23

24 **Key points:**

25 1. The black carbon (BC) transport across the Himalayas can overcome a majority of mountain
26 ridges, but the valley transport is much more efficient.

27 2. The complex topography results in stronger overall crossing-Himalayas transport primarily
28 due to the enhanced valley wind, deeper valley channels, and induced small-scale favorable
29 circulation.

30 3. The complex topography generates 50% higher transport flux of BC across the Himalayas
31 and 30-50% stronger BC radiative heating in the atmosphere up to 10 km over the Tibetan
32 Plateau (TP) than that with the smoother topography, which implies that global climate models
33 with relatively coarse resolution may introduce significant negative biases in estimating BC
34 radiative forcing over the TP due to smooth topography.

35 4. The different topography also leads to different distributions of snow cover and BC forcing
36 in snow over the TP.
37

38 **Abstract**

39 Most of previous modeling studies about black carbon (BC) transport and impact over the
40 Tibetan Plateau (TP) conducted simulations with horizontal resolutions coarser than 10 km that
41 may not be able to resolve well the complex topography of the Himalayas. In this study, the
42 two experiments covering entire Himalayas with the Weather Research and Forecasting Model
43 coupled with chemistry (WRF-Chem) at the horizontal resolution of 4 km but with two
44 different topography datasets (4-km complex topography and 20-km smooth topography) are
45 conducted for pre-monsoon season (April, 2016) to investigate the impacts of topography on
46 modeling the transport and distribution of BC over the TP. Both experiments show evident
47 accumulation of aerosols near the southern Himalayas during the pre-monsoon season,
48 consistent with the satellite retrievals. The observed episode of high surface BC concentration
49 at the station near the Mt. Everest due to heavy biomass burning near the southern Himalayas
50 is well captured by the simulations. The simulations indicate that the prevailing up-flow across
51 the Himalayas driven by the large-scale circulation during the daytime is the dominant
52 transport mechanism of South Asian BC into the TP, and is much stronger than that during the
53 nighttime. The simulation with 4-km topography resolves more valleys and mountain ridges,
54 and shows that the BC transport across the Himalayas can overcome a majority of mountain
55 ridges but the valley transport is more efficient. The complex topography results in stronger
56 overall crossing-Himalayas transport primarily due to the enhanced valley wind, deeper valley
57 channels, and induced small-scale favorable circulation. This results in 50% higher transport
58 flux of BC across the Himalayas and 30-50% stronger BC radiative heating in the atmosphere
59 up to 10 km over the TP from the simulation with 4-km complex topography than that with 20-
60 km smoother topography. The different topography also leads to different distributions of snow
61 cover and BC forcing in snow. This study implies that global climate models generally with
62 even coarser resolutions than 20 km and therefore relatively smoother topography may
63 introduce significant negative biases in estimating light absorbing aerosol radiative forcing
64 over the TP.

65

66

67

68

69

70 **1. Introduction**

71 The Tibetan Plateau (TP) is the highest plateau in the world with an average elevation
72 over 4 km and an area of approximately $2.5 \times 10^6 \text{ km}^2$, known as the world's third pole (Qiu,
73 2008), and its enormous dynamic and thermal effects have a huge impact on large-scale
74 atmospheric circulation through the energy exchange with the atmosphere especially the
75 troposphere, such as Asian monsoon (e.g., Ye and Wu, 1998; Duan and Wu, 2005; Wu et al.,
76 2007, 2012; Boos and Kuang, 2013; Chen and Bordoni, 2014; He et al., 2019; Zhao et al.,
77 2019). In addition, the glacial melting water of TP is one of the important sources of water
78 resources of the Indus River, Ganges River, Yangtze River, and Yellow River in Asia (e.g.,
79 Singh and Bengtsson, 2004; Barnett et al., 2005; Immerzeel et al., 2010; Lutz et al., 2014).
80 Previous studies found aerosols in the atmosphere over/around the TP could change the
81 regional climate of Asia (e.g., Qian et al., 2011, 2015; Lau et al., 2017, 2018). Model
82 simulations showed that the absorptive aerosols changed the surface radiative flux over the TP
83 by $5\text{-}25 \text{ W m}^{-2}$ during the pre-monsoon season in April and May and led to the changes in
84 summer monsoon circulations (Qian et al., 2011). Meanwhile, aerosol may affect the
85 atmosphere by modulating the vertical structure of cloud and precipitation around the TP, and
86 thus change the distribution of atmospheric latent heat around the TP, which is the main driving
87 force of regional atmosphere circulations (e.g., Li et al., 2010, 2017, 2019). Moreover, when
88 absorbing aerosols settle on the snow-covered areas, they will blacken the surface of snow
89 cover and glacier to a large extent (e.g., Hansen and Nazarenko, 2004; Ramanathan and
90 Carmichael, 2008; Lau et al., 2010, 2018; Lee et al., 2013; Zhang et al., 2017, 2018), reduce
91 the snow albedo so as to absorb more solar radiation and cause the consequences of accelerated
92 melting (e.g., Ramanathan et al., 2007; Ming et al., 2009; Yasunari et al., 2010; Ji et al., 2015;
93 Zhang et al., 2015). According to the Intergovernmental Panel on Climate Change Fifth
94 Assessment Report (IPCC AR5), the radiative forcing caused by the important component of
95 absorbing aerosols, black carbon (BC), on the surface snow is 0.04 W m^{-2} ($0.02\text{-}0.09 \text{ W m}^{-2}$)
96 on global average, and the regional forcing (such as over the Arctic and the Himalayas) can be
97 considerably large.

