**Abstract.** We present a multi-year time series of column abundances of carbon monoxide (CO), hydrogen cyanide (HCN), and ethane (C<sub>2</sub>H<sub>6</sub>) measured using Fourier-transform infrared (FTIR) spectrometers at ten sites affiliated with the Network for Detection of Atmospheric Composition Change (NDACC). Six are high-latitude sites: Eureka, Ny-Ålesund, Thule, Kiruna, Poker Flat, and St. Petersburg, and four are mid-latitude sites: Zugspitze, Jungfraujoch, Toronto, and Rikubetsu. For each site, the inter-annual trends and seasonal variabilities of the CO time series are accounted for, allowing background column amounts to be determined. Enhancements above the seasonal background were used to identify possible wildfire pollution events. Since the abundance of each trace gas emitted in a wildfire event is specific to the type of vegetation burned and the burning phase, correlations of CO to the long-lived wildfire tracers HCN and C<sub>2</sub>H<sub>6</sub> allow for further confirmation of the detection of wildfire pollution. A GEOS-Chem tagged CO simulation with Global Fire Assimilation System (GFASv1.2) biomass burning emissions was used to determine the source attribution of CO concentrations at each site from 2003-2018. For each detected wildfire pollution event, FLEXPART back-trajectory simulations were performed to determine the transport times of the smoke plume. Accounting for the loss of each species during travel, the enhancement ratios of HCN and C<sub>2</sub>H<sub>6</sub> with respect to CO were converted to emission ratios. We report mean emission ratios with respect to CO for HCN and C<sub>2</sub>H<sub>6</sub> of 0.0047 and 0.0092, respectively, with a standard deviation of 0.0014 and 0.0046, respectively, determined from 23 boreal North American wildfire events. Similarly, we report mean emission ratios for HCN and C<sub>2</sub>H<sub>6</sub> of 0.0049 and 0.0100, respectively, with a standard deviation of 0.0025 and 0.0042, respectively, determined from 39 boreal Asian wildfire events.

The agreement of our emission ratios with literature values illustrates the capability of ground-based FTIR measurements to quantify biomass burning emissions. We provide a comprehensive dataset that quantifies HCN and C<sub>2</sub>H<sub>6</sub> emission ratios from 62 wildfire pollution events. Our dataset provides novel emission ratio estimates, which are sparsely available in the published literature, particularly for boreal Asian sources.

## 1 Introduction

The Arctic is a major receptor for pollution from mid-latitude regions (Stohl et al., 2006; Law and Stohl, 2007; Shindell et al., 2008). Boreal wildfires are well known to have considerable impacts on the Arctic atmosphere and climate (Amiro et al., 2009; Warneke et al., 2009). In the Northern hemisphere, boreal wildfires are a dominant source of particulate and trace gas emissions, brought on by persistent warm and dry conditions resulting in increased fire risk and ignition from lightning. Both periods of greater fire risk and lightning activity are expected to occur with increasing frequency at Northern high-latitudes as a result of anthropogenic-induced climate change (Krause et al., 2014; Veraverbeke et al., 2017). The magnitude and intensity of boreal wildfire activity are also projected to increase with future climate change (Amiro et al., 2009; Westerling et al., 2006; Flannigan et al., 2009; Wotton et al., 2010; Boulanger et al., 2014).

Boreal wildfires contribute to the emission of a large number of reactive trace gas species, including volatile organic compounds (VOCs), which promote the production of tropospheric ozone (O<sub>3</sub>) and the formation of aerosols (Jaffe et al., 1999, 2004; Parrington et al., 2013; Wentworth et al., 2018) and therefore negatively impact air quality. Emissions of these species remain highly uncertain as a result of the dependence of emissions on fuel types (Andreae and Merlet, 2001; Akagi et al., 2011; Andreae, 2019); emissions from a particular event are strongly influenced by local meteorology, which has a direct influence on the burning phase and the emission of each species (Yokelson et al., 1996, 1999, 2003; Goode et al., 1999, 2000). Additionally, these reactive species are short-lived, but may have lifetimes that range from days to weeks, which may be long enough for them to undergo long-range transport to the Arctic. Furthermore, these species may have secondary sources within a smoke plume, while the injection of a smoke plume into the free troposphere may further extend their lifetime. Therefore it is necessary to measure the concentrations of these reactive trace gas species downwind in order to predict their influence on a global scale.

Quantifying the influence of biomass burning on the Arctic atmosphere requires long-term, dedicated measurements of the transported emissions in the Arctic. The Arctic is a difficult region to study as a result of the lack of dedicated measurement stations. Ground-based solar-absorption Fourier-transform infrared (FTIR) spectrometers have proven to be a useful tool for quantifying trace species abundances. The Network for the Detection of Atmospheric Composition Change (NDACC; www.ndacc.org; De Mazière et al., 2018) provides a global network of FTIR instruments that routinely measure the biomass burning tracers CO, hydrogen cyanide (HCN) and ethane (C<sub>2</sub>H<sub>6</sub>), in addition to a multitude of other trace gas species. The FTIR instruments of NDACC have previously been utilized to study biomass burning emissions. Zhao et al. (1997, 2000, 2002) identified Asian and Siberian biomass burning sources as major contribution to the measured concentrations of CO, HCN and C<sub>2</sub>H<sub>6</sub> from ground-based FTIR measurements in Rikubetsu (43°N, 143°E), Japan. Paton-Walsh et al. (2004, 2005, 2010)

50 used solar-absorption FTIR measurements in Australia (Darwin (34°S, 150°E) and Wollongong (34°S, 150°E)) to quantify emissions of various trace gas species from Australian wildfires. Vigouroux et al. (2012) examined the influence of biomass burning in Southern Africa and Madagascar on FTIR measurements of HCN, C<sub>2</sub>H<sub>6</sub>, acetylene (C<sub>2</sub>H<sub>2</sub>), methanol (CH<sub>3</sub>OH) and formic acid (HCOOH) at Reunion Island (21°S, 55°E) located in the Indian Ocean.

More recently, FTIR measurements in the Arctic have proven to be particularly useful, providing observational coverage of  
55 trace gas species where measurements from other platforms are scarce or non-existent. Viatte et al. (2013) identified enhancements of CO, HCN and C<sub>2</sub>H<sub>6</sub> in FTIR measurements at Eureka (80°N, 86°W), Canada that were attributed to the 2010 Russian wildfires. A subsequent study by Viatte et al. (2014) demonstrated the utility of FTIR in measuring the biomass burning species acetylene (C<sub>2</sub>H<sub>2</sub>), methanol (CH<sub>3</sub>OH), formic acid (HCOOH) and formaldehyde (H<sub>2</sub>CO) at Eureka. Analogous retrievals of these species were also performed for measurements from a second high-Arctic site at Thule (77°N, 69°W), Greenland and  
60 emission ratios and emissions factors were derived for these species from FTIR measurements at both Thule and Eureka by Viatte et al. (2015). Measurements of ammonia (NH<sub>3</sub>) by solar-absorption FTIR spectroscopy was first demonstrated by Paton-Walsh et al. (2004) and later by Dammers et al. (2015). Lutsch et al. (2016) provided the first measurements of NH<sub>3</sub> in the high Arctic and determined emission ratios and emission factors for the 2014 Northwest Territories wildfires of Canada. The contribution of 2017 Canadian wildfires to NH<sub>3</sub> in the Arctic was examined using FTIR measurements at Eureka and Thule  
65 by Lutsch et al. (2019). The results of these studies highlight the ability of FTIR spectroscopy to measure a number of trace gas species, many of which are difficult to assess using satellite-based or other platforms. Furthermore, the ability of ground-based FTIR instruments to measure a variety of trace gas species over a long-term time period is particularly useful in order to investigate composition of transported wildfire plumes.

These previous studies have illustrated the ability of FTIR measurements to quantify biomass burning emissions by determining the emission ratios and emission factors of various trace gas species. Accurate emission ratios and emission factors are  
70 required to simulate biomass burning in chemical transport models; however, previously reported values are highly variable (Andreae and Merlet, 2001; Akagi et al., 2011; Andreae, 2019 and the references therein) as a result of the natural variability of emissions as well as possible discrepancies in sampling methods.

Each of these previous mentioned FTIR studies have only considered individual events or events that occurred in a short  
75 time series. Measurements using FTIR have been routinely made since the mid-1980s (Zander et al., 2008) and the number of measurement sites have increased since the inception of the Network for Detection of Stratospheric Change (NDSC; Kurylo, 1991) in 1991, which has been formally known as NDACC since 2005 (De Mazière et al., 2018). Several global FTIR sites have been measuring the biomass burning tracers CO, HCN and C<sub>2</sub>H<sub>6</sub> over the last two decades. Yurganov (2004) identified enhanced CO columns in 1998 detected using FTIR measurements at several Northern mid- to high-latitude NDACC FTIR  
80 sites from 1996-2002. The 1998 CO anomaly was attributed to Siberian wildfires. A similar study by Yurganov et al. (2005) examined the 2002 and 2003 CO anomalies from Siberian wildfires using satellite-based, in situ and FTIR measurements in the Northern hemisphere. Currently, no study has explicitly examined the long-term and inter-annual variability of biomass burning species using FTIR measurements. A recent study by Petetin et al. (2018) investigated the impact of biomass burning on CO concentrations measured by the In-service Aircraft for a Global Observing System (IAGOS), which focused on airport

85 clusters in Europe, North America, Asia, India and Southern Africa over the period 2002-2017. To our knowledge, no previous study has assessed the contribution of biomass burning to CO measurements in the Arctic and high-latitude regions.

In this paper, the influence of wildfires on atmospheric composition from 2003-2018 is examined using FTIR measurements of multiple trace gas species from three high-Arctic NDACC sites: Eureka, Canada; Ny-Ålesund, Norway and Thule, Greenland. Three Arctic sites are also included: Kiruna, Sweden; Poker Flat, Alaska and St. Petersburg, Russia. Additional  
90 measurements are obtained at four mid-latitude sites: Zugspitze, Germany; Jungfraujoch, Switzerland; Toronto, Canada and Rikubetsu, Japan. Potential wildfire pollution events are first identified in the CO time series at each site through the detection of anomalous enhancements of CO. For the CO enhancements detected at each site, enhancement ratios of HCN and C<sub>2</sub>H<sub>6</sub> with respect to CO are calculated. Since CO, HCN and C<sub>2</sub>H<sub>6</sub> are co-emitted from biomass burning sources, a linear correlation for the enhancement ratios of HCN and C<sub>2</sub>H<sub>6</sub> indicate wildfire pollution events. The detection of wildfire pollution at each  
95 site was further confirmed using total aerosol optical depth (AOD) measurements from adjacent AERONET (Aerosol Robotic Network) sites. A GEOS-Chem tagged CO simulation from 2003-2018 was performed to identify the source attribution for the detected events at each FTIR site in addition to quantifying the contribution to CO from various biomass burning source regions.

This paper quantifies the impact of more than 60 detected wildfire events, on six Arctic sites and four mid-latitude sites using  
100 FTIR measurements of multiple trace gas species. In addition to replicating published emissions ratios, we provide, for the first time, a comprehensive set of emission ratios for HCN and C<sub>2</sub>H<sub>6</sub> across multiple wildfire events. The reported emission ratios comport with published values, demonstrating the ability of FTIR to capture wildfire plumes, as well as provide much needed longer-term estimates of emissions ratios and their variability. Furthermore, we identify and characterize the contribution of biomass burning to CO measurements specifically at each FTIR site.

105 The structure of this paper is summarized as follows. Sections 2.1-2.4 provides an overview of each FTIR site, the GEOS-Chem tagged CO simulation, AERONET data, and FLEXPART model used in the this study. Section 2.5 describes the methods used to detect wildfire pollution events in the FTIR time series. A comparison of the GEOS-Chem model to FTIR measurements is provided in Section 3.2. The retrieved FTIR products for CO, HCN and C<sub>2</sub>H<sub>6</sub> are presented in Section 3.1 and the detected wildfire pollution events at each FTIR site are presented in Section 3.3. In Section 4.1, the calculated emission ratios are  
110 discussed, while in Section 4.2, a description of the wildfire contribution to CO measurements at each site is provided. The conclusions and summary of this study are highlighted in Section 5.

## 2 Methods

### 2.1 FTIR Sites and Retrievals

The NDACC FTIR sites included in this study were selected to provide coverage of high- and mid-latitude regions and are  
115 listed in Table 1. Due to the broad spectral range measured at high resolution, typically from 700-4400 cm<sup>-1</sup> at 0.0035 cm<sup>-1</sup> resolution, a multitude of trace gas species may be retrieved from solar-absorption FTIR measurements. Measurements of CO, HCN, and C<sub>2</sub>H<sub>6</sub>, all of which are standard products of the NDACC Infrared Working Group (IRWG) are the focus

of this study. Retrievals of each species were performed by processing of solar-absorption spectra using the SFIT4 (<https://wiki.ucar.edu/display/sfit4/>) or PROFITT9 (Hase et al., 2004, for Kiruna and Zugspitze) retrieval algorithm which use the optimal estimation method (Rodgers, 2000) to obtain volume mixing ratio (VMR) profiles and integrated column abundances by iteratively adjusting VMR profiles to minimize the difference between the measured and calculated spectra (Pougetchev et al., 1995; Rinsland et al., 1998). Further details of the instrumentation and retrievals for each FTIR site are given in the references listed in Table 1.

