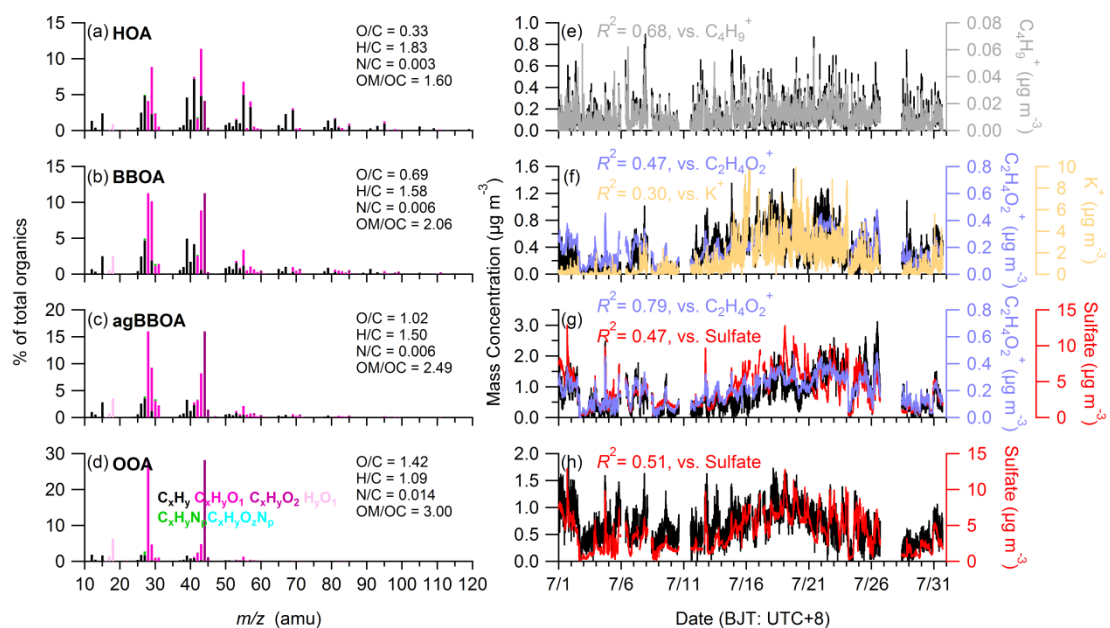

711

712 **Figure 3.** (a) Scatterplot and linear regression (black solid line) of measured NH_4^+ versus predicted NH_4^+ based on the mass
 713 concentrations of SO_4^{2-} , NO_3^- , and Cl^- , (b) the mass contributions of PM_{10} chemical species as a function of total PM_{10} mass
 714 concentration, and the average size distributions of (c) mass concentrations and (d) mass contributions of NR- PM_{10} species in this
 715 study.

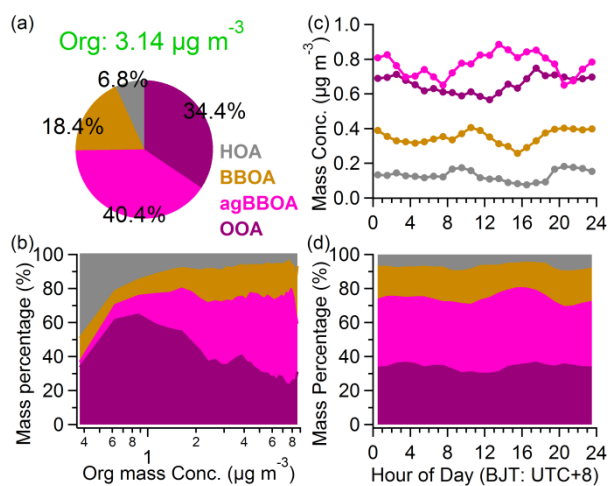

716

717 **Figure 4.** (a) The average high-resolution mass spectrum of organics colored with six ion categories (pie charts shows the
 718 average contributions of the six ion categories), (b) diurnal variations of element ratios (O/C, H/C, N/C, and OM/OC), and
 719 scatterplots of (c) f_{44} vs. f_{43} and (d) $f_{\text{CO}_2^+}$ vs. $f_{\text{C}_2\text{H}_3\text{O}^+}$ colored by time of the day, where the corresponding values of four
 720 organic components are also shown.

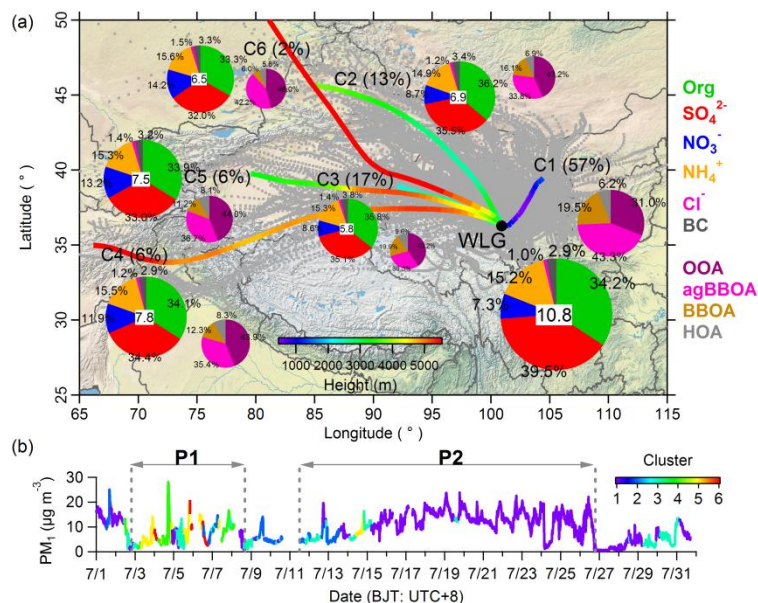

721

722 **Figure 5.** PMF results of (left) high-resolution mass spectra colored by six ion categories for the four OA factors at $m/z < 120$,
 723 (right) temporal variations of the four OA factors and corresponding comparison with tracer species.

724

725 **Figure 6.** The average mass contributions of four organic components to total organics (a) during the entire study period and (b)
 726 as a function of total organics mass concentrations, as well as the diurnal variations of (c) mass concentrations and (d) mass
 727 contributions of four organic components in this study.

728

729 **Figure 7. (a)** The 72h backward air mass trajectories (grey dotted lines) and average trajectory clusters (solid lines colored
 730 according to height) calculated at 1 h intervals for the entire study period. Pie charts show the average mass contributions of PM₁
 731 species to total PM₁ (average PM₁ mass are marked in the central of pie charts) and OA components to total organics belong to
 732 each cluster (areas of pie charts are scaled by the corresponding average mass), respectively. **(b)** Temporal variation of PM₁ mass
 733 concentration colored by the corresponding cluster name in this study. The markers of P1 and P2 represent two different periods
 734 that selected in this study.

735

736 **Figure 8. (a)** The occurrence frequency of six air mass trajectory clusters, **(b)** average contributions of PM₁ chemical species to
 737 total PM₁, and **(c)** average contributions of four organic components to total organics during P1 and P2, respectively.