98 The TP is surrounded by various sources of pollutants. Over the South of TP, previous
99 studies have suggested that South Asia was the main source of pollutants transported to the
100 plateau (e.g., Cong et al., 2009, 2015a, b; Kopacz et al., 2011; Lu et al., 2012; Zhao et al., 2013;
101 Wang et al., 2015; Zhang et al., 2015; Kang et al., 2015; Li et al., 2016; Chen et al., 2018; Kang
102 et al., 2019). A huge blanket or layer of “haze” composes of light-absorbing carbonaceous

103 aerosol particles that often erupts in the pre-monsoon season over South Asia and has a
104 significant influence on the plateau (e.g., Prasad and Singh, 2007; Engling and Gelencser,
105 2010). Among them, biomass burning emission reaching the maximum in pre-monsoon season
106 over South Asia is one of the dominant sources (e.g., Cong et al., 2015b). Many studies
107 investigated the transport mechanisms of South Asian pollutants to the TP and found that the
108 pollutants transported across the Himalayas were mainly due to the combination of large-scale
109 circulation and regional wind (e.g., Hindman and Upadhyay, 2002; Cao et al., 2010; Dumka et
110 al., 2010; Marinoni et al., 2010; Cong et al., 2015a; Kang et al., 2015; Lüthi et al., 2015; Zhang
111 et al., 2017). Cong et al. (2015a) conducted seven-day backward air-mass trajectories
112 experiment and found strong westerly passed through western Nepal, northwest India and
113 Pakistan (i.e., southern Himalayas) in the pre-monsoon season. Dumka et al. (2010) and Kang
114 et al. (2015) inferred from the trajectory analysis that long-distance transport from Africa and
115 Europe may also affect the BC concentration of Himalayas in addition to the influence of
116 regional pollution.

117 Although previous studies have confirmed the transport of pollutants across the Himalayas,
118 the complex topography of Himalayas complicates transport mechanisms. On one hand, Cao
119 et al. (2010) revealed that the Himalayas acted as a huge barrier to the transport of a large
120 amount of BC over the plateau based on model simulations. On the other hand, some studies
121 found that the valleys across the Himalayas served as channels for efficient transport of
122 pollutants (e.g., Hindman and Upadhyay, 2002; Marinoni et al., 2010). Marinoni et al. (2010)
123 analyzed the observation of wind at a station of the southern Himalayas and found that a distinct
124 valley wind system with the prominent southerly continuously transported pollutants to the
125 plateau. Most of these studies used observations and back-trajectory models to demonstrate the
126 transport pathways of pollutants to the TP, which cannot explicitly reveal the transport
127 mechanisms underneath, in particular quantifying the impacts of complex topography.

128 A few of modeling studies investigated the pollutant transport mechanisms using 3-D
129 chemical transport models (e.g., Kopacz et al., 2011; Liu et al., 2015; Zhang et al., 2017; Yang
130 et al., 2018). However, most of them simulated transport processes at relatively coarse
131 horizontal resolutions (e.g., 20-100 km), which cannot resolve well the complex topography of
132 Himalayas. It is noteworthy that studies about the aerosol climatic impact over the TP also used
133 climate models at relatively coarse horizontal resolutions (e.g., Flanner and Zender, 2005;
134 Menon et al., 2010; Kopacz et al., 2011; Qian et al., 2011, 2015; He et al., 2014; Zhang et al.,
135 2015; Ji et al., 2016). So far, there is only one study that used a chemical transport model at a
136 horizontal resolution of sub-10 km to investigate pollutant transport mechanisms over the

137 eastern Himalayas (Cao et al., 2010). Furthermore, none of studies assessed quantitatively the
138 impacts of topography on modeling the pollutant transport across the Himalayas and hence on
139 estimating aerosol distribution and radiative forcing over the TP.

140 In order to examine the potential impacts of complex topography on pollutant transport
141 across the Himalayas over the TP, this study conducts multiple experiments with the Weather
142 Research and Forecasting Model coupled with chemistry (WRF-Chem, Grell et al., 2005;
143 Skamarock et al., 2008). The WRF-Chem model is selected because it includes the interaction
144 between meteorology and aerosol and is widely used for regional modeling of aerosol and its
145 climatic impact (e.g., Cao et al., 2010; Zhao et al., 2010, 2011, 2012, 2014; Wu et al., 2013;
146 Gao et al., 2014; Huang et al., 2015; Fan et al., 2015; Feng et al., 2016; Zhong et al., 2017;
147 Sarangi et al., 2019; Liu et al., 2020). The model has also been used to investigate the aerosol
148 transport and climatic impact over the Himalayas region (e.g., Feng et al., 2016; Cao et al.,
149 2010; Sarangi et al., 2019). The model is suitable for simulations at hydrostatic and non-
150 hydrostatic scales and thus can be used for investigating the impacts of resolution-dependent
151 feature, such as topography, on modeling results. In particular, the meteorological part of the
152 model (WRF) has been systematically evaluated and used to investigate the impacts of
153 resolutions on simulations of moisture transport and climate over the Himalayas region (e.g.,
154 Shi et al., 2008; Karki et al., 2017; Lin et al., 2018). All of these previous studies with the
155 model lay the foundation for this modeling study.

156 Two experiments with different topography representations are conducted to investigate
157 the impacts of topography complexity on the pollutant transport across the Himalayas and the
158 resulting radiative forcing over the TP. The simulations are conducted for April 2016 in pre-
159 monsoon season, because South Asia is seriously polluted during this period and the pollutants
160 transported to the TP during the period may have significant impacts on Asian monsoon system
161 (e.g., Lau et al., 2006a, b; Ding et al., 2009; Kuhlmann and Quaas, 2010; Qian et al., 2011,
162 2015). In addition, the observed concentration of BC at the observation station besides Mt.
163 Everest shows an evident pollution episode from April 5th to 16th of 2016, deserving the
164 investigation of the transport mechanisms. The rest of the paper is organized as follows. Section
165 2 describes briefly the WRF-Chem model, the physics parameterizations, and the model
166 configuration for this study, followed by a description of data for evaluation. The series of
167 numerical experiments at different resolutions are analyzed in Section 3. The findings are then
168 summarized and discussed in Section 4.