### 2.1.1 High-Arctic Sites

The highest-latitude FTIR site of NDACC is Eureka, located on Ellesmere Island in the Canadian Archipelago. It has been shown in previous studies that Eureka is regularly influenced by the transport of boreal wildfire emissions from North America and Asia (Viatte et al., 2013, 2014, 2015; Lutsch et al., 2016, 2019). Located approximately 500 km from Eureka is the site Thule on the Northwest coast of Greenland, which provides complementary measurements to Eureka as wildfire pollution events detected at Eureka are generally also observed in measurements at Thule (Viatte et al., 2015; Lutsch et al., 2019). Ny-Ålesund in Spitsbergen, Norway is the second highest-latitude FTIR site of NDACC. Ny-Ålesund is isolated from the direct influence of anthropogenic and wildfire emissions, but is affected by the long-range transport of pollution originating from Northern hemisphere mid-latitudes. For the purposes of this study, Eureka, Ny-Ålesund and Thule will be referred to as the “clean” high-Arctic ( $>75^{\circ}\text{N}$ ) sites because they are free of local pollution sources.

### 2.1.2 Arctic Sites

The Arctic sites are defined as those located between  $60^{\circ}\text{N}$  and  $75^{\circ}\text{N}$ , and include Poker Flat, Alaska; Kiruna, Sweden; and St. Petersburg, Russia. Poker Flat is strongly influenced by the transport of anthropogenic pollution from Siberia and Asia (Kasai et al., 2005b). Asian anthropogenic emissions have been found to be a predominant source of pollution in Alaska, with a greater influence in years with strong El Niño conditions (Fisher et al., 2010). Siberian wildfires are a substantial source of summertime pollution in Alaska (Jaffe et al., 2004; Warneke et al., 2009) in addition to local wildfires within the boreal forests of Alaska. It should be noted that for this reason, and the dependence of FTIR measurements on clear-sky conditions, smoke plumes within Alaska may prevent measurements by FTIR. As a result, summertime measurements at Poker Flat can be sparse.

Kiruna is mainly influenced by anthropogenic emissions from mid-latitude Europe; however, aerosol smoke layers from injection of Canadian wildfire emissions into the lower stratosphere have been identified in the past at Kiruna (Fromm et al., 2000). Similarly, the urban site of St. Petersburg would be most sensitive to local sources within Europe. Both Kiruna and St. Petersburg may sample the long-range transport of boreal Asian plumes that could circle the Northern Hemisphere (Damoah et al., 2004), although such plumes would be well aged and diluted. Through injection of wildfire emissions into the upper troposphere and lower stratosphere, North American boreal wildfire plumes may be efficiently transported to Europe (Khaykin et al., 2018; Hu et al., 2019). Although the effects of the long-range transport of wildfire emissions on air quality are likely to be minimal, they can have an influence on tropospheric composition of long-lived species.

### 150 2.1.3 Alpine Sites

Both Zugspitze and Jungfraujoch are considered clean Alpine sites, isolated from local pollution sources and therefore provide measurements that are representative of background concentrations of central Europe (Franco et al., 2015). For the purpose of this study, as the result of the close proximity between the two sites (~200 km), Zugspitze and Jungfraujoch are considered to be complementary to one another. Differences in measured column amounts between the two sites as a result of long-range transport are likely due to their altitude differences, 2964 m a.s.l. and 3580 m a.s.l. for Zugspitze and Jungfraujoch, respectively. It has been previously shown that Zugspitze is weakly influenced by nearby pollution sources, while Jungfraujoch is considered a remote site, mainly influenced by long-range transport (Henne et al., 2010). However, as a result of the high altitudes of these sites, the measured composition is largely driven by long-range transport in the mid to upper troposphere.

### 2.1.4 Mid-latitude Sites

160 Toronto, an urban site, is most sensitive to local pollution sources in southeast Canada and the United States (Whaley et al., 2015) and periodically subject to wildfire pollution episodes as demonstrated by Griffin et al. (2013) and Whaley et al. (2015). Rikubetsu, located in Hokkaido, Japan, is free of considerable local anthropogenic pollution sources, with contributions of CO mainly due to transported Asian anthropogenic emissions (Zhao et al., 2000). In the summertime, Rikubetsu is influenced by the transport of biomass burning pollution from within Asia (Li et al., 2000), while the region of Hokkaido is often affected by pollution episodes from Siberian wildfires of boreal Asia (Jeong et al., 2008; Tanimoto et al., 2000; Yasunari et al., 2018).

## 2.2 GEOS-Chem

To interpret the influence of anthropogenic, chemical, and biomass burning sources on CO columns at each FTIR site, the GEOS-Chem chemical transport model is used (<http://geos-chem.org/>; Bey et al., 2001b) in a tagged simulation of CO at a horizontal resolution of  $2^{\circ} \times 2.5^{\circ}$  with 47 vertical hybrid levels. GEOS-Chem version 12.1.1 (The International GEOS-Chem User Community, 2018) was used and driven by global meteorological inputs from the MERRA-2 (Modern-Era Retrospective Analysis for Research and Applications, Version 2; Gelaro et al., 2017) from the NASA Global Modeling and Assimilation Office (GMAO). MERRA-2 is produced with the GMAO/GEOS-5 (Goddard Earth Observing System) Data Assimilation System Version 5.12.4. The GEOS-Chem simulation was initialized with a 1-year spin-up from 1 January 2002 to 1 January 2003. Chemical and transport operator time-steps of 1 hr and 10 min, respectively, were used.

175 Biomass burning emissions are from GFASv1.2 (Global Fire Assimilation System, Kaiser et al., 2012; Giuseppe et al., 2018) which assimilates Moderate Resolution Imaging Spectroradiometer (MODIS) burned area and fire radiative power (FRP) products to estimate emissions for open fires. GFASv1.2 emissions have a  $0.1^{\circ} \times 0.1^{\circ}$  horizontal resolution with daily temporal resolution. GFAS was chosen for the availability of emissions over the analysis period from 2003-2018. Global anthropogenic emissions are provided from the EDGARv4.3.1 (Emission Database for Global Atmospheric Research, Crippa et al., 2016) emissions inventory, overwritten by regional emission inventories in the Northern hemisphere as described in Fisher

et al. (2010). Biogenic emissions of precursor VOCs are from the Model of Emissions of Gases and Aerosols from Nature (MEGANv2.1; Guenther et al., 2012) and biofuel emissions are taken from Yevich and Logan (2003).

The main loss mechanism for CO is from photochemical oxidation by the hydroxyl radical (OH). The OH fields are prescribed in the tagged CO simulation and were obtained from the TransCom experiment (Patra et al., 2011) which implements  
185 semi-empirically calculated tropospheric OH concentrations from Spivakovsky et al. (2000) to reduce the high bias of OH from the GEOS-Chem full-chemistry simulation (Shindell et al., 2006). Surface emissions in GEOS-Chem are released within the boundary layer, and boundary layer mixing is implemented using the non-local mixing scheme of Holtslag and Boville (1993). Biomass emissions are released by uniformly distributing emissions from the surface to the mean altitude of maximum injection based on the injection height information as described in Rémy et al. (2017) which includes an injection height  
190 parameterization by Sofiev et al. (2012) and a plume rise model by Freitas et al. (2007).

GEOS-Chem version 12.1.1 tagged CO simulation includes the improved secondary CO production scheme of Fisher et al. (2017), which assumes production rates of CO from CH<sub>4</sub> and NMVOC oxidation from a GEOS-Chem full-chemistry simulation therefore reducing the mismatch between the CO-only simulation and the full-chemistry simulation. The anthropogenic source regions are shown in Figure 1, while biomass burning source regions are implemented following the standard GFED  
195 (Giglio et al., 2013) regions and are also shown in Figure 1.

### 2.3 AERONET

The Aerosol Robotic Network (AERONET; <https://aeronet.gsfc.nasa.gov>; Holben et al., 1998) is a federation of ground-based remote sensing aerosol networks established by NASA and PHOTONS (PHotométrie pour le Traitement Opérationnel de Normalisation Satellitaire; Univ. of Lille 1, CNES, and CNRS-INSU). AERONET consists of a network of CIMEL sun photometers which provides globally distributed observations of spectral aerosol optical depth (AOD). At each AERONET site,  
200 observations are recorded every 15 minutes and are cloud screened. Inversion of aerosols products and cloud screening for the AERONET Version 3 database are described in (Giles et al., 2019). AERONET sites selected for this study were based on the availability of data during the operational period of the FTIR instruments and proximity to the FTIR site. The selected AERONET sites nearest to the NDACC FTIR sites are listed in Table 1.

### 205 2.4 FLEXPART

The FLEXPART (FLEXible PARTicle, Stohl et al., 2005) Lagrangian transport model version 10.02 is used to diagnose the potential emission sensitivity (PES) of FTIR measurements in order to estimate the travel times of identified wildfire plumes at each FTIR site. The model is driven by meteorological data from the National Centers for Environmental Prediction (NCEP) Climate Forecast System (CFSv2) 6-hourly product (Saha et al., 2011) at  $0.5^\circ \times 0.5^\circ$  horizontal resolution. In this study, an  
210 ensemble of 24,000 particles are released from the location of each FTIR site for each day of fire-affected measurements. The particles are released from the surface to an altitude of 12.71 km at each FTIR site, which corresponds to the FTIR tropospheric column. The FLEXPART model is run backwards in time for a total of 14 days, simulating the transport of the released particles.

The FLEXPART output is the surface residence time of the released particles in each  $0.5^\circ \times 0.5^\circ$  model output grid box. The residence time is related to the PES and is indicative of the sensitivity of the released particles to source emissions.

## 215 2.5 Detection and Attribution of Wildfire Pollution Events

### 2.5.1 Enhancement Detection in FTIR CO Time Series

As will be shown in Section 3.1.1, a seasonal cycle of CO is observed, with the amplitude varying by site location. Over a long time series, CO may be subject to inter-annual trends as a result of changing emissions of CO and its precursors. Additionally, non-clear sky conditions and instrument downtime result in periodic gaps in measurements and non-uniform time intervals  
220 between measurements. As a result of these factors it can be difficult to determine baseline or ambient column amounts of CO and therefore to detect enhancements of CO in the FTIR time series. To mitigate these influences, we account for the seasonal cycle and inter-annual variability of the CO time series measured at each FTIR site following Thoning et al. (1989):

$$C(t) = a_0 + a_1t + a_2t^2 + \sum_{n=1}^4 b_n \cos(2\pi nt) + c_n \sin(2\pi nt), \quad (1)$$

where  $C$  is the CO column amount as a function of time  $t$ . The coefficients  $a_n$  account for the inter-annual trends of CO, while  
225 the fourth-order Fourier series with coefficients  $b_n$  and  $c_n$  captures the seasonal cycle of CO. The choice of order for both the polynomial and Fourier components of the fits were limited to third and fourth order, respectively, following past studies (Thoning et al., 1989; Zellweger et al., 2009).

Enhancements in CO are identified following Zellweger et al. (2009). First, the fitted function is subtracted from the data to yield the residual. Assuming a normal distribution of baseline values around the fitted function, the negative residual is  
230 mirrored into the positive direction. Enhanced CO measurements are defined as those greater than a specified threshold of the mirrored residual above the fitted function. The threshold is defined as a multiple of the standard deviation  $\sigma$  of the mirrored negative residual. The threshold is  $1\sigma$  for all sites, with the exception of Rikubetsu and Poker Flat where a  $2\sigma$  standard deviation was used as a result of the greater variability CO due to nearby Asian anthropogenic and biomass burning sources respectively. It should be noted that the contribution of the biomass burning sources to the fitted function of Equation 1 is  
235 representative of an increase in the seasonal background of CO due to the accumulation of CO from biomass burning sources during the wildfire season. Enhanced CO measurements detected by the method described above would therefore correspond to anomalous enhancements which exceed the seasonal background.

For each event, all fire-affected measurements are found based on a qualitative assessment of the CO time series in conjunction with GEOS-Chem CO and AERONET AOD time series. Periods of fire-affected measurements are determined for  
240 periods in which an increase in the GEOS-Chem total biomass burning contribution to CO is observed. The total biomass burning contribution of is defined as the sum of all biomass burning tracers in Table 2. The AERONET AOD provides additional evidence for the presence wildfire smoke when enhanced AOD is observed simultaneously with enhanced FTIR CO and GEOS-Chem biomass burning CO. It should be noted that enhanced AOD may also be the result of anthropogenic pollution;

however, enhanced AOD is likely of wildfire origin when simultaneously enhanced with GEOS-Chem biomass burning CO. Furthermore, aerosol scavenging from a smoke plume may result in the absence of enhanced AOD (Franklin et al., 2014). For these reasons, AOD is only used as a supplementary means of identifying wildfire pollution.

### 2.5.2 Trace Gas Correlations

To isolate potential wildfire pollution events, we exploit the fact that trace gas emissions from wildfires are specific to burning phase and vegetation type (Ward and Hardy, 1991; Yokelson et al., 1999; Andreae and Merlet, 2001; Yokelson et al., 2009; Akagi et al., 2011; Urbanski, 2013, 2014) and therefore it would be expected that emissions of CO, HCN and C<sub>2</sub>H<sub>6</sub> originating from a wildfire source would be correlated within a plume. Emissions at the fire source are characterized by the emission ratio (ER; Andreae and Merlet, 2001; Akagi et al., 2011) relative to CO, which quantifies the amount of a trace gas species emitted relative to the amount of CO emitted. Since FTIR observations of this kind are measuring the emissions downwind of the source, the enhancement ratio (EnhR; Lefer et al., 1994) is considered:

$$\text{EnhR}_X = \frac{d[X]}{d[\text{CO}]} \quad (2)$$

where [X] is the column amount of the trace gas of interest, and [CO] is the column of CO. The enhancement ratio is related to the emission ratio with the influence of plume aging by chemical loss, deposition and dilution of the plume during transport. Lifetimes of CO, HCN and C<sub>2</sub>H<sub>6</sub> are generally longer than plume transport times which range from several days to approximately two weeks (Damoah et al., 2004) and therefore these species do not undergo considerable chemical loss. Furthermore, we do not take into account the background concentrations, which can cause uncertainty in interpreting the enhancement ratio as the ambient conditions are likely to vary along the plume trajectory (Yokelson et al., 2013). This assumption has been employed extensively in past studies of wildfire emissions using FTIR (Paton-Walsh et al., 2010; Vigouroux et al., 2012; Viatte et al., 2013, 2015; Lutsch et al., 2016, 2019) as taking into account a constant background of each species does not influence the slope of the trace gas correlations.

To calculate the enhancement ratios from the FTIR measurements, the detected CO enhancements for each event were paired with the nearest HCN and C<sub>2</sub>H<sub>6</sub> measurement taken within 1 hr at all sites with the exception of St. Petersburg and Toronto where a 2 hr window was used. The time interval was chosen to maximize the number of pairs since CO, HCN and C<sub>2</sub>H<sub>6</sub> are measured using different spectral filters and hence the measurements do not occur simultaneously. For events with paired measurements of HCN or C<sub>2</sub>H<sub>6</sub> with CO that are fewer than 6, the event is omitted. Setting a minimum number of pairs mitigates the potential of false detections as a result of spurious measurements.

The unified least-squares fitting procedure of York et al. (2004) which accounts for errors in both the ordinal and abscissa coordinates was used to determine a linear regression for the paired fire-affected measurements. The errors correspond to the reported retrieval uncertainties of the respective species. The slope of the linear regression is the enhancement ratio for the respective species defined in Equation 2. To identify enhancements due to wildfire pollution events, we require that the

275 correlation coefficient ( $r$ ) be greater than or equal to 0.6 for both the enhancement ratios of HCN and C<sub>2</sub>H<sub>6</sub>, unless otherwise stated.

HCN is retrieved from NDACC Filter 2 measurements, which is generally covered at least once per measurement sequence of all filters. Similarly, C<sub>2</sub>H<sub>6</sub> is retrieved through filter NDACC filter 3. All filters have a different response to the input solar beam intensity and therefore, the measurement noise may vary between subsequent measurements of different filters. For this reason, adequate signal may not be obtained through all filters in the case of partially cloudy or non-clear sky conditions. It was found that for all sites, with the exception of Jungfraujoch, there are a greater number of CO measurements than HCN or C<sub>2</sub>H<sub>6</sub>. Because of this non-uniform distribution of measurements, the number of detected wildfire events is limited by the number of paired measurements for HCN or C<sub>2</sub>H<sub>6</sub> with CO. For this reason, for Ny-Ålesund, Poker Flat and Rikubetsu, the enhancement ratio correlation criteria were omitted, resulting in a lower confidence for the detected wildfire pollution events.

285 Lastly, source attribution of the detected wildfires events was performed using the GEOS-Chem tagged CO simulation. For each event, the mean contribution of each of the biomass burning CO tracers over the period of the event was determined. The source region was then attributed to the CO tracer for which the mean contribution was a maximum.

## 2.6 Estimation of Plume Travel Times

For each of the detected wildfire pollution events at each FTIR site, the travel times of the plume from the source region to the FTIR site was determined as follows. For each day of fire-affected measurements, the FLEXPART model was initialized releasing an ensemble of 24,000 air-tracer particles over a 24 hr period. Particles were released from the surface of the FTIR site to a maximum altitude of 12.71 km, corresponding to the FTIR tropospheric columns used in this study. The FLEXPART model was run backwards in time for 14 days to yield the surface residence time of the released particles at a temporal resolution of 3 hrs and horizontal resolution of 0.5°×0.5° with global coverage. The daily GFAS global CO emissions were regridded from 0.1°×0.1° to 0.5°×0.5° to match the horizontal resolution of the FLEXPART output.

For each day of the FLEXPART output, the daily total residence time in each model grid box was determined. The product of GFAS CO emissions (molec s<sup>-1</sup>) and the residence time (s) of the FLEXPART air-tracer particles is indicative of the sensitivity of the released particles to wildfire CO emissions. The travel time for each FLEXPART simulation is then estimated by the number of days backwards in time for which the sensitivity is a maximum for the identified wildfire source region of the respective event. A mean travel time for each plume is determined by the mean of all travel times for each day of fire-affected measurements in the identified event; the standard deviation is an estimation of the uncertainty.

## 2.7 Emission Ratios

The enhancement ratios (Section 2.5.2), which were used to isolate wildfire pollution events, and the travel times (Section 2.6) were used to calculate the emission ratio (ER) of the respective trace gas species. The emission ratio represents the wildfire source emissions, assuming the plume was unaged (Lefer et al., 1994). To calculate the emission ratio, we assume the first-

order loss of each species following Viatte et al. (2013, 2015) and Lutsch et al. (2016). The emission ratio may then be related to the enhancement ratio as:

$$ER_X = \text{EnhR}_X \cdot \frac{\exp\left(\frac{t}{\tau_X}\right)}{\exp\left(\frac{t}{\tau_{CO}}\right)}. \quad (3)$$

where  $X$  is the trace gas of interest,  $t$  is the plume travel time and  $\tau$  is the lifetime of the species. We assume lifetimes of 30, 75 and 45 days for CO, HCN and C<sub>2</sub>H<sub>6</sub>, respectively, following Viatte et al. (2013, 2015); Lutsch et al. (2016). For each identified wildfire event the emission ratio of HCN and C<sub>2</sub>H<sub>6</sub> is calculated using Equation 3 and mean travel time for the event. The uncertainty of the calculated emission ratios include the enhancement ratio uncertainty, determined from the standard error of the linear regression, and the travel time uncertainty. The uncertainty of the lifetime of each species was not included as the lifetime can be variable during plume transport and therefore cannot be quantified.

## 315 3 Results

### 3.1 Retrieved FTIR Products

#### 3.1.1 Time Series

The weekly-mean time series of CO, HCN and C<sub>2</sub>H<sub>6</sub> tropospheric partial columns for each site are shown in Figures 2, 3 and 4 respectively. The tropospheric partial columns are the integrated column amounts from the surface to an altitude of 12.71 km at each site. In this study, all presented column amounts correspond to this partial column for CO, HCN and C<sub>2</sub>H<sub>6</sub>. The weekly mean is taken over all years of measurements for the respective species at each site, while the shaded region indicates a  $1\sigma$  deviation from the mean. For all sites, the seasonal cycle of CO shows a maximum in winter and early spring (February-March), with decreasing total columns through the spring. The main sources of CO are the combustion of fossil fuels and biomass burning, while oxidation of VOCs and CH<sub>4</sub> are also a considerable source (Holloway et al., 2000). The main sink of CO is due to reaction with OH, leading to a lifetime of approximately 1-2 months (Bey et al., 2001a). In winter and spring months, decreased sunlit hours limits OH production by photolysis of ozone, therefore minimizing the loss of CO. The seasonal cycle of OH largely drives the seasonal variations of CO. Transport of CO from mid-latitude to high-latitude regions also contributes to the seasonal cycle as the isentropic transport is greater in the winter and spring months (Klonecki, 2003; Stohl et al., 2006). Furthermore, the stronger seasonal cycle of OH production also contributes to the greater seasonal amplitudes at high latitudes as observed in Figure 2.

Enhanced tropospheric columns of CO are observed in the summertime, mainly in July-September at all sites as illustrated in Figure 2 as a result of the hemispheric influence of boreal wildfires (Honrath, 2004). These enhancements are most pronounced at the clean high-Arctic sites of Eureka and Thule, which are strongly influenced by boreal fires in North America and Asia as will be shown in Section 4.2. Ny-Ålesund also exhibits an increase in CO beginning in August as a result of the accumulation

335 of CO from Northern Hemisphere biomass burning sources. Poker Flat, located in the boreal forests of Alaska is greatly influenced by boreal wildfire emissions in these regions; however, in many instances these events result in smokey conditions that prevent FTIR measurements. As a result detection of enhancements at Poker Flat are likely to be underestimated due to the strong influence of wildfire smoke.

A slight increase in CO concentrations is observed at Zugspitze and Jungfraujoch as a result of the long-range transport of 340 boreal wildfire emissions. Emissions from these events are often lofted into the free troposphere where long-range transport is favored (Jaffe et al., 2004; Val Martin et al., 2006). However, the transport of emissions over continental scales results in the dilution of the smoke plume and therefore, the enhancements observed at Zugspitze and Jungfraujoch are not as pronounced as for the other sites.

St. Petersburg and Toronto are urban sites that are strongly influenced by local anthropogenic sources, but enhanced columns 345 of CO are observed in July and August as a result of the boreal wildfire influence as will be shown in Section 4.2. Rikubetsu is strongly affected by anthropogenic CO sources from Asia, resulting in the large variability of CO (Zhao et al., 1997, 2002). The greatest enhancements at Rikubetsu are observed in July and August, due to boreal Asian wildfires in Siberia as will discussed in Section 4.2.

HCN has a long atmospheric lifetime ranging from days to months, while its dominant source is due to biomass burning 350 emissions (Li et al., 2000, 2003, 2009). Plant and fungal emissions represent a minor source of HCN, while dry deposition to the ocean and oxidation by OH are the main sinks (Cicerone and Zellner, 1983). As a result, HCN will accumulate in the Northern hemisphere in the summer months due to the influence of wildfire and biogenic emissions. The seasonal cycle of HCN peaks in the summer months with low total columns in the winter and fall as illustrated in Figure 3. A sharp maximum is observed in August at the high-Arctic sites (Eureka, Thule and Ny-Ålesund) due to activation of its biogenic sources and the 355 onset of wildfire emissions. A similar increase in the HCN total columns is observed at the high-latitude sites (Kiruna, Poker Flat and St. Petersburg), although not as pronounced. For Toronto, enhanced total columns are also observed in August due to wildfires, consistent with the CO time series. Rikubetsu shows the greatest concentrations of HCN in the spring in May, with a secondary peak in August. The springtime enhancements of HCN are due to the earlier onset of East and Southeast Asian biomass burning, which occurs annually from March to May (Streets et al., 2003).

360 The seasonal cycle of C<sub>2</sub>H<sub>6</sub> is similar to that of CO, as shown in Figure 4. The primary sources of C<sub>2</sub>H<sub>6</sub> include natural gas production, biofuel use and biomass burning (Rudolph, 1995; Logan et al., 1981; Xiao et al., 2008). The main loss of C<sub>2</sub>H<sub>6</sub> is due to reaction with OH, resulting in an average lifetime of approximately three months (Xiao et al., 2008). The summertime wildfire influence of C<sub>2</sub>H<sub>6</sub> is less pronounced than for CO and HCN. Enhancements of C<sub>2</sub>H<sub>6</sub> are particularly evident at Eureka and Thule, due to the generally clean background of these sites, while wildfire enhancements of C<sub>2</sub>H<sub>6</sub> are not evident at the 365 other sites due to the influence of local sources in addition to dilution of the plume during long-range transport. Therefore, C<sub>2</sub>H<sub>6</sub> enhancements due to wildfire pollution are not generally apparent over background concentrations. Additionally, the emissions of C<sub>2</sub>H<sub>6</sub> are an order of magnitude lower than those of HCN for boreal forest, temperate forests and peatland burning sources (Andreae and Merlet, 2001; Akagi et al., 2011; Andreae, 2019).

### 3.1.2 Retrieved VMR Profiles and Total Column Averaging Kernels

370 The VMR profiles of CO, HCN and C<sub>2</sub>H<sub>6</sub> for all sites are shown in the appendix Figures A1, A2 and A3. A priori profiles  
for CO, HCN and C<sub>2</sub>H<sub>6</sub> are from a 40-year (1980-2020) mean from the Whole Atmosphere Community Climate Model  
(WACCMv4; Eyring et al., 2007; Marsh et al., 2013) which has been chosen the NDACC IRWG for use by all sites. For all  
sites, a single a priori profile is used for each species, with the exception of Thule where monthly-mean a priori profiles derived  
375 from the 40-yr WACCMv4 simulation are used. In all cases, the profiles of each species are similar between sites and tend not  
to show drastic differences. It should be noted, that these profiles do not represent the true atmospheric profile of the species  
due to limited vertical resolution of the measurement, which is inherent in remote sensing measurements of this kind. The  
retrieved profiles generally follow a similar shape to the a priori profile, where deviations from the a priori are a result of the  
measurement. In general, the profiles of all species exhibit greatest variability in the troposphere due to the abundance of these  
species in this region. The tropospheric column of CO, HCN and C<sub>2</sub>H<sub>6</sub> comprise, on average, greater than approximately 90%  
380 of the total column for CO, 95% for HCN, and 98% for C<sub>2</sub>H<sub>6</sub>.