169

170 **2. Methodology**

171 **2.1 Model and experiments**

172 2.1.1 WRF-Chem model

173 In this study, the version of WRF-Chem updated by University of Science and Technology
174 of China (USTC version of WRF-Chem) is used. This USTC version of WRF-Chem includes
175 some additional capabilities such as the diagnosis of radiative forcing of aerosol species, land
176 surface coupled biogenic volatile organic compound (VOC) emission, aerosol-snow
177 interaction compared with the publicly released version (Zhao et al., 2013a, b, 2014, 2016; Hu
178 et al., 2019; Du et al., 2020). The Model for Simulating Aerosol Interactions and Chemistry
179 (MOSIAC) (Zaveri et al., 2008) and the Carbon Bond Mechanism-Z (CBM-Z) gas phase
180 mechanisms (Zaveri and Peters, 1999) are selected. The MOSAIC aerosol scheme uses an
181 approach of segmentation to represent aerosol size distribution with four or eight discrete size
182 bins (Fast et al., 2006). It consists of a range of physical and chemical processes such as
183 nucleation, condensation, coagulation, aqueous phase chemistry, and water uptake by aerosol.
184 The parameterization of dry deposition of aerosol mass and number is according to the method
185 of Binkowski and Shankar (1995), including particle diffusion and gravitational effects.
186 Aerosol-cloud interactions were included in the model by Gustafson et al. (2007) for
187 calculating the activation and re-suspension between dry aerosols and cloud droplets. The wet
188 removal of grid-resolved stratiform clouds/precipitation includes two aspects, namely in-cloud
189 removal (rainout) and below-cloud removal (washout) by Easter et al. (2004) and Chapman et
190 al. (2009), respectively. Aerosol optical properties such as single scattering albedo (SSA) and
191 scattering asymmetry and so on are calculated at each model grid through the function of
192 wavelength. The shortwave (SW) and longwave (LW) refractive indices of aerosols use the
193 Optical Properties of Aerosols and Clouds (OPAC) data set (Hess et al., 1998), with a detailed
194 description of the computation of aerosol optical properties can be found in Barnard et al. (2010)
195 and Zhao et al. (2013a). For both short wave and long wave radiation, aerosol radiation
196 feedback combined with the Rapid Radiative Transfer Model (RRTMG) (Mlawer et al., 1997;
197 Iacono et al., 2000) was implemented by Zhao et al (2011). For the diagnosis of the optical
198 properties and direct radiative forcing of various aerosol species in the atmosphere, the method
199 described by Zhao et al (2013a) is adopted. The radiative forcing of light absorbing aerosol in
200 surface snow is estimated with the Snow, Ice, and Aerosol Radiative model (SNICAR)
201 (Flanner and Zender, 2005) in the land surface scheme as introduced by Zhao et al. (2014).

202 More details about the coupling between the WRF-Chem and SNICAR models can be found
203 in Zhao et al. (2014).

204 2.1.2 Numerical experiments

205 In this study, the WRF-Chem simulations are performed with two nested domains (one-
206 way nesting), one outer domain at 20 km horizontal resolution with 350×250 grid cells (62°E
207 -112°E, 1°N -38°N) and one inner domain at 4 km horizontal resolution with 400×300 grid
208 cells (75°E -92°E, 23°N -35°N) (Fig. 1). The inner domain roughly covers the entire Himalayas.
209 The WRF-Chem simulations conducted in this study use the terrain following coordinate
210 (Skamarock et al., 2008). To resolve the vertical structure of transport across the Himalayas,
211 the simulations are configured with 54 vertical layers and denser layers near the surface. For
212 example, averaged over a region (26°N-28°N, 76°E-80°E) near the southern Himalayas, there
213 are about 17 layers below 2 km above the ground (Fig. 2). The goal of this study is to investigate
214 the impacts of different representations of topography on the transport of BC across the
215 Himalayas. Therefore, besides this control experiment, one sensitivity experiment is also
216 conducted with the same configuration as the control one except that the topography of the
217 inner domain at 4 km resolution is prescribed to follow that at 20 km resolution similar as
218 previous studies (e.g., Shi et al., 2008; Wu et al., 2012; Lin et al., 2018). More specifically, the
219 sensitivity experiment applies a single value for each nested 5×5 grids over the inner domain
220 as the corresponding grid of 20 km over the outer domain. The two experiments are referred to
221 the simulations with complex and smooth topography, respectively, hereafter. Fig. 3 shows the
222 spatial distribution of terrain height over the inner domain with complex (4-km dataset) and
223 smooth (20-km dataset) topography. It is evident that the terrain is much smoother from the
224 20-km dataset than from the 4 km dataset. The mountain ridges and valleys can be resolved to
225 some extent in the 4-km dataset but mostly missed or underestimated at 20-km. The probability
226 distributions of terrain height from the 20-km and 4-km datasets (Fig. S1 in the supporting
227 material) show that the difference between the two datasets is small for the terrain height lower
228 than ~4.5 km but is significant for the terrain height above ~4.5 km. The difference of results
229 from the two experiments over the inner domain is analyzed as the impacts of topography
230 representations. Therefore, all the results shown below are from the simulations of the inner
231 domain at 4 km resolution with different topography if not otherwise stated.

232 The simulations are conducted for March 29th-April 20 of 2016 for the reason as discussed
233 in the introduction. The results of April 1th-20th are analyzed for the observed pollution episode
234 to allow a few days spin-up for chemical initial condition. The meteorological initial and lateral

235 boundary conditions are derived from the European Centre for Medium-Range Weather
236 Forecasts (ECMWF) reanalysis data at $0.5^{\circ}\times 0.66^{\circ}$ horizontal resolution and 6 h temporal
237 intervals (ERA-Interim dataset). The modeled u and v component wind, atmospheric
238 temperature, and geopotential height over the outer domain are nudged towards the reanalysis
239 data with a nudging timescale of 6 h following previous studies (e.g., Stauffer and Seaman,
240 1990; Seaman et al., 1995; Liu et al., 2012; Zhao et al., 2014; Karki et al., 2017; Hu et al., 2016,
241 2020). Spectral nudging method is applied to balance the performance of simulation at the large
242 and small scales (Liu et al., 2012), and only to the layers above the planetary boundary layer
243 (PBL) with nudging coefficients of $3\times 10^{-4} \text{ s}^{-1}$. A wave number of three is selected for both
244 south-north and west-east directions. Please note that the choices of nudging coefficients and
245 wave numbers for spectral nudging in this study are empirical. The purpose of nudging is to
246 simulate reasonably large-scale feature so that small-scale impacts from the complex
247 topography can be focused. Therefore, the modeling sensitivity to these choices is not tested in
248 this study. The results show that the simulations with nudging method can reproduce the large-
249 scale circulation at 700 hPa and higher over the outer domain compared to the reanalysis dataset
250 with the spatial correlation coefficient of 0.96-0.98.

251 The Mellor-Yamada-Nakanishi-Niino (MYNN) planetary boundary layer scheme
252 (Nakanishi and Niino, 2006), Community Land Model (CLM) land surface scheme (Oleson et
253 al., 2010), Morrison 2-moment microphysics scheme (Morrison et al., 2009), Kain-Fritsch
254 cumulus scheme (Kain, 2004), and Rapid Radiative Transfer Model (RRTMG) longwave and
255 shortwave radiation schemes (Iacono et al., 2000) are used in this study. The chemical initial
256 and boundary conditions are provided by a quasi-global WRF-Chem simulation for the same
257 time period to include long-range transported chemical species. The quasi-global WRF-Chem
258 simulation is performed at $1^{\circ}\times 1^{\circ}$ horizontal resolution using a quasi-global channel
259 configuration with 360×130 grid cells ($180^{\circ}\text{W}-180^{\circ}\text{E}$, $60^{\circ}\text{S}-70^{\circ}\text{N}$). More details about the
260 general configuration of quasi-global WRF-Chem simulation can be found in Zhao et al.
261 (2013b) and Hu et al. (2016). The detailed configuration of WRF-Chem experiments is
262 summarized in Table 1. Due to the lack of publicly available in-situ observations, this study
263 does not tend to evaluate systematically the simulated meteorological fields over the Himalayas
264 region. However, as shown in Table 1, the choice of physical parameterizations in this study
265 follows that of one previous study (Karki et al., 2017) that evaluated systematically the WRF
266 simulation for one entire year over the Himalayas region. Their results showed that the WRF
267 simulation at convection-permitting scale could generally capture the essential features of

268 meteorological fields such as precipitation, temperature, and wind over the Himalayas region.
269 Therefore, the WRF-Chem simulations in this study are reliable to investigate the impacts of
270 topography over the Himalayas region.

271 2.1.3 Emissions

272 Anthropogenic emissions for outer and inner simulation domains are obtained from the
273 Hemispheric Transport of Air Pollution version-2 (HTAPv2) at $0.1^\circ \times 0.1^\circ$ horizontal resolution
274 and a monthly temporal resolution for year 2010 (Janssens-Maenhout et al., 2015), except that
275 emissions of East Asia are from the MIX Asian anthropogenic emission inventory at $0.1^\circ \times 0.1^\circ$
276 horizontal resolution for 2015 (Li et al., 2017). Biomass burning emissions are obtained from
277 the Fire Inventory from National Center for Atmospheric Research (FINN) with hourly
278 temporal resolution and 1 km horizontal resolution (Wiedinmyer et al., 2011) for the simulation
279 period, and are vertically distributed following the injection heights suggested by Dentener et
280 al. (2006) from the Aerosol Comparison between Observations and Models (AeroCom) project.
281 Sea-salt emission follows Zhao et al. (2013b), which includes correction of particles with
282 radius less than $0.2 \mu\text{m}$ (Gong, 2003) and dependence of sea-salt emission on sea surface
283 temperature (Jaeglé et al., 2011). The vertical dust fluxes are calculated with the Georgia
284 Tech/Goddard Global Ozone Chemistry Aerosol Radiation and Transport (GOCART) dust
285 emission scheme (Ginoux et al., 2001), and the emitted dust particles are distributed into the
286 MOSAIC aerosol size bins following a theoretical expression based on the physics of scale-
287 invariant fragmentation of brittle materials derived by Kok (2011). More details about the dust
288 emission scheme coupled with MOSAIC aerosol scheme in WRF-Chem can be found in Zhao
289 et al. (2010, 2013b).

290 As shown in Fig. 1, anthropogenic fossil fuel emissions of BC are high over Northeast
291 India. The fossil fuel BC emissions over Nepal, the country nearby the southern Himalayas,
292 are relatively low. Instead, biomass burning emissions of BC are extremely high in Nepal and
293 Northwest India (South Himalayas, 26°N - 29°N). Averaged over the South Himalayas of inner
294 domain that may significantly affect the pollutant transport into the TP, the biomass burning
295 emissions of BC are much higher than its anthropogenic fossil fuel emissions, particularly for
296 the pollution episode (Fig. 4). The anthropogenic BC emissions are set constant through April,
297 while biomass burning emissions show a strong fire event in April 5-16. During the event, the
298 biomass burning BC emissions can be close to a factor of 2 of the anthropogenic fossil fuel BC
299 emissions over South Himalayas.

300

301 2.2 Dataset

302 Three datasets are used to compare with the modeling results to demonstrate the pollutant
303 episode and spatial distribution. One is from the Moderate Resolution Imaging
304 Spectroradiometer (MODIS) instruments on Aqua and Terra satellites. The MODIS Aerosol
305 Product monitors the ambient aerosol optical thickness over the oceans globally and over the
306 continents. Daily Level 2 Aerosol Optical Depth (AOD) at 550 nm products with the spatial
307 resolution of 10 km×10 km (at nadir) from both Aqua and Terra are applied. When compared
308 with the modeling results, the simulations are sampled at the satellite overpass time and
309 location. The second one is from the Aerosol Robotic Network (AERONET) (Holben et al.,
310 1998) that has ~100 similar globally distributed sun and sky scanning ground-based automated
311 radiometers, which provide measurements of aerosol optical properties throughout the world
312 (Dubovik and King, 2000; Dubovik et al., 2002). In this study, AERONET measured AOD at
313 675 nm and 440 nm from two sites over the TP, Qomolangma site (QOMS, 86.94°E, 28.36°N)
314 and Namco site (NAM, 90.96°E, 30.77°N) are used to derive the AOD at 550 nm (using the
315 Angström exponent) for comparison with modeling results at 550 nm. All of the retrievals of
316 AOD are at quality level 2, and the uncertainty of AOD measurements is about 0.01 (Holben
317 et al., 2001). In this study, the available data in April 2016 are used to evaluate the modeling
318 results during the same period.