For the purposes of this study, normalized total column averaging kernel values near unity throughout the troposphere are  
desired, which would minimize biases due to differences in the vertical sensitivities when computing the ratios of columns of  
different species in calculating the enhancement ratio described in Section 2.5.1. The mean normalized total column averaging  
kernels, referred to as simply the total column averaging kernel hereinafter, for CO, HCN and C<sub>2</sub>H<sub>6</sub> are described in the  
385 Appendix A and shown in appendix Figure A4. For all sites, the total column averaging kernels of CO show a value near 1  
throughout the troposphere, with a slight decrease to values below unity above 5 km. For HCN, the total column averaging  
kernels increase from the surface, with maximum values in the upper troposphere. The total column averaging kernels of C<sub>2</sub>H<sub>6</sub>  
show similar structure to HCN, with maximum values in the mid to upper troposphere. For all sites, it can be concluded that  
CO retrievals exhibit minimal sensitivity bias in the troposphere. For HCN and C<sub>2</sub>H<sub>6</sub>, the total column averaging kernel is  
390 greatest in the upper troposphere.

### 3.2 GEOS-Chem to FTIR CO Comparison

In order to use the GEOS-Chem tagged CO simulation to interpret the FTIR, it is necessary to evaluate the performance of the  
model with respect to FTIR measurements. To do so, GEOS-Chem CO partial column profiles are smoothed by the normalized  
FTIR CO total column averaging kernel following Rodgers and Connor (2003):

$$395 \hat{x}_m = x_a + \mathbf{a}^T (\mathbf{x}_m - \mathbf{x}_a), \quad (4)$$

where  $\hat{x}_m$  is the smoothed model total column,  $x_a$  is the FTIR a priori total column,  $\mathbf{x}_m$  is the model partial column profile,  
 $\mathbf{a}$  is the FTIR total column averaging kernel, and  $\mathbf{x}_a$  is the FTIR a priori partial column profile. Although the smoothing  
has a minor influence on the smoothed partial column ( $\sim 1\%$ ) it is performed here to mitigate any biases as a result of the a  
priori profile. The GEOS-Chem CO profiles, FTIR CO profiles and total column averaging kernels are daily averaged and the

400 daily averaged GEOS-Chem profiles are subsequently smoothed. Correlations of the smoothed GEOS-Chem and FTIR CO tropospheric partial columns are shown in Table 3.

For all sites, moderate to strong linear correlations are observed with correlation coefficients ( $r$ ) ranging from a minimum of 0.66 for Toronto to a maximum of 0.86 at Ny-Ålesund, Thule and Kiruna. The slope of the linear regression is indicative of the GEOS-Chem bias relative to the FTIR measurements, with a slope greater than 1.0 representing a high-bias and a slope  
405 less than 1.0 representative of a low-bias. For all sites, GEOS-Chem has a low bias as seen in Table 3. The slopes range from a minimum of 0.49 at Jungfraujoch to a maximum of 0.84 at Rikubetsu.

The underestimation of GEOS-Chem CO is common amongst global CTMs as a result of errors in emissions, transport, and biases in the OH concentrations (Shindell et al., 2006). It is likely that the consistent underestimation of GEOS-Chem CO at all sites is partly due to a high bias of OH (Muller et al., 2018). Seasonal variability of the GEOS-Chem bias is observed as  
410 shown Table 3. The consistent underestimation of GEOS-Chem at Zugspitze and Jungfraujoch may be the result of excessive stratosphere-to-troposphere exchange (Fischer et al., 2000; Hoor et al., 2002; Pan et al., 2004) contributed by the coarse model resolution, resulting in a low bias of CO in the upper troposphere. A similar underestimation of GEOS-Chem CO in a full-chemistry simulation in comparison to Jungfraujoch FTIR measurements was observed by Té et al. (2016). The high altitude of Zugspitze and Jungfraujoch makes these sites more susceptible to this bias in comparison to the lower altitude sites (Ordóñez  
415 et al., 2007). The underestimation at Toronto, and the lower correlation (0.66) than all other sites is possibly the result of the temporal and spatial variability of CO being not well captured due to the coarse model resolution ( $2^\circ \times 2.5^\circ$ ).

Seasonal variability of the GEOS-Chem minus FTIR relative difference is also observed as shown in Table 3. The representation of the seasonal variability of transport at mid-latitudes and errors in the seasonality are likely to be contributing factors to the variability of the GEOS-Chem minus FTIR CO difference. However, biomass burning emissions are also seasonally  
420 dependent and underestimation of GEOS-Chem CO may be partially reflective of an underestimation of GFAS emissions. Particularly evident is the greater underestimation of GEOS-Chem at Rikubetsu in the summer months, during the boreal wildfire season. Eureka and Thule exhibit a greater underestimation of GEOS-Chem in July and August when the boreal wildfire influence is greatest as will be shown in Section 8. A similar decrease in the GEOS-Chem minus FTIR relative difference is also observed at Kiruna, Poker Flat, St. Petersburg and Toronto. These differences could be indicative of the unresolved  
425 plume transport in the model as a result of its coarse vertical resolution (Rastigejev et al., 2010; Eastham and Jacob, 2017). Additionally, the summertime low CO bias in GEOS-Chem may also be contributed by an underestimation of the secondary production of CO from biogenic emissions of NMVOCs.

### 3.3 Detected Wildfire Pollution Events

Wildfire events in the the FTIR time series at each site were identified using the method described in Section 2.5. Enhancements  
430 of CO were first identified following Section 2.5.1 and correlated with coincident measurements of HCN and C<sub>2</sub>H<sub>6</sub> to calculate their enhancement ratios with respect to CO as described in Section 2.5.2. For the period of fire-affected measurements for each identified event, source attribution was determined using the GEOS-Chem tagged CO simulation. The source attribution for the detected wildfire pollution events in the FTIR time series is illustrated in Figure 5. The mean travel times determined

using the FLEXPART back-trajectory simulations and the calculated emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> are tabulated in Table 4.

The detected episodic wildfire pollution events at all sites were attributed to either BONA or BOAS sources. Missed detections of wildfire events in the FTIR time series are largely the result of the gaps in measurements, which may either be due to non-clear-sky conditions or instrument downtime. For Poker Flat, the presence of nearby wildfire sources result in large gaps in measurement as a result of the wildfire smoke. Coincident measurements of CO, HCN and C<sub>2</sub>H<sub>6</sub> are generally not limiting factors for the detection of wildfire events. Under normal conditions, measurements are made by cycling through a series of spectral filters and all filters are usually sampled equally. The NDACC IRWG recommends the use of seven broadband spectral filters. They are used at all sites, with the exception of St. Petersburg and Jungfraujoch, where non-standard filters are used. Measurements of CO can be made through two of the seven spectral filters, while HCN and C<sub>2</sub>H<sub>6</sub> are made through a single spectral filter. When a sufficient number of CO enhancements were detected, the coincident criteria of six paired measurements of HCN or C<sub>2</sub>H<sub>6</sub> for the calculation of the enhancement ratio was achieved. However, the exception being Ny-Ålesund, Poker Flat and Rikubetsu, where the lower measurement density of these sites prevented the calculation of enhancement ratios. For all sites where the enhancement ratios of HCN and C<sub>2</sub>H<sub>6</sub> were used as part of the detection, there may be missed events due to assigning a minimum correlation coefficient of 0.6 to the calculations. There may be cases where CO, HCN and C<sub>2</sub>H<sub>6</sub> are simultaneously enhanced due to wildfire emissions; however, there may be poor correlation as a result of mixing of the plume with ambient air, or mixing of plumes of separate sources. However, setting a minimum correlation coefficient for the enhancement would ensure that only coherent plumes are detected, therefore providing more reliable estimates of the emission ratios.

The reported mean travel times are found to vary by site and source region as shown in Table 4. A minimum mean plume travel time of 3 days was found for Poker Flat from BONA sources due to nearby Alaskan wildfire sources. The travel times are typically longer at all sites, 10 days or greater for BOAS sources. Comparable travel times between BONA and BOAS sources are observed for Ny-Ålesund, Kiruna, Zugspitze and Jungfraujoch. For Eureka, Thule and Toronto, mean travel times of 8, 9 and 7 days are found for BONA and are shorter than BOAS, due to the proximity of these sites to BONA sources.

Temporal correlation of events amongst all sites is observed, with events occurring near in time at different sites is attributed to the same source. Particularly evident are the 2012 Siberian wildfires (Kozlov et al., 2014; Teakles et al., 2017) observed at several sites and attributed to BOAS. Similarly, the 2017 Canadian wildfires (Khaykin et al., 2018; Peterson et al., 2018; Kirchmeier-Young et al., 2019; Lutsch et al., 2019) are also observed at a number of sites. Although, the majority of detected events from 2003-2018 are attributed to BOAS (63), from 2013-2018 there is an observed increase in the number of events attributed to BONA, with 18 BONA and 17 BOAS events detected during this period amongst all sites. Prior to 2013, 14 BONA and 46 BOAS events were detected. The recent increase in BONA events could be indicative of changes in large-scale climatic patterns (Macias Fauria and Johnson, 2008) resulting in an increase in lightning-induced wildfires (Macias Fauria and Johnson, 2006; Veraverbeke et al., 2017). However, this apparent increase in BONA events does not take into account the possibility of missed detections due to instrument downtime or cloudy sky conditions. The calculated emission ratios will be discussed in the following section and the contributions of the biomass burning source regions to CO tropospheric columns at each site will

be presented in Section 4.2.

470

## 4 Discussion

### 4.1 Emission Ratios

The calculated emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> are compared to the literature values in Table 4. For BONA, our mean emission ratios of HCN range from 0.0026 (Zugspitze) to 0.0052 (Thule), whereas our mean emission ratios of C<sub>2</sub>H<sub>6</sub> range from 0.0081 (Thule) to 0.0136 (Kiruna). Our values derived from FTIR-based methods are well within the range of literature values derived from ground-, satellite- and aircraft-based methods. Furthermore, across all sites, our mean emission ratios of C<sub>2</sub>H<sub>6</sub> are greater than the mean emission ratios of HCN. Similarly, previous studies have reported greater C<sub>2</sub>H<sub>6</sub> relative to HCN emission ratios, with the exception of the values reported by Hornbrook et al. (2011) and Simpson et al. (2011).

For BOAS, our mean emission ratios of HCN range from 0.0021 (Zugspitze) to 0.0072 (Thule), whereas our mean emission ratios of C<sub>2</sub>H<sub>6</sub> range from 0.0071 (St. Petersburg) to 0.0105 (Eureka). There are a limited number of literature values for BOAS, particularly those derived from aircraft-based studies. Notwithstanding, our FTIR-derived HCN and C<sub>2</sub>H<sub>6</sub> emission ratios are within the range of available published values (Table 4) across all sites, with the exception of C<sub>2</sub>H<sub>6</sub> in Toronto. The higher C<sub>2</sub>H<sub>6</sub> emission ratio estimate for Toronto, relative to other sites, may be explained by nearby anthropogenic sources of C<sub>2</sub>H<sub>6</sub>, which may contaminate the plume and yield higher emission ratio estimates (Franco et al., 2016; Tzompa-Sosa et al., 2017). As was observed for BONA, the mean C<sub>2</sub>H<sub>6</sub> emission ratios are greater than the mean HCN emission ratios for BOAS across all sites. This comparison of C<sub>2</sub>H<sub>6</sub> to HCN emission ratios is in agreement with published findings, with the exception of Hornbrook et al. (2011).

Our FTIR-derived HCN emission ratios are greater than published estimates based on Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS) measurements, as reported by Tereszchuk et al. (2011); Rinsland et al. (2007); Tereszchuk et al. (2013) for BONA and Tereszchuk et al. (2013) for BOAS. Solar occultation measurements of the ACE-FTS have a lower altitude range, of approximately 6 km. Consequently, a plume detected by ACE-FTS may correspond to flaming combustion and injection of emissions into the upper troposphere. Flaming, relative to smoldering combustion is associated with lower HCN emissions (Urbanski, 2013). Indeed, literature values of HCN ratios derived from ground-based FTIR measurement were higher than those derived from ACE-FTS solar occultation measurements (Griffin et al., 2013; Viatte et al., 2015; Lutsch et al., 2016).

Aircraft instruments tend to measure the composition of fresh plumes with minimal plume aging. Therefore, the variability of the emission ratios reported for aircraft-based studies is likely to be reflective of the variability of emissions due to multiple factors that influence the emissions within a wildfire event, such as the type of vegetation that is burned (Akagi et al., 2011; Andreae and Merlet, 2001; Andreae, 2019), the burning phase (Yokelson et al., 1996, 1999, 2003; Goode et al., 1999, 2000; Urbanski, 2013) and pyrolysis temperature (Sekimoto et al., 2018) of the burn. These factors, however, are likely to vary regionally and may also vary with time in a particular event.

Taken together, our FTIR-derived mean emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> for BONA and BOAS sources are congruent with published literature values, supporting the validity of the use of FTIR-based methods to quantify the transport of emissions from BONA and BOAS sources. We report HCN and C<sub>2</sub>H<sub>6</sub> emission ratios across multiple sites in the Arctic and mid-latitude regions. Moreover, the FTIR-derived emission ratios presented here provide novel estimates for regions wherein published values are not available, particularly for BOAS sources, adding to the sparsely populated dataset, and providing greater insight into the variability of emissions.