319 The third one is the measurement of surface BC mass concentration collected during the
320 simulation period for April 4-20 of 2016 at the Qomolangma (Mt. Everest) Station for
321 Atmospheric and Environmental Observation and Research, Chinese Academy of Sciences
322 (QOMS, 86.94°E, 28.36°N) which is located at the northern slope of the Himalayas, about
323 4276 meters above sea level. The BC mass concentration is measured with the widely-used
324 instrument Aethalometer (AE-33) that can provide real-time BC mass concentration
325 measurements. The calibration of air flow is routinely conducted to maintain the data quality.
326 The instrument estimates the BC mass concentration based on the optical method through
327 measuring the reduction in light intensity induced by BC. The method assumes that the
328 relationship between attenuation and BC surface loading is linear for low attenuation values.
329 However, this relationship becomes nonlinear when the attenuation values are high due to a
330 filter saturation effect, which may lead to underestimation of the high BC concentration. The
331 detection limit of AE-33 instrument is 5 ng/m³, and the uncertainty is estimated to be within
332 10% (e.g., Chen et al., 2018; Bansal et al., 2019; Kant et al., 2019). The dataset of BC mass
333 concentration used in this study was reported by Chen et al., (2018), where more details about
334 the measurements can be found.

335 3. Results

336 3.1 Spatial distribution of BC around the TP

337 Figure 5 shows the spatial distributions of column integrated BC mass within the inner
338 domain from the simulations at 4 km resolution with complex and smooth topography averaged
339 for April 1-20, 2016, and the difference between the two is also shown. For both experiments,
340 the southern Himalayas is an apparent boundary line for the distribution of BC with a sharp
341 gradient across the Himalayas. The high BC mass loading exists near the southern Himalayas
342 reaching over 10 mg/m^2 , which is largely contributed by the biomass burning emissions during
343 the period (Fig. 4), while the value reduces significantly to less than 0.4 mg/m^2 over the TP. In
344 general, the column BC mass loading from the simulation with complex topography is higher
345 over the TP and lower over the region to the south of Himalayas compared with the smooth
346 topography. Figure 6 displays the spatial distributions of AOD from the MODIS retrievals and
347 the simulations at 4 km with two different topography averaged for April 1-20, 2016. In general,
348 both simulations reproduce the overall spatial distribution of AOD, with the large values near
349 the southern Himalayas, consistent with the BC mass loading. The difference between the
350 simulations and retrievals may be partly related to the uncertainties in emissions particularly
351 for biomass burning emissions. Other than intense emissions, the wind circulation around the
352 TP may also play an important role in accumulating BC near the southern Himalayas. Because
353 of the block of Himalayas, the wind circulation at 500 hPa is divided into two branches as
354 westerly and northwesterly. Both of them are relatively dry airflows with little effect on
355 pollutant removal, favor the accumulation of pollutants near the southern Himalayas, and carry
356 the pollutants to the TP (e.g., Dumka et al., 2010; Kang et al., 2015; Cong et al., 2015a).

357 The AOD retrieved at two AERONET sites over the TP are compared with the two
358 simulations for April 1-20, 2016 (Fig. 7). The AOD at the QOMS site near the northern
359 Himalayas is higher than that at the NAM site inside of the TP. Both simulations can capture
360 this gradient. The simulation with complex topography produces higher AOD than does the
361 one with smooth topography at both sites. The modeling biases (normalized mean bias, NMB)
362 reduce from -46% (smooth topography) to 9% (complex topography) at the QOMS site and
363 from -26% (smooth topography) to -10% (complex topography) at the NAM site. Although the
364 correlation coefficient between the simulations and observation increases from 0.37 (smooth
365 topography) to 0.53 (complex topography) at the QOMS site, it is similar (~ 0.2) between the
366 two simulations at the NAM site. The correlation coefficient is higher at the QOMS site near
367 the source region than the NAM site farther away, which may indicate the model processes

368 affecting the transport over the TP still need examination with more observations. The NAM
369 site over the eastern TP may also be affected by other sources that are not counted in this study.
370 The modeling of temporal variations of pollutants over the TP deserves further investigation
371 with more observations.

372 There is one in-situ observational station (QOMS) near the Mt. Everest (black dot shown
373 in Fig. 1) to collect the surface BC concentration. The observed surface BC concentration at
374 this station is compared with the corresponding simulations for this period as shown in Figure
375 8. Without local emission source, the surface BC concentration at QOMS is primarily
376 contributed by the transport. The temporal variation of observed surface BC concentration
377 correlates highly with the biomass burning emissions as shown in Fig. 4, with the peak value
378 on April 11 reaching $\sim 3 \text{ ug/m}^3$. One sensitivity experiment without biomass burning emissions
379 shows that the simulated BC concentration at QOMS will be significantly reduced without the
380 peak (not shown), which further proves that the BC concentration over the northern Himalayas
381 can be largely influenced by the pollution episode near the southern Himalayas. It is noteworthy
382 that both simulations can reproduce the episode in time and magnitude, and the difference at
383 this station is small. The spatial distribution of difference in surface BC concentration between
384 the two simulations (Fig. S2) is more heterogeneous than that of column BC mass (Fig. 5),
385 reflecting the impact of topography on transport (see the discussion in Section 3.2).

386

387 **3.2 Transport flux into the TP**

388 To further understand the difference in BC surface concentration and column mass loading
389 over the TP between the two simulations with different topography, Figure 9 shows the
390 longitude-height cross section of BC transport flux along the cross line (shown as the black
391 dash line in Fig. 3) from the two simulations at local time (LT) 03:00 and 15:00 averaged for
392 April 1-20 to represent nighttime and daytime transport, respectively. The PBL height along
393 the cross line is also shown as the black dash line. The transport flux is calculated by projecting
394 the wind field perpendicularly to the cross line and then multiplying the BC mass concentration
395 along the cross line. More specifically, the transport flux is calculated as following:

$$396 \quad \text{TF} = C * (u * \sin \alpha + v * \sin \beta) \quad (1)$$

397 Where α is the angle between east-west wind component and the cross line, β is the angle
398 between south-north wind component and the cross line, and C is the BC mass concentration
399 at the grid along the cross line. The flux is estimated at each model level. Positive values
400 represent the transport towards the TP, while negative values represent the transport away from