Precise knowledge of the emission ratios of various trace and particulate species is required for more accurate modeling of biomass burning emissions in chemical transport models. The emission ratio, may be converted to an equivalent emission factor with the use of the emission factor of the reference species, usually CO. The emission factor of CO is determined from reported literature values (i.e., Andreae and Merlet 2001; Akagi et al. 2011; Andreae 2019) which are derived from laboratory or field measurements, relating the mass of CO emitted per unit mass of dry matter burned for various vegetation types. Given the dependence of the emission factor of the species of interest on the emission factor of CO, it is advantageous to consider the emission ratios. Biomass burning emission inventories are dependent on a single emission factor for each species per vegetation type or biome. These values are obtained from literature values such as reported by Akagi et al. (2011, ?); Andreae and Merlet (2001); Andreae (2019). These literature values are the reported means of emission ratios or emission factors obtained from laboratory studies or field observations from ground-based, aircraft or satellite measurement platforms. Measurements of emission ratios by these methods may only sample a single or small number of events. Aircraft measurements are often made on a campaign basis, targeting biomass burning plumes near the source or along a flight transect. As a result measurements made by aircraft-based measurements may only sample the plume over a short period of time and may not capture the natural variability of emissions.

Satellite observations are particularly useful as they provide global coverage; however, emission ratios derived from satellite observations are limited by the instrument's capability to measure multiple trace gas species simultaneously. To our knowledge, the only satellite-based measurements of HCN and C<sub>2</sub>H<sub>6</sub> emission ratios for boreal vegetation types are reported by Rinsland et al. (2007) and Tereszchuk et al. (2011, 2013) using ACE-FTS. Although ACE-FTS has global coverage, observations of biomass burning plumes is dependent on the temporal and spatial sampling of the instrument intersecting the biomass burning plume. As result, measurements within of a biomass burning plume, may only occur in a small number of instances.

Ground-based measurements, particularly by FTIR have sampled boreal wildfire plumes on several occasions (i.e., Viatte et al. 2013, 2015 and Lutsch et al. 2016) providing emission ratios of both HCN and C<sub>2</sub>H<sub>6</sub>. Each of these studies, have only considered a single or select number of events. Measurements of emissions ratios using FTIR are dependent on the smoke plume passing over the FTIR site. However, FTIR measurements within a smoke plume, may sample the plume over several days, providing temporal converge. The emission ratios derived by FTIR measurements may therefore capture the temporal variability of the emissions, resulting in a time-averaged emission ratio since the emission ratio is derived from the slope of trace gas correlations during the course of the wildfire pollution event.

Using a long-term timeseries and network of FTIR instruments provides several advantages to quantifying the emission ratios of biomass burning species. The long-term timeseries enables the detection of greater number of wildfire pollution events as was

illustrated in Section 3.3, all of which may have variable emissions due to vegetation type and the burning phase of combustion. The transport of emissions from a particular wildfire source to each FTIR site is dependent on the meteorological conditions, therefore each site is likely to sample different plumes of varying origins providing a means of capturing the variability of emissions between events. These aspects enable a network of FTIR instruments to capture a large number of wildfire events to quantify the emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> along with its variability. Emission ratios derived by a network of FTIR instruments therefore provide more robust estimates of the emission ratios and their respective variability.

Our reported mean emission ratios, and their comparison to literature values, should be interpreted in light of several limitations. The enhancement and emission ratios were obtained from measurements spanning several days, and therefore may not sufficiently capture shorter-term variability in wildfire emissions (e.g. Lutsch et al., 2019) and may be more susceptible to smoldering phase combustion. Smoldering phase combustion may be a persistent source of emissions that may last several weeks, leading to prolonged periods of fire-affected measurements. Chemical aging of the plume may also affect the calculated emission ratios. Here we have assumed lifetimes of CO, HCN and C<sub>2</sub>H<sub>6</sub>; however, the actual lifetimes of these species may vary within a smoke plume, which is dependent on the availability of OH. The assumed transport times of the plume may also influence emission ratio estimates. In this study, we calculated plume travel times based on the FLEXPART back-trajectories, which correspond to the sensitivity of column measurements to surface emissions. The injection of wildfire emissions into the free troposphere could enable more efficient transport, decreasing the plume travel time (Heilman et al., 2014). Thus, it is likely that the assumed travel times exceed the actual travel times. However, differences in travel times of several days will only have a minor influence on the calculated emission ratio as assumed lifetimes of each species is much longer the travel times. Plume diffusion and mixing with background air (McKeen and Liu, 1993; McKeen et al., 1996; Ehhalt et al., 1998; Xiao et al., 2007) may also decrease the emission ratios, which are not accounted for by the first-order loss assumed for each species; however, plume mixing may be partially captured by the loss of the linear correlation between the trace gas species in ambient or background conditions.

## 4.2 Wildfire Contribution to CO

The GEOS-Chem tagged CO simulation provides a means of evaluating the contribution of CO from anthropogenic, chemical and biomass burning sources to the measured CO columns at each FTIR site. Figures 7 to 10 show the daily-averaged GEOS-Chem and FTIR CO tropospheric columns (surface-12.71 km) for the simulation period from 2003-2018. The relative contribution of biomass burning tracers are also shown. Biomass burning tracers with a mean contribution of less than 3% are not shown. For all GEOS-Chem tagged CO tracers, the partial column profile was linearly interpolated onto the FTIR retrieval grid to account for the differences in surface elevation of the model and FTIR sites.

For all sites, the oxidation of CH<sub>4</sub> is the greatest contribution to the tropospheric CO column as illustrated in Figure 6. The magnitude of this source is similar amongst all sites, with the exception of Zugspitze and Jungfrauoch due to their high altitude. Anthropogenic Asian CO sources exhibit the greatest seasonal amplitude at all sites, due to the magnitude of the emissions and the influence of seasonally variable transport (Klonecki, 2003; Stohl et al., 2006; Fisher et al., 2010). European and North American anthropogenic sources show a similar seasonal cycle but smaller in amplitude in comparison to the Asian source. Of

note, at Zugspitze and Jungfraujoch, comparable contributions from anthropogenic sources in Asia, North America, Europe and the rest of the world are observed. The oxidation of NMVOCs is a considerable source at all sites, with little seasonal dependence. A slight increase in the NMVOC contribution is observed in the summertime, particularly in July and August, as a result of emissions of NMVOC from biogenic sources and wildfires (Guenther et al., 2000; Wentworth et al., 2018).

575 Biomass burning sources of CO exhibit the greatest differences amongst sites as seen in Figure 6. For most sites, the onset of the biomass burning contribution begins in May with a maximum in August. Similar to the anthropogenic influence, Zugspitze and Jungfraujoch are generally isolated from the direct influence of biomass burning emissions and only show a minor enhancement in the summer. For Rikubetsu, the onset of the biomass burning contributions is observed earlier than for the other sites beginning in March as a result of the influence of Asian biomass burning sources (CEAS, SEAS and EQAS),  
580 with slight influence in the summer for boreal emissions from BOAS. The contributions of the biomass burning sources to each site are discussed below.

#### 4.2.1 High-Arctic Sites

The high-Arctic sites of Eureka, Ny-Ålesund and Thule illustrate strong summertime enhancements of CO and HCN as seen in Figures 2 and 3, with a moderate enhancement of C<sub>2</sub>H<sub>6</sub> shown in Figure 4. These enhancements have a maximum in July and  
585 August and from Figure 7, it is observed that the enhancements are largely due to the influence of BONA and BOAS wildfires. Wildfires in temperate regions (TENA and CEAS) are a small contribution to the CO tropospheric column (<5%) but do not contribute to the detected episodic enhancements. A moderate contribution to CO from CEAS and SEAS is observed, but these are not a source of anomalous enhancements.

Similar contributions are observed for BONA and BOAS among the high-Arctic sites, with a stronger influence from BONA  
590 to Eureka and Thule resulting in episodic enhancements of CO contributing greater than 40% to the CO tropospheric column. The strong influence of these sources is the result of the proximity of the high-Arctic sites to these source regions, as well as the efficient summertime isentropic transport (Stohl, 2006). As a result, the direct influence of wildfire plumes at the high-Arctic sites is observed in the FTIR time series, where the effects of plume dilution are minimal.

Furthermore, an early onset in April of the BOAS contribution is observed and is likely the result of the contribution from  
595 Siberian wildfires. Siberian wildfires are associated with low-level injected emissions, mainly within the planetary boundary layer and lower free troposphere (Val Martin et al., 2018). The low-level injection of these emissions and the high latitudes of the sources favor efficient transport to the Arctic (Stohl, 2006). In contrast, the Asian sources, CEAS and SEAS, show minor contributions to the CO tropospheric columns at the high-Arctic sites. Transport of these emissions to the Arctic are limited due to the higher potential temperature of these regions in the summertime, preventing isentropic transport to the Arctic (Klonecki,  
600 2003; Stohl, 2006).

#### 4.2.2 Arctic Sites

For the high-latitude European sites Kiruna and St. Petersburg, smaller contributions to CO from BONA and BOAS sources are observed, with peak contributions ranging from approximately 5 to 44% for BONA and 12 to 37% for BOAS, with slightly

smaller contributions at Kiruna. The smaller contributions from these sites in comparison to the high-Arctic sites is partly due  
605 to the greater distances from the wildfire sources. The transport of emissions to these sites is a result of long-range westerly  
transport that exceeds 11 days as shown in Table 4. Because of the long travel times, the plume is often diluted, and therefore,  
does not generally lead to the episodic enhancements observed at the high-Arctic sites. In contrast, Poker Flat is predominantly  
influenced by Alaskan wildfires, with contributions to the CO tropospheric column exceeding 50% in many cases. Similarly,  
the proximity of Poker Flat to BOAS sources makes BOAS a significant contributor to episodic CO enhancements, comparable  
610 to the local BONA source.

Similar to the high-Arctic sites, contributions from TENA, CEAS and SEAS to the Arctic sites are minimal and do not  
contribute to the episodic enhancements of CO, HCN and C<sub>2</sub>H<sub>6</sub> detected in the FTIR time series. However, Poker Flat and St.  
Petersburg generally exhibit greater contributions from CEAS. For Poker Flat, this is the result of Asian outflow transporting  
emissions from Asia over the Atlantic to Alaska. For St. Petersburg, the proximity to the CEAS sources makes it susceptible  
615 to this source. Particularly evident is the large enhancement in July and August of 2010 due to wildfires in the Moscow region  
(Konovalov et al., 2011; Witte et al., 2011; Yurganov et al., 2011) although not detected in the FTIR time series as there were  
no measurements during that period.

#### 4.2.3 Alpine Sites

The alpine sites, Zugspitze and Jungfraujoch shown in Figure 9, differ the most from the other sites considered in this study as  
620 a result of their high altitude. It is seen that Zugspitze and Jungfraujoch are most strongly influenced by BOAS, with a mean  
seasonal maximum contribution of approximately 14% at both sites. The contribution of BOAS emissions to the enhanced  
columns at Zugspitze and Jungfraujoch are due to hemispheric-scale transport with transport times exceeding 10 days, leading  
to a perturbation to background concentrations of each species. As a result, the enhancements detected in the FTIR time  
series or GEOS-Chem do not result in the large, episodic enhancements observed at the high-Arctic sites. The contributions  
625 from trans-Atlantic transport of BONA emissions, however, exhibit these anomalous enhancements on occasion. Particularly  
evident are the BONA wildfires of 2013-2015 and 2018. Emissions from boreal Canadian wildfires may be injected into the  
free troposphere (Val Martin et al., 2018) and in some cases the lower stratosphere (Fromm et al., 2000; Khaykin et al., 2018;  
Peterson et al., 2018) which may enable the efficient transport of the plume over inter-continental scales (Heilman et al., 2014).

SEAS emissions are a larger contributor to CO enhancements for Zugspitze and Jungfraujoch than for the Arctic or high-  
630 Arctic sites. However, such enhancements are not observed in the FTIR time series as the contribution from SEAS is small  
in comparison to Asian anthropogenic sources as illustrated in Figure 6. Transport of Asian biomass burning CO emissions  
to Europe had been identified in the springtime by Petetin et al. (2018) and attributed to uplifting of emissions into the free  
troposphere and efficient transport of the westerlies (Bey et al., 2001a). In all cases, Zugspitze and Jungfraujoch are most  
susceptible to emissions that reach the free troposphere where long-range transport is favored (Petetin et al., 2018).

Anomalous enhancements in the Rikubetsu time series are dominated by the outflow of BOAS emissions that begin in early springtime and persist throughout the summer and autumn. Episodic BOAS enhancements are observed annually, with contributions that generally exceed 20% and are larger than 50% in many years. The greatest enhancement from BOAS was observed in 2003 as result of the exceptional emissions from Siberia wildfires (Jaffe et al., 2004; Ikeda and Tanimoto, 2015). Although  
640 the contribution from BOAS at Rikubetsu is highly variable between years, anomalous enhancements are observed annually in the GEOS-Chem time series, while detection of events in the FTIR time series is limited by the temporal sampling of the FTIR instrument. CEAS and SEAS have moderate contributions ( $\sim 10\%$ ) to the CO tropospheric column at Rikubetsu in the spring and fall although the influence of these sources are often masked by the greater BOAS emissions during these periods. Other biomass burning sources have minimal contributions and Asian anthropogenic sources are dominant throughout the year  
645 as shown in Figure 6.