401 the TP. It is evident that BC is imported into the TP during the day and night on the west of
402 $\sim 85^\circ\text{E}$, although the transport flux is much larger during the daytime than nighttime. On the
403 east of $\sim 85^\circ\text{E}$, BC is imported into the TP during the day but exported slightly from the TP
404 during the night. The difference of transport flux between on the west and east of $\sim 85^\circ\text{E}$ is
405 primarily due to the influence of large-scale westerly that is relatively weak on the east of
406 $\sim 85^\circ\text{E}$ compared with the west (Fig. 5). If removing the mean flux during the simulation period,
407 the transport flux anomalies show evident diurnal variation between the day and night (Fig. S3
408 in the supporting material). This suggests that on average, the large-scale westerly is one of the
409 key mechanisms transporting BC across the Himalayas into the TP, while the circulation
410 anomalies strengthen the prevailing import transport during the daytime and weaken the import
411 during the night, particularly in the west of $\sim 85^\circ\text{E}$. The strong transport is primarily within the
412 PBL during the daytime, and the deeper PBL during the daytime allows BC over the source
413 region mixed to higher altitude, which also leads to stronger import transport during the day
414 than the night.

415 The difference between the simulations with two different topography is evident. The
416 mountain ridges are much higher and valleys are much deeper with the complex topography
417 than with the smooth topography. The simulation with smooth topography produces
418 overwhelming crossing-Himalayas transport towards the TP within the PBL, in particular
419 during the daytime. Although, in the simulation with complex topography, the mountain ridges
420 resolved weaken the crossing-Himalayas transport compared to the simulation with smooth
421 topography, the overall positive values near the surface indicate that the transport can overcome
422 most mountain ridges along the Himalayas. The transport fluxes near the surface from the
423 simulation with complex topography become close-to-zero only at a few mountain ridges that
424 are 6.5 km or higher. To better demonstrate the transport pathway across mountain ridges, one
425 cross-section across the mountain ridge as shown as one black solid line in Fig. 3 is taken as
426 one example. Figure 10 shows the latitude-height cross section of BC mass concentration and
427 transport flux across one mountain ridge from the simulations with complex and smooth
428 topography at local time (LT) 03:00 and 15:00 averaged for April 1-20, 2016. Near the southern
429 part of mountain, the elevated concentration of BC mass accumulates and can mix up reaching
430 as high as 5 km with the much stronger transport during the daytime. It is obvious that the
431 mountain ridge in the simulation with smooth topography is quite low. With the high mountain
432 ridge resolved by the complex topography, the simulated BC transport flux can still cross the
433 mountain. Analysis of transport flux across a few more mountain ridges indicates similar
434 results (not shown). The results above indicate that the transport of pollutants can cross a

435 majority of mountain ridges of Himalayas, which is consistent with the observation-based
 436 estimate by Gong et al. (2019) that also found pollutants could overcome the blocking effect
 437 of mountain ridges of Himalayas as a transport pathway. On the other hand, the resolved deeper
 438 valleys in the simulation with complex topography enhance the transport flux compared to the
 439 one with the smooth topography. Similarly, Figure 11 shows one example of latitude-height
 440 cross section of BC mass concentration and transport flux across one valley from the
 441 simulations with complex and smooth topography at local time (LT) 03:00 and 15:00 averaged
 442 for April 1-20, 2016. The transport is much stronger and deeper along the valley from the
 443 simulation with complex topography than the one with smooth topography. Again, analysis of
 444 transport flux across a few more valleys does not show different results (not shown).

445 In order to further demonstrate the overall inflow flux across the Himalayas, the vertically
 446 integrated BC mass flux along the longitudinal cross section (as shown in Fig. 9) from the
 447 simulations with different topography is shown in Figure 12. The terrain heights from the two
 448 simulations along the cross section are also shown as black lines. The total mass flux is
 449 calculated by integrating the right-hand term of equation (1) as following:

$$450 \quad \text{ITF} = \int_{z=z_{sf c}}^{z=z_{top}} \delta z * C * (u * \sin \alpha + v * \sin \beta) \quad (2)$$

451 Where δz is the thickness of each vertical model level. Similarly, positive values represent
 452 the transport towards the TP, while negative values represent the transport away from the TP.
 453 More evidently, the positive BC inflows towards the TP occur not only through the valleys but
 454 also across the mountain ridges with both topography. The negative values only exist to the
 455 east of 88°E. With complex topography, higher mountain ridges can reduce the transport flux
 456 to some extent compared to the smooth topography. The complex topography results in
 457 significantly larger BC inflow towards the TP compared to the smooth topography, particularly
 458 corresponding to the deep valleys, such as the Karnali River Valley around 82°E and the Kali
 459 Gandaki Valley around 84°E.

460 One reason for the enhanced transport across the Himalayas with the complex topography
 461 is the resolved deeper valleys that lead to the increased valley wind. The wind across the valleys
 462 can be significantly larger with the complex topography than the smooth one (Fig. S4). The
 463 enhanced valley wind across the Himalayas has also been found by previous studies with
 464 observations and numerical simulations (Egger et al., 2000; Zängl et al., 2001; Carrera et al.,
 465 2009; Karki et al., 2017; Lin et al., 2018). The second impact of resolved complex topography
 466 on the BC transport is that more BC masses can be transported with the deeper valley channels
 467 (Fig. S5a, b). With deeper valley, the column of high-concentration BC is deeper. Even with

468 similar wind velocity, the transport flux can be larger. The third impact is through changing
469 the small-scale circulation around the Himalayas due to the increase of topography complexity
470 of Himalayas. The simulation with complex topography produces more near-surface winds
471 following the direction towards the TP compared to the one with smooth topography (Fig. S6),
472 which favors the BC transport across the Himalayas. Lastly, the simulated PBL heights from
473 the two experiments are a little different (Fig. 9), which may also contribute partly to the
474 different transport flux. The sensitivity of PBL height and structure to topography complexity
475 that can result in different surface heat has been studied before (e.g., Wagner et al., 2014).