Toronto is most strongly influenced by wildfires of BONA, with detected events in the FTIR time series including 2014 from the Northwest Territories wildfires (Lutsch et al., 2016; Kochtubajda et al., 2019), 2015 from wildfires in Saskatchewan (Dreessen et al., 2016) and the 2017 British Columbia wildfires (Peterson et al., 2018). Although it is in close proximity to TENA sources, mainly from the Western and Southern United States, Toronto is minimally influenced by TENA as the  
650 magnitude of these emissions is much smaller than for BONA. Background contributions from CEAS and SEAS are also observed in the springtime although the contribution from Asian anthropogenic sources is dominant. BOAS is also a significant contribution to CO at Toronto in the summertime, but does not generally result in anomalous enhancements as a result of the longer transport times from this region. The 2018 enhancements were attributed to BOAS, while in June 2012, enhancements were present in the FTIR time series and appear to occur simultaneously with the large BOAS contribution ( $>30\%$ ). Minor  
655 contributions ( $<5\%$ ) from CEAS are observed in the springtime and autumn, while a moderate influence from SEAS of  $\sim 10\%$  is observed in the spring.

## 5 Conclusions

Boreal wildfires of North America (BONA) and Asia (BOAS) were found to be the greatest contributors to episodic CO enhancements at ten Northern hemisphere FTIR sites: Eureka, Ny-Ålesund, Thule, Kiruna, Poker Flat, St. Petersburg, Zugspitze,  
660 Jungfrauoch, Toronto and Rikubetsu. Wildfire pollution events were identified by detection of enhancements of CO in the FTIR time series. With the exception of Ny-Ålesund, Poker Flat and Rikubetsu, detected CO enhancements were correlated with coincident measurements of HCN and  $C_2H_6$  to determine their enhancement ratios with respect to CO, providing evidence for wildfires as the source of these pollution events.

For the detected wildfire events, the calculated enhancement ratios of HCN and  $C_2H_6$  were converted to emission ratios  
665 using a mean plume travel time calculated from FLEXPART back-trajectories. Plume travel times were found to vary between sites and source regions, with a minimum of 3 days for BONA events transported to Poker Flat, to maximum of 14 days for BOAS transported to Zugspitze. With the exception of Rikubetsu (8 days) and Zugspitze (14 days), travel times were

comparable for BOAS sources at all sites, ranging from 10-12 days on average. For BONA, the travel times varied by site with a minimum of 3 days at Poker Flat to a maximum of 12 days at Kiruna and Ny-Ålesund.

670 A total of 23 emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> were found for BONA, and 38 for BOAS. The calculated emission ratios were found to agree well with previous published values, illustrating the FTIR observations of this kind are able to capture the long-range transport of wildfire emissions. Average emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> for BONA of 0.0047 and 0.0092, respectively, were found, with standard deviations of 0.0014 and 0.0046, respectively. Similarly, for BOAS, mean HCN and C<sub>2</sub>H<sub>6</sub> emissions ratios of 0.0049 and 0.0100, respectively, with standard deviations of 0.0025 and 0.0042, respectively, were  
675 found. Due to the similarity of emission ratios found for BONA and BOAS, there is no clear distinction in emissions between the two sources. Furthermore, the emission ratios found here provide additional constraints on the variability of HCN and C<sub>2</sub>H<sub>6</sub> emissions, adding to the sparsely populated literature dataset, particularly for BOAS. Moreover, the emission ratios quantified using the long-term time series obtained from a network of FTIR instruments enabled the detection of a larger number of wildfire pollution events, enabling more robust estimates of the HCN and C<sub>2</sub>H<sub>6</sub> emission ratios whereas previous studies from  
680 aircraft-, satellite- or ground-based measurement platforms have only focused on single and few number of events.

The results of this study confirm the ability of ground-based FTIR measurements to capture the transport of boreal wildfire emissions. Furthermore, we extend our findings by quantifying the contribution of wildfire sources to CO measurements at each site using the GEOS-Chem tagged CO simulations. For Eureka and Thule, BONA and BOAS sources were found to contribute to greater than 40% of the CO tropospheric partial column in many cases. A similar influence of BONA and BOAS  
685 wildfires was observed at Ny-Ålesund. Kiruna was also strongly influenced by the trans-Atlantic transport of BONA emissions and hemispheric transport of BOAS emissions, which may contribute ~5-40% of the CO tropospheric partial column during the summer months from June through September of each year. A similar contribution was observed at St. Petersburg, albeit lower in magnitude. The GEOS-Chem tagged CO simulation illustrated the strong influence of both BONA and BOAS sources at Poker Flat, which in several years exceeded 60% of the CO tropospheric column.

690 The Alpine sites, Zugspitze and Jungfraujoch, are isolated from major biomass burning sources, but on occasion are subject to the transport of both BONA and BOAS emissions, which were detected in the FTIR time series at both sites. However, these emissions are generally a small contribution to the tropospheric CO partial column (~10%). Toronto was mainly influenced by North American wildfires of BONA contributing ~10-20% of the CO column. Asian anthropogenic sources strongly influence the CO background at Rikubetsu, which was also considerably influenced by BOAS wildfires.

695 Given the substantial contribution of wildfire sources to CO at sites in this study, and the ability of FTIR to quantify wildfire emissions, future studies should examine the long-term effect of biomass burning emissions on reactive trace gas species. Reactive trace gas species of interest that are readily measured by FTIR include acetylene (C<sub>2</sub>H<sub>2</sub>, e.g., Paton-Walsh et al., 2010; Vigouroux et al., 2012; Viatte et al., 2014, 2015), methanol (CH<sub>3</sub>OH, e.g., Rinsland et al., 2009; Vigouroux et al., 2012; Viatte et al., 2014, 2015), formic acid (HCOOH, e.g. Zander et al., 2010; Viatte et al., 2014, 2015), formaldehyde  
700 (H<sub>2</sub>CO, Paton-Walsh et al., 2004; Vigouroux et al., 2009; Viatte et al., 2014, 2015; Vigouroux et al., 2018) and ammonia (NH<sub>3</sub>, e.g., Paton-Walsh et al., 2004; Dammers et al., 2015; Lutsch et al., 2016, 2019). FTIR measurements can inform future studies

to characterize the long-range transport of these species to elucidate the chemical mechanisms within a smoke plume and potential impacts on air-quality.

705 *Code and data availability.* The FTIR data are available from the NDACC data repository at <ftp://ftp.cpc.ncep.noaa.gov/ndacc/>. The GEOS data used in this study have been provided by the Global Modeling and Assimilation Office (GMAO) at NASA Goddard Space Flight Center. The GEOS-Chem model code used is available here: <http://dx.doi.org/10.5281/zenodo.2249246> (The International GEOS-Chem User Community, 2018). The AEORONET data used are available here: [https://aeronet.gsfc.nasa.gov/cgi-bin/draw\\_map\\_display\\_aod\\_v3](https://aeronet.gsfc.nasa.gov/cgi-bin/draw_map_display_aod_v3). The FLEXPART was downloaded from: <https://www.flexpart.eu/downloads>. Any additional data may be obtained from Erik Lutsch ([elutsch@physics.utoronto.ca](mailto:elutsch@physics.utoronto.ca))

## 710 **Appendix A: Averaging Kernels**

The averaging kernel characterizes the vertical information content of the retrievals as described in Rodgers (2000). We consider the total column averaging kernel ( $\mathbf{a}$ ), rather than the averaging kernel matrix ( $\mathbf{A}$ ). We define the total column averaging kernel vector:

$$\mathbf{a} = \mathbf{C}^T \mathbf{A}, \tag{A1}$$

715 where  $\mathbf{C}$  is the total column operator in units of molecules  $\text{cm}^{-2}$  and  $T$  denotes the transpose. The VMR averaging kernel matrix  $\mathbf{A}$  is in VMR/VMR units. The total column averaging kernel may be normalized:

$$\hat{a}_i = a_i / C_i, \tag{A2}$$

where  $i$  is the index of the  $i$ th level of the FTIR vertical retrieval grid. The normalized total column averaging kernel ( $\hat{\mathbf{a}}$ ) is unitless and represents the sensitivity to a change in partial column for the vertical level  $i$ . The normalized total column averaging kernel may then be applied to the partial column profile to obtain the smoothed column, as shown in Section 3.2.

720 For all species and sites, the total column averaging kernels are not highly variable in time. The variability of the total column averaging kernel is mainly due the changes in the vertical distribution of the species. In particular, total column averaging kernel values generally increase with greater concentration of the species. There is some dependence on the solar zenith angle (SZA) of the measurement which varies seasonally, as the SZA is related to the sampled slant path through the atmosphere. At high SZAs, the longer slant path results in greater degrees of freedom for signal (DOFS), and hence greater averaging kernel values. The a priori covariance matrix, which is site and species dependent, also influences the total column averaging kernel.

*Author contributions.* This study was designed by EL, KS and DBAJ. TB, SC, JWH, FH, YK, EM, MM, IM, TN, JN, IO, MO, AVP, RS and TW contributed to the FTIR measurements used. JAF contributed to the updated GEOS-Chem tagged CO simulation that was used. The analysis was performed by EL. The paper was prepared by EL with contributions from all authors.

730 *Competing interests.* The authors declare they have no competing interests.

*Acknowledgements.* Bruker FTIR measurements were made at PEARL by the Canadian Network for the Detection of Atmospheric Composition Change (CANDAC), which has been supported by the Atlantic Innovation Fund/Nova Scotia Research Innovation Trust, Canada Foundation for Innovation, Canadian Foundation for Climate and Atmospheric Sciences, Canadian Space Agency (CSA), Environment and Climate Change Canada (ECCC), Government of Canada International Polar Year funding, Natural Sciences and Engineering Research  
735 Council (NSERC), Northern Scientific Training Program, Ontario Innovation Trust, Polar Continental Shelf Program, and Ontario Research Fund. **Table 2.** Summary of the source regions used in the GEOS-Chem tagged CO simulation.

Type	Name	Description
<b>Anthropogenic</b>	NA	North America
	EU	Europe
	AS	Asia
	ROW	Rest of World
<b>Biomass Burning</b>	BONA	Boreal North America
	TENA	Temperate North America
	CEAM	Central America
	NHSA	Northern Hemisphere South America
	SHSA	Southern Hemisphere South America
	EURO	Europe
	MIDE	Middle East
	NHAF	Northern Hemisphere Africa
	SHAF	Southern Hemisphere Africa
	BOAS	Boreal Asia
	CEAS	Central East Asia
	SEAS	Southeast Asia
	EQAS	Equatorial Asia
	AUST	Australia and New Zealand
<b>Other</b>	CH <sub>4</sub>	Methane oxidation
	NMVOC	Non-methane volatile organic compound oxidation

**Table 3.** Correlation coefficient ( $r$ ) and slope of GEOS-Chem versus FTIR CO tropospheric partial columns and the monthly-mean relative difference of GEOS-Chem minus FTIR [(model-FTIR)/FTIR] CO tropospheric partial columns over all years for measurements from 2003-2018.

**Table 4.** Mean emission ratios of HCN and C<sub>2</sub>H<sub>6</sub> for BONA and BOAS for all detected wildfire events. The value in parenthesis is the 1 $\sigma$  standard deviation of the mean, or the uncertainty for single events. The number of detected events for each site and mean travel times (days) are also given. The summarized studies were selected based on the availability of HCN and C<sub>2</sub>H<sub>6</sub> emission ratios for boreal North American and boreal Asian sources. The studies included consists of emission ratios derived from multiple platforms including aircraft, ground-based FTIR and satellite observations. For each of these studies emissions ratios are reported for a single event or for the mean of several events. The value in parentheses is the reported error or standard deviation.

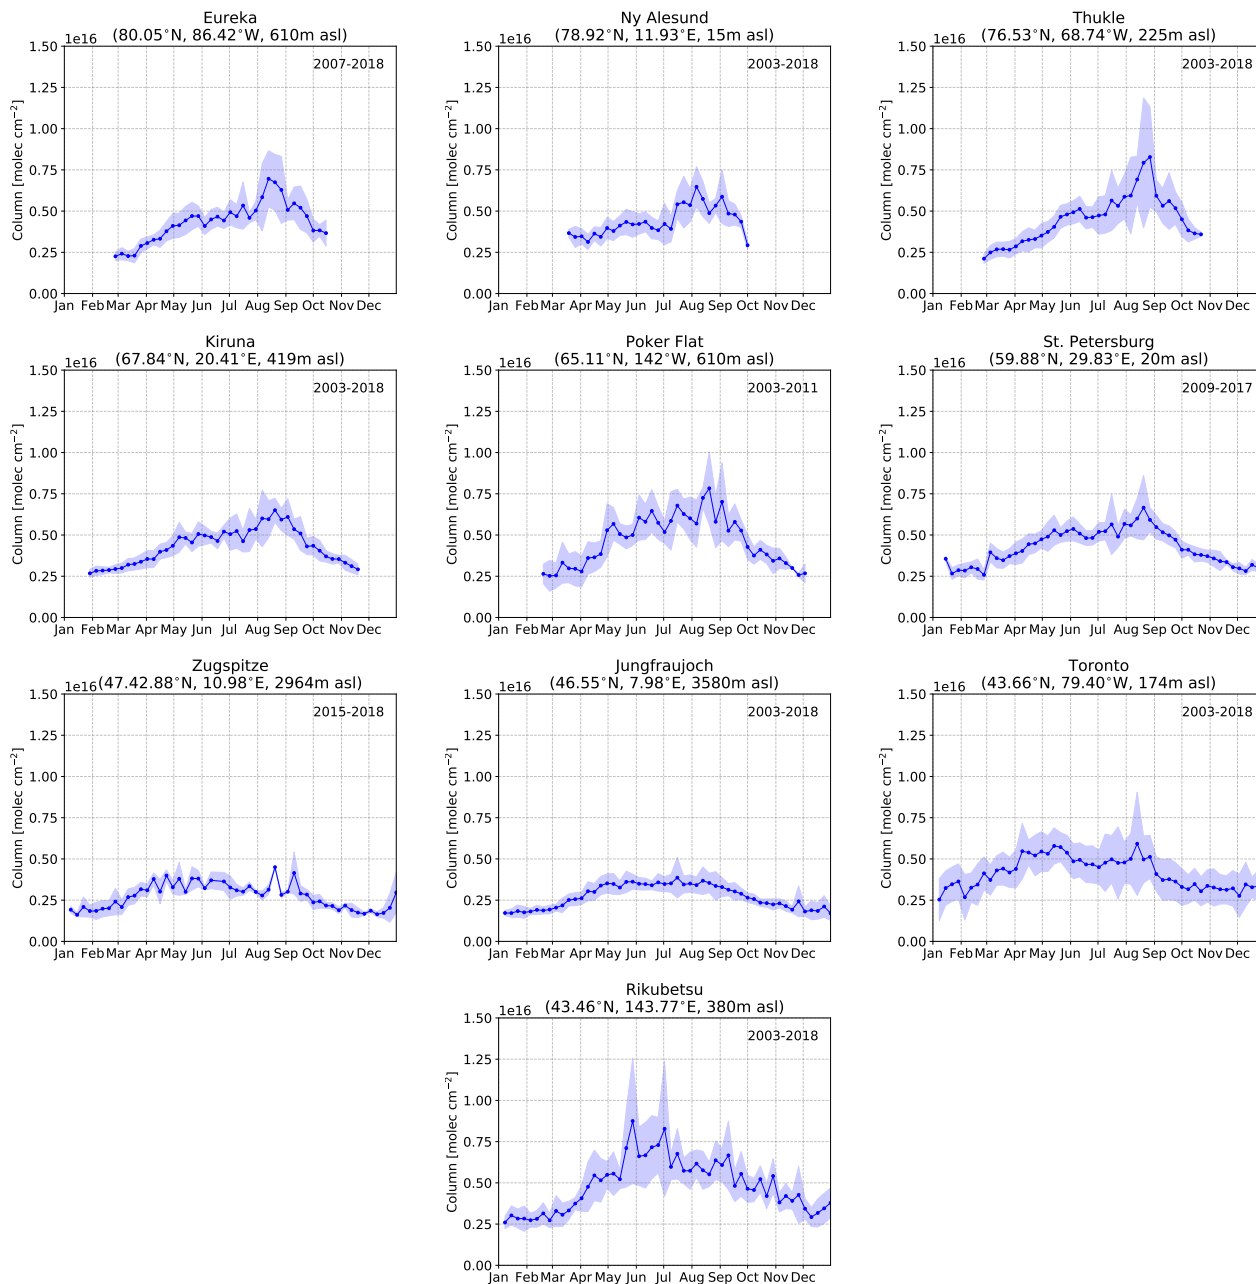

Site	BONA				BOAS			
	Num. Events	Travel Time	ER HCN	ER C <sub>2</sub> H <sub>6</sub>	Num. Events	Travel Time	ER HCN	ER C <sub>2</sub> H <sub>6</sub>

**Figure 1.** Locations of ground-based FTIR sites used in this study. The biomass burning regions (shaded), and anthropogenic source regions (black rectangles) used for the GEOS-Chem tagged CO simulation are also shown and summarized in Table 2.

**Figure 2.** Mean CO tropospheric partial columns weekly-averaged over all years of measurements at each site. The years included in the mean are listed in the top right corner of each panel. The shaded region represents a  $1\sigma$  standard deviation from the mean.

**Figure 3.** Same as Fig. 2 but for HCN.

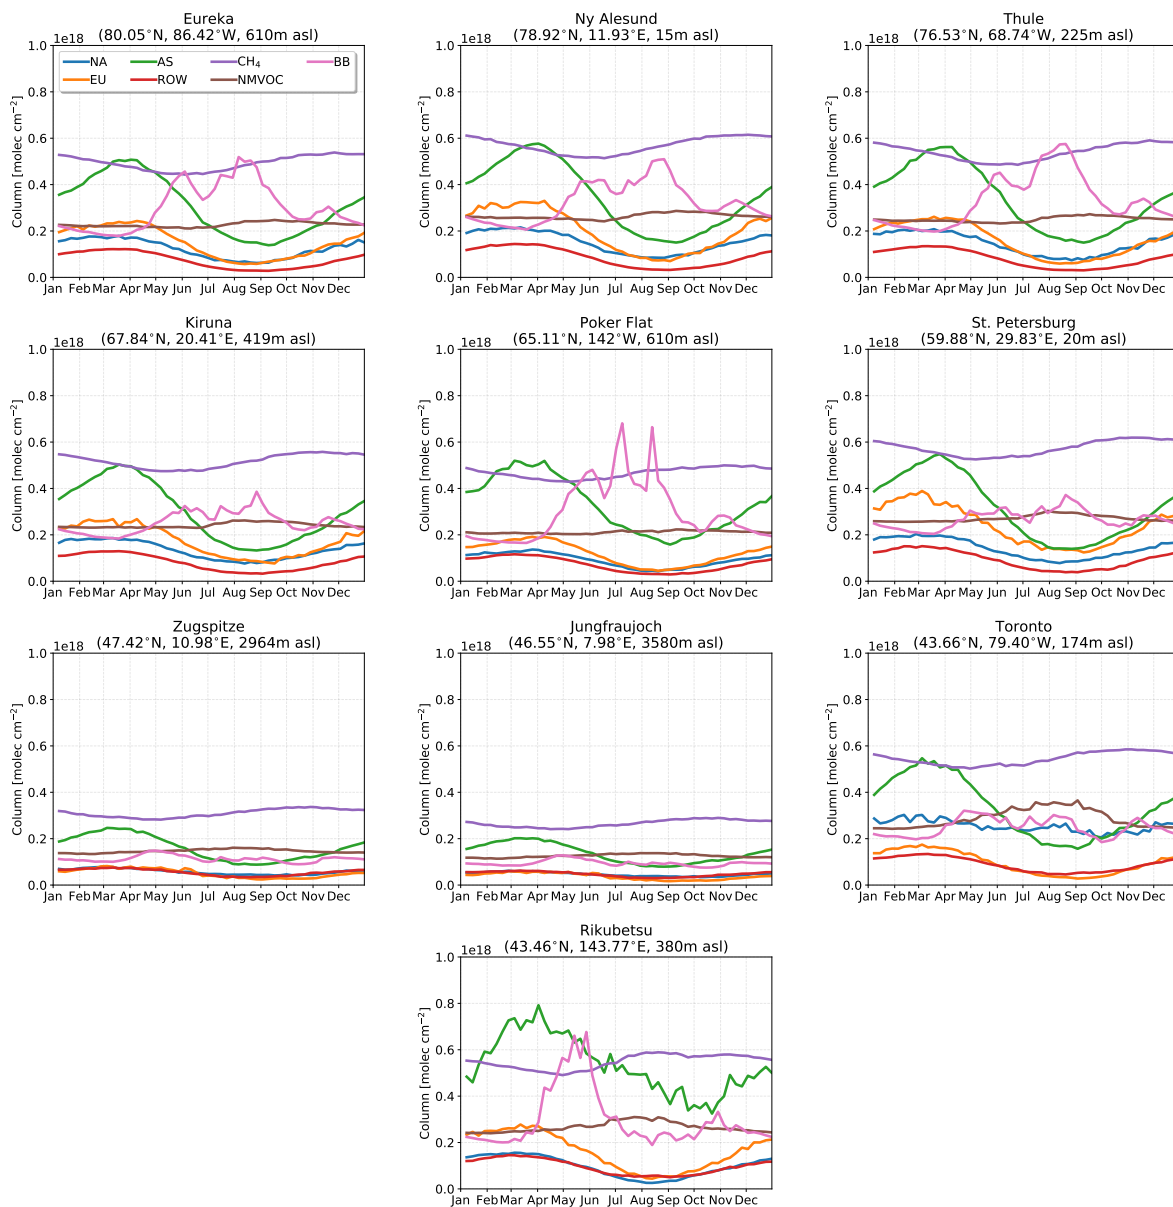

**Figure 4.** Same as Fig. 2 but for  $C_2H_6$ .

**Figure 5.** Summary of detected wildfire pollution events. The grey bars indicate periods of CO measurements and the coloured points represent the identified wildfire pollution events and their respective source attributed by the GEOS-Chem tagged CO simulation.

**Figure 6.** Weekly-mean GEOS-Chem tagged CO tracer tropospheric columns. The tagged CO tracer correspond to those listed in Table 2. The total biomass burning (BB) contribution is shown and is the sum of all biomass burning tracers from Table 2.

**Figure 7.** Daily-mean CO tropospheric column time series for FTIR and GEOS-Chem (top panel) from 2003-2018 for the high-Arctic sites: Eureka, Ny-Ålesund and Thule. The bottom panel shows the relative contribution (%) of the BONA, TENA, BOAS, CEAS and SEAS CO tracers in the GEOS-Chem simulation to the total CO tropospheric column. The grey shaded regions indicate periods of fire-affected measurements identified in the FTIR time series and summarized in [Figure 5](#)