476 This turns out that the overall BC inflow with the complex topography is much stronger
477 than that with the smooth topography. Figure 13 shows the accumulated integrated total
478 transport flux of BC across the Himalayas estimated from the simulations with complex and
479 smooth topography for April 1-20, 2016. The accumulated import flux of BC increases during
480 the period in both experiments, and the difference between the two experiments gradually
481 increases with the time. At the end of period, the simulation with complex topography estimates
482 a total import flux of BC of $\sim 1.5 \times 10^4$ Ton that is $\sim 50\%$ higher than $\sim 1.0 \times 10^4$ Ton estimated
483 based on the simulation with smooth topography. The sensitivity analysis by moving the cross
484 line (cross-section of the analysis in Fig. 9, 12, 13) towards or away from the TP within a
485 certain distance and re-calculating the flux indicates that the impacts of topography on the
486 simulated results do not change significantly.

487 All the analysis above focuses on investigating the BC transport flux across the Himalayas.
488 Although the inflow can reflect the impact of transport on the BC mass over the TP to some
489 extent, the change of BC mass concentration is eventually determined by the convergence of
490 transport. Therefore, the contribution of each model process (transport, dry-deposition,
491 emission, PBL mixing, and wet deposition) to the increase of BC column mass averaged over
492 the TP (with elevation > 4 km) during this episode is analyzed for both simulations following
493 the methodology introduced by Du et al. (2020). The results show that the two main processes
494 affecting the BC column mass over the TP during the period are transport and dry deposition.
495 The transport is the dominant process that increases the BC column mass over the TP, while
496 the dry deposition reduces it. The contribution of transport to the increase of BC column mass
497 over the TP during the episode from the simulation with complex topography is significantly
498 larger than that with the smooth topography, which is consistent with the results shown by
499 analyzing the transport flux across the Himalayas.

500

501 **3.3 Radiative forcing of BC over the TP**

502 The BC transported over the TP could significantly influence the regional climate and
503 water resources over Asia through heating the atmosphere and accelerating the melting of snow
504 and glacier (e.g., Qian et al., 2011, 2015; Lau et al., 2017). Therefore, the impact of the complex
505 topography on estimating the BC radiative heating profile in the atmosphere and radiative
506 forcing in surface snow deserves investigation. Figure 14 shows the vertical profiles of BC
507 induced radiative heating rate in the atmosphere averaged over the TP (with elevation > 4 km)
508 within the inner domain shown in Fig.1 for April 1-20, 2016 from the simulations with complex
509 and smooth topography. Both simulations generate higher BC heating rate near the surface and
510 the rate gradually decreases with altitude, which is consistent with the vertical profiles of BC
511 mass concentration averaged over the TP (Fig. S7 in the supporting material). The BC heating
512 rate over the TP from the simulation with complex topography is ~0.17 K/day near the surface
513 and reduces to ~0.08 K/day at 8 km, which is ~50% and ~30%, respectively, higher than that
514 from the simulation with smooth topography at the corresponding altitudes. The higher BC
515 heating rate over the TP estimated by the simulation with complex topography is consistent
516 with its higher BC column mass (Fig. 5) and concentration profile (Fig. S7).

517 The BC radiative forcing in surface snow is controlled by both the distributions of BC
518 mass concentration and snow coverage (e.g., Zhao et al., 2014). Figure 15 shows the spatial
519 distributions of snow water equivalent (SWE) averaged for April 1-20, 2016 from the
520 simulations with two topography. The difference between the two is also shown. It shows that
521 the simulation with complex topography generates more areas with higher SWE compared to
522 that with the smooth topography over the TP. Along the Himalayas, the simulated SWE is
523 higher over the mountain ridges with the complex topography, particularly for the East
524 Himalayas, while the smooth topography leads to broader snow coverage over the West
525 Himalayas. The difference in SWE between the two simulations is highly correlated with their
526 difference in precipitation (Fig. S8 in the supporting material). Along the Himalayas, the
527 simulated precipitation with the complex topography is larger than that with the smooth
528 topography at the mountain ridges and smaller at the valleys. Over the TP, the overall
529 precipitation is larger with the complex topography than that with the smooth topography (Fig.
530 S8). Previous studies have found that the topography could significantly affect the precipitation
531 over the Himalayas region (e.g., Bookhagen and Burbank, 2010; Wulf et al., 2016; Cannon et
532 al., 2017; Karki et al., 2017).

533 Figure 16 shows the spatial distributions of BC radiative forcing in the surface snow over
534 the TP averaged for April 1-20, 2016 from the simulations with two topography, and the

535 difference between the two is also shown. The BC radiative forcing in surface snow is largely
536 coincident with the spatial distributions of SWE as shown in Fig. 15, mainly due to the
537 heterogeneous distributions of snow cover over the TP. The BC radiative forcing in surface
538 snow over the TP from the simulation with complex topography reaches 5 W/m^2 where the
539 snow exists, larger than that with the smooth topography. Along the Himalayas, the simulation
540 with complex topography produces higher BC snow forcing over the mountain ridges,
541 particularly over the eastern Himalayas, while the one with the smooth topography simulates
542 higher BC snow forcing over most areas of western Himalayas due to its broader snow
543 coverage there. Overall, the complex topography leads to higher BC forcing in snow over the
544 TP and the eastern Himalayas and lower BC forcing in snow over the western Himalayas, and
545 therefore results in the different distribution of BC forcing in snow over the TP and Himalayas,
546 compared to that with the smooth topography.

547

548 **4. Summary and discussion**

549 In this study, the model experiments with different topography are conducted to illustrate
550 the impacts of complexity of topography of Himalayas on BC transport from South Asia to the
551 TP. The observed pollution episode at the QOMS station besides the Mt. Everest during the
552 pre-monsoon season is simulated. The observed surface BC concentration shows a peak of ~ 3
553 ug/m^3 much larger than the background value of $< 0.4 \text{ ug/m}^3$ over the TP. The observed
554 temporal variation of surface BC concentrations correlates highly with that of biomass burning
555 emissions near the southern Himalayas, indicating the significant impacts of biomass burning
556 on the pollutants over the TP. The simulations can reproduce the episode in time and magnitude,
557 and are used to investigate the BC transport mechanisms and the impacts of topography.