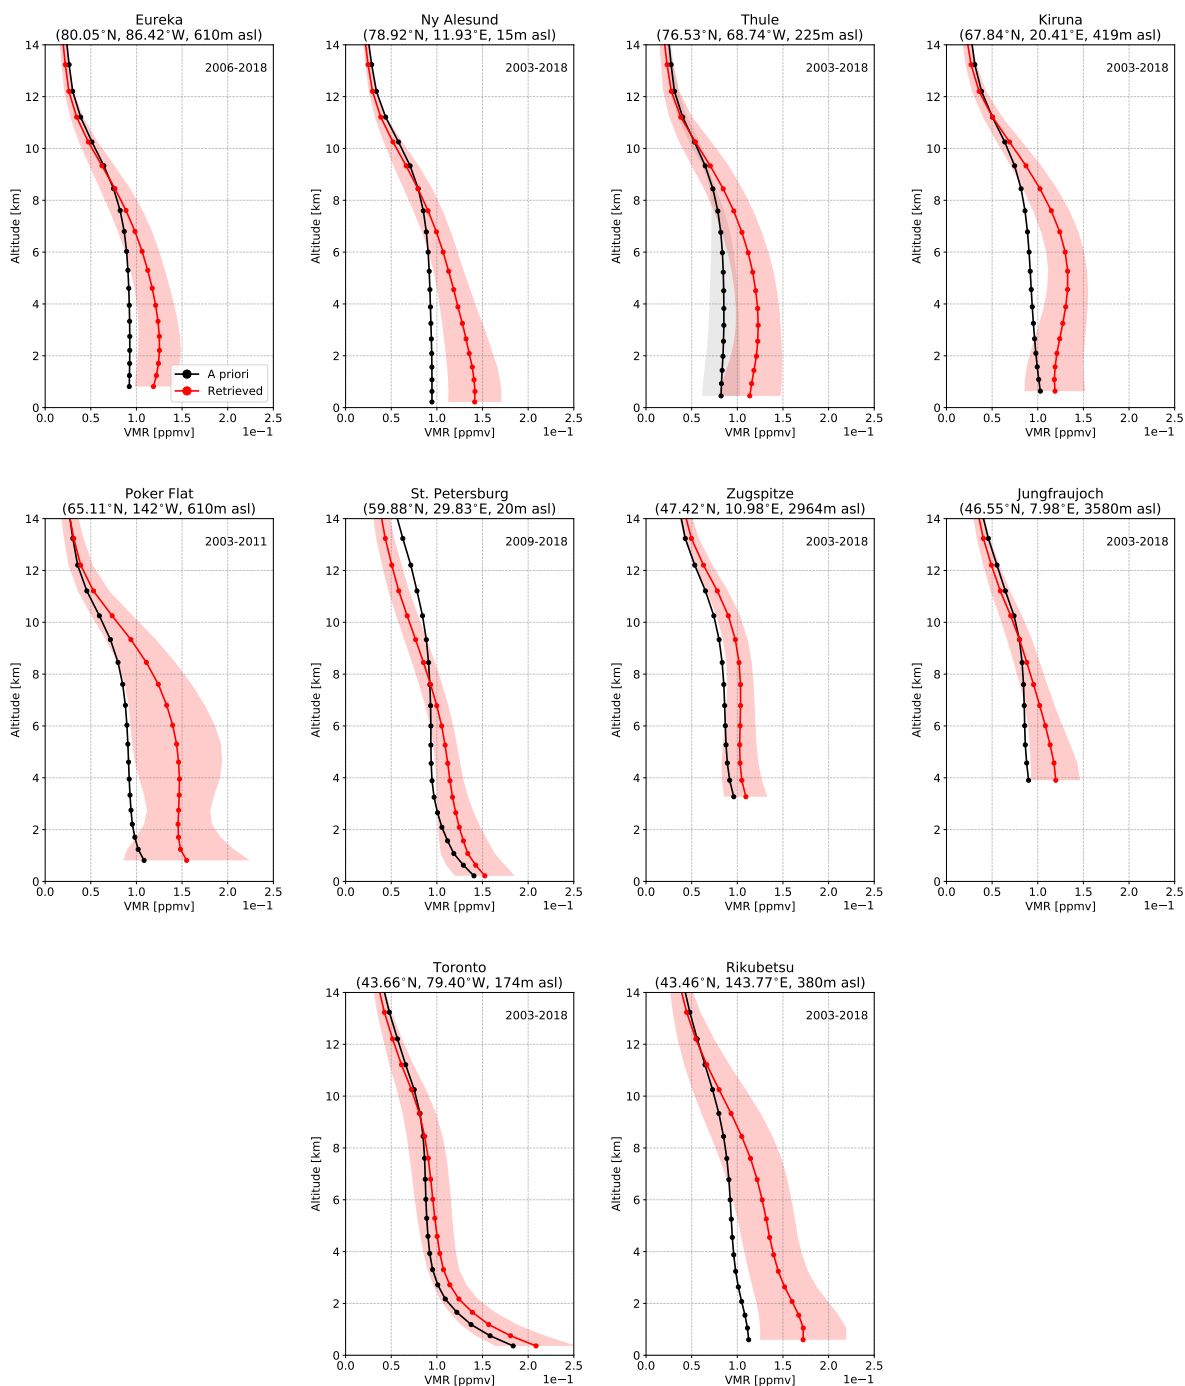

**Figure 8.** Same as Figure 7 but for the Arctic sites: Kiruna, Poker Flat and St. Petersburg .

**Figure 9.** Same as Figure 7 but for the alpine sites: Zugspitze and Jungfrauoch.

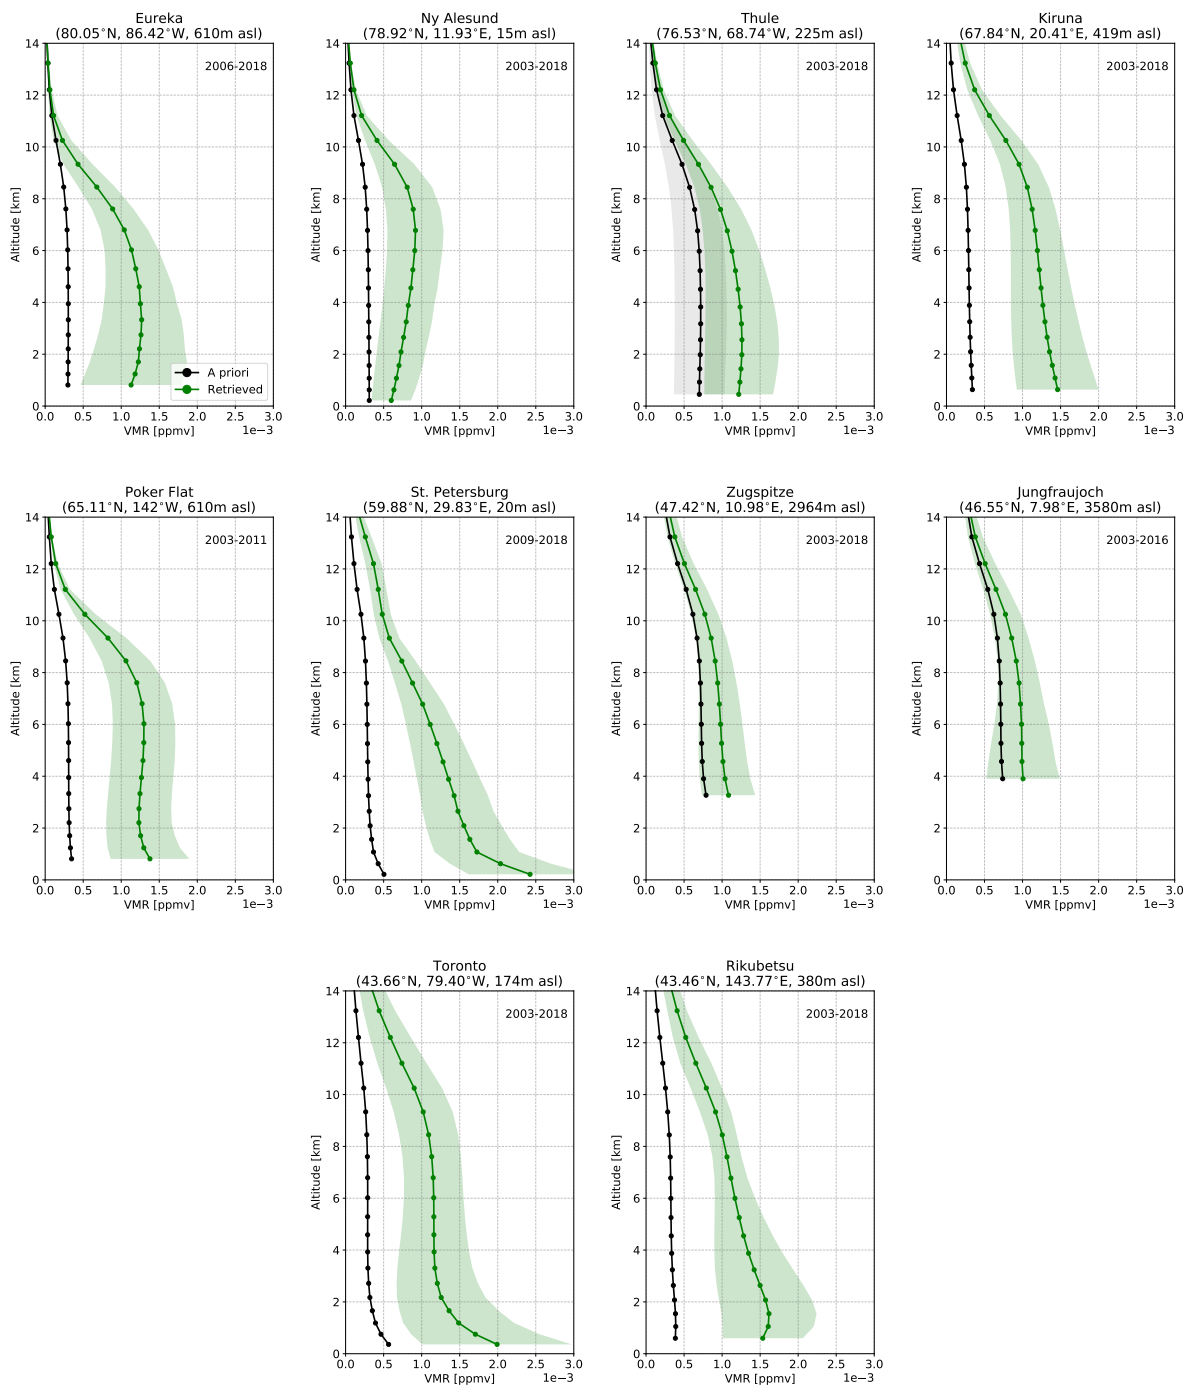

**Figure 10.** Same as Figure 7 but for the mid-latitude sites: Rikubetsu and Toronto.

**Figure A1.** Mean retrieved (red) and a priori (black) VMR profiles of CO taken over all years of measurements at each site. The shaded region indicates the  $1\sigma$  standard deviation from the mean. The circle markers indicate the layer centers of the FTIR vertical retrieval grid.

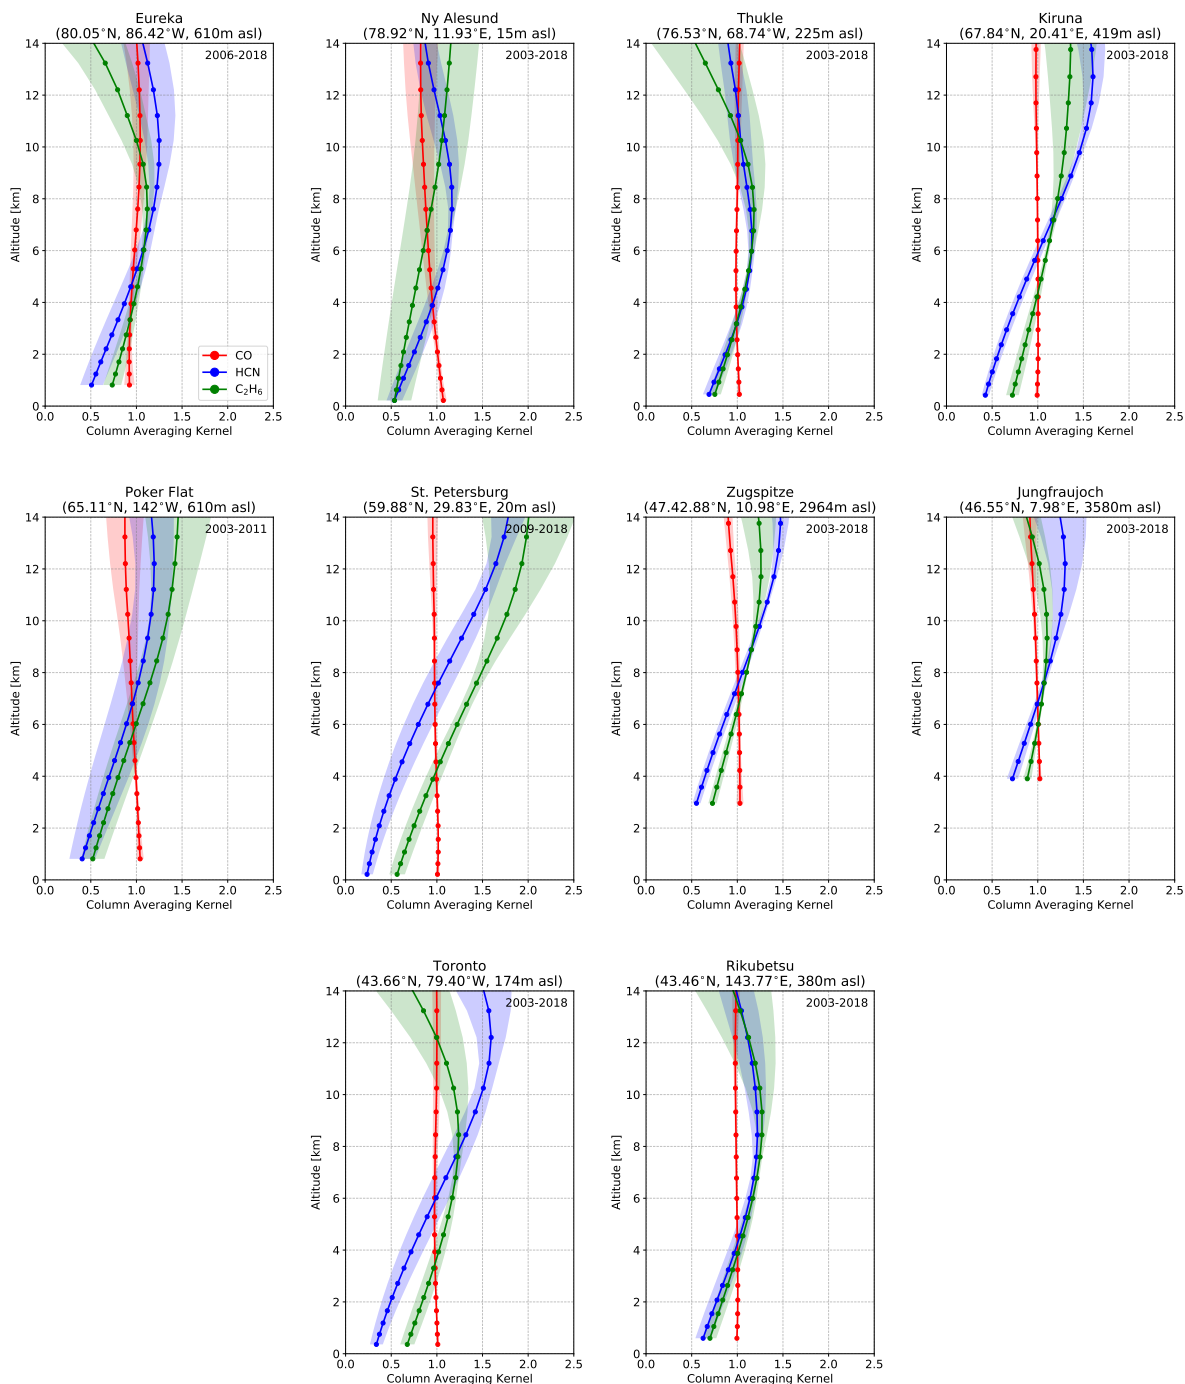

**Figure A2.** Same as Fig. A1 but for HCN.

**Figure A3.** Same as Fig. A1 but for  $C_2H_6$

**Figure A4.** Mean CO, HCN and C<sub>2</sub>H<sub>6</sub> normalized total column averaging kernels in units of molec cm<sup>-2</sup>/ molec cm<sup>-2</sup>, taken over all years of measurements at each site. The shaded region indicates a 1σ standard deviation from the mean. The circle markers indicate the layer centers of the FTIR vertical retrieval grid.