558 The high BC mass loading during the simulation period accumulates near the southern
559 Himalayas driven by the large-scale circulation, which is also observed by satellites. The
560 modeling results demonstrate that the westerly favors the accumulation of pollutants near the
561 southern Himalayas and can carry the pollutants to the TP during the day and night, which is
562 consistent with previous modeling studies (e.g., Kopacz et al., 2011). The transport is stronger
563 across the West Himalayas than that across the East. The deeper PBL during the daytime allows
564 BC over the source region mixed to higher altitude, which also leads to stronger import
565 transport during the day than the night. It is noteworthy that the BC accumulated near the
566 southern Himalayas can be transported across the Himalayas overcoming a majority of
567 mountain ridges, which is consistent with the observation-based estimate by Gong et al. (2019)

568 that also found pollutants could overcome the blocking effect of the mountain ridges of
569 Himalayas. However, the transport through the valleys is found much stronger and more
570 efficient than across the mountain ridges and the enhancement effect cannot be ignored. The
571 complex topography results in 50% higher overall transport flux across the Himalayas during
572 the simulation period than that with the smooth topography, primarily due to the enhanced
573 valley wind, deeper valley channels, and induced small-scale favorable circulation. This turns
574 out that the simulation with complex topography produces 30-50% higher BC radiative heating
575 rate in the atmosphere up to 10 km averaged over the TP than does the simulation with smooth
576 topography.

577 Previous studies also found the induced change of circulation and transport due to the
578 complex topography at convection-permitting scales with the focus on the meteorological
579 fields (e.g., Karki et al., 2017; Lin et al., 2018). However, most of them conducted the sub-10
580 km simulations over a much smaller region (e.g., 101×96 grids at 5 km in Karki et al., 2017,
581 and 181×121 grids at 2 km in Lin et al., 2018) compared to this study (400×300 grids at 4 km).
582 Karki et al. (2017) found that the complex topography resolving more valleys and mountain
583 ridges yielded more realistic strong and narrower winds and also small-scale mountain-valley
584 circulations over the Himalayas region compared to the smoother topography. Lin et al. (2018)
585 analyzed the simulations over the region situated in the central Himalayas (87°E-89°E) with
586 very complex terrain including several high mountains and low valleys, e.g., Mt. Everest, Mt.
587 Kanchenjunga, and the Yadong Valley. Although Lin et al. (2018) simulated enhanced
588 moisture flux along the valley, the overall moisture transported was lower with the complex
589 topography (10 km resolution) compared to that with the smooth topography (30 km
590 resolution). The difference between their study and this study can be due to several factors.
591 First, Lin et al. (2018) focused on a relatively small region of Himalayas (87°E-89°E) compared
592 to that in this study (75°E-92°E). The lower-level transport flux simulated in this study also
593 exhibits weaker wind with complex topography between 87°E and 89°E (Fig. 9 and 12), maybe
594 due to several very high mountains such as Mt. Everest and Mt. Kanchenjunga over this area.
595 Second, the spatial (horizontal and vertical) distributions between air pollutants and moisture
596 are also different and may contribute partly to the different impacts of topography on the overall
597 transport flux across the Himalayas.

598 For the BC radiative forcing in surface snow, the simulation with complex topography
599 produces stronger forcing over the TP than that with the smooth one. The complex topography
600 makes the distribution of BC forcing in surface snow quite different from the simulation with

601 smooth topography, partly due to its different distribution of surface snow. The simulated BC
602 radiative forcing in snow is distributed more heterogeneously than those in previous studies
603 using global models at relatively coarse resolutions (e.g., Qian et al., 2011). He et al. (2014)
604 used a global chemical transport model to simulate the BC forcing in snow at the horizontal
605 resolution of $\sim 0.2^\circ$ and obtained the similar distribution as the simulation with smooth
606 topography in this study with the high values over the western Himalayas. However, their
607 simulated values near the Himalayas are higher than the simulated results of this study, which
608 may be due to their estimation are averaged for November-April.

609 This study highlights the importance of resolving complex topography of the Himalayas
610 in modeling the aerosol transport across the Himalayas and radiative impact over the TP.
611 Although this study focuses on the impacts of topography on the simulated results, the
612 additional analysis (Fig. S9-11 in the supporting material) of the outer domain simulation at 20
613 km resolution and the inner domain simulation at 4 km with different topography indicates that
614 the resolution-dependent difference between 20 km and 4 km is largely contributed by their
615 different representations of topography over the Himalayas region, consistent with previous
616 studies (e.g., Karki et al., 2017; Lin et al., 2018). Climate models at coarser horizontal
617 resolutions than 20 km and thus with relatively smooth topography may underestimate the
618 aerosol transport from South Asia to the TP during the pre-monsoon season and represent
619 inappropriately the aerosol radiative forcing in the atmosphere and surface snow over the TP.
620 Since this study only demonstrates the potential impacts for a relatively short period, a longer-
621 term study should be conducted to examine the impacts of topography on aerosol climatic
622 effect over the TP. In addition, the active convection during the monsoon season may also play
623 an important role on pollutant transport across the Himalayas, which deserves further
624 investigation. Furthermore, aerosol impact on cloud and precipitation, particularly during the
625 monsoon season, and thus on the latent heat in the atmosphere and the associated responses
626 may also depend on the complex topography. Previous studies based on observations found
627 that the rain frequency and intensity reached the highest and the cloud thickness reached the
628 deepest at the foothill of Himalayas and decreased as the elevation increased up to the TP (e.g.,
629 Chen et al., 2017; Fu et al., 2018; Zhang et al., 2018), which was explained by Fu et al. (2018)
630 due to the blocking of the air flow by the steep slope of southern Himalayas. However, the
631 large amount of transported aerosol along the slope from the foothill up to the TP may also
632 play a role. These potential impacts of aerosols on regional hydro-climate around the TP and
633 over Asia using high-resolution model that can resolve the complex topography of Himalayas
634 and TP deserve further investigation.

635 **Data availability**

636 The released version of WRF-Chem can be downloaded from
637 http://www2.mmm.ucar.edu/wrf/users/download/get_source.html. The updated USTC
638 version of WRF-Chem can be downloaded from <http://aemol.ustc.edu.cn/product/list/> or
639 contact chunzhao@ustc.edu.cn. Also, the code modifications will be incorporated the release
640 version of WRF-Chem in future.

641

642 **Author contributions**

643 Meixin Zhang and Chun Zhao designed the experiments, conducted and analyzed the
644 simulations. All authors contributed to the discussion and final version of the paper.
