27 **Abstract:**

28 Air pollution by particulate matter in China affects human health, the ecosystem and the climate.  
29 However, the chemical composition of particulate aerosol, especially of the organic fraction, is still  
30 not well understood. In this study, particulate aerosol samples with a diameter of  $\leq 2.5 \mu\text{m}$  ( $\text{PM}_{2.5}$ )  
31 were collected in January 2014 in three cities located in Northeast, East and Southeast China,  
32 namely Changchun, Shanghai and Guangzhou. Organic aerosol (OA) in the  $\text{PM}_{2.5}$  samples was  
33 analyzed by ultrahigh performance liquid chromatography (UHPLC) coupled to high-resolution  
34 Orbitrap mass spectrometry in both negative mode (ESI<sup>-</sup>) and positive mode electrospray  
35 ionization (ESI<sup>+</sup>). After non-target screening including the assignment of molecular formulas, the  
36 compounds were classified into five groups based on their elemental composition, i.e., CHO,  
37 CHON, CHN, CHOS and CHONS. The CHO, CHON and CHN groups present the dominant signal  
38 abundances of 81–99.7% in the mass spectra and the majority of these compounds were assigned  
39 to mono- and polyaromatics, suggesting that anthropogenic emissions are a major source of urban  
40 OA in all three cities. However, the chemical characteristics of these compounds varied between  
41 the different cities. The degree of aromaticity and the number of polyaromatic compounds were  
42 substantially higher in samples from Changchun, which could be attributed to the large emissions  
43 from residential heating (i.e. coal combustion) during winter time in Northeast China. Moreover,  
44 the ESI<sup>-</sup> analysis showed higher H/C and O/C ratios for organic compounds in Shanghai and  
45 Guangzhou compared to samples from Changchun, indicating that OA undergoes more intense  
46 photochemical oxidation processes in lower latitude regions of China and/or is affected to a larger  
47 degree by biogenic sources. The majority of sulfur-containing compounds (CHOS and CHONS) in  
48 all cities were assigned to aliphatic compounds with low degrees of unsaturation and aromaticity.  
49 Here again, samples from Shanghai and Guangzhou show a greater chemical similarity but differ  
50 largely from those from Changchun. It should be noted that the conclusions drawn in this study are  
51 mainly based on comparison of molecular formulas weighted by peak abundance, and thus, are  
52 associated with inherent uncertainties due to different ionization efficiencies for different organic  
53 species.

54 **1. Introduction**

55 In the last decades, China has experienced rapid industrialization and urbanization accompanied by  
56 severe and persistent particulate air pollution (Huang et al., 2014; Sun et al., 2014; Ding et al., 2016;  
57 Song et al., 2018; Shi et al., 2019; Xu et al., 2019). These particulate air pollution extremes can not  
58 only influence the regional air quality and human health in China, but also lead to a global

59 environmental problem due to long-distance transport of pollutants. To better understand the effects  
60 of air pollution on air quality and human health, chemical characterization of fine particle  
61 (particulate matter with an aerodynamic diameter of less than 2.5  $\mu\text{m}$ , or  $\text{PM}_{2.5}$ ) is crucial. However,  
62 the chemical composition of  $\text{PM}_{2.5}$  in China is still poorly understood due to a wide variety of  
63 natural and anthropogenic sources as well as complex multiphase chemical reactions (Lin et al.,  
64 2012a; Huang et al., 2014; Ding et al., 2016; Wang et al., 2017; Wang et al., 2018; An et al., 2019;  
65 Tong et al., 2019; Wang et al., 2019a; Wang et al., 2019b). In particular, compared to the fairly  
66 well understood nature of the inorganic fraction of aerosol, the organic fraction, also named organic  
67 aerosol (OA), is considerably less understood in terms of chemical composition, corresponding  
68 precursors, sources and formation mechanisms (Huang et al., 2017).

69 During pollution events in China, OA accounts for as high as more than 50% of the total mass of  
70 fine particle (An et al., 2019). Chemical compounds in OA cover a large complexity of species  
71 including alcohols, aldehydes, carboxylic acids, imidazoles, organosulfates, organonitrates and  
72 polycyclic aromatic hydrocarbons (PAHs) (Lin et al., 2012a; Rincón et al., 2012; Kourtchev et al.,  
73 2014; Wang et al., 2018; Elzein et al., 2019; Wang et al., 2019a). Thus, the capacity of traditional  
74 analytical techniques is limited to identify the compounds in OA and the majority (> 70%) of OA  
75 has not been identified yet as specific compounds (Hoffmann et al., 2011). The insufficient  
76 knowledge of chemical composition of OA hinders a better understanding of the sources, formation  
77 and atmospheric processes of air pollution in China.

78 Recently, ultrahigh resolution mass spectrometry (UHRMS), such as Fourier transform ion  
79 cyclotron resonance mass spectrometry (FTICR-MS) and Orbitrap-MS, coupled with soft  
80 ionization sources (e.g., electrospray ionization (ESI) and atmospheric pressure chemical ionization  
81 (APCI)) have been introduced to elucidate the molecular composition of OA (Nizkorodov et al.,  
82 2011; Lin et al., 2012a; Lin et al., 2012b; Rincón et al., 2012; Noziere et al., 2015; Kourtchev et al.,  
83 2016; Tong et al., 2016; Tu et al., 2016; Brüggemann et al., 2017; Wang et al., 2017; Fleming et  
84 al., 2018; Laskin et al., 2018; Song et al., 2018; Wang et al., 2018; Brüggemann et al., 2019;  
85 Daellenbach et al., 2019; Ning et al., 2019; Wang et al., 2019a). Due to the two outstanding features  
86 of high resolving power and high mass accuracy, UHRMS can give precise elemental compositions  
87 of individual organic compounds. However, UHRMS studies on Chinese urban OA are very limited.  
88 Wang et al. (Wang et al., 2017) characterized OA in Shanghai and showed variations in chemical  
89 composition among different months and between daytime and nighttime. Our recent Orbitrap MS  
90 study (Wang et al., 2018) showed that wintertime OA in  $\text{PM}_{2.5}$  collected in Beijing, China and  
91 Mainz, Germany were very different in terms of chemical composition. In contrast, for summertime

92 OA from Germany and China, Brüggemann et al. (2019) found similar compounds and  
93 concentrations of terpenoid organosulfates in PM<sub>10</sub>, demonstrating that biogenic emission can  
94 significantly affect OA composition at both locations. Ning et al. (2019) analyzed the OA collected  
95 in a coastal Chinese city (Dalian) and found that more organic compounds were identified in haze  
96 days compared to non-haze days. Nonetheless, since severe particulate pollution in China occurs  
97 on a large-scale, more UHRMS studies are needed to fully elucidate the chemical composition of  
98 OA in different Chinese cities.

99 In this study, PM<sub>2.5</sub> aerosol samples were collected in three Chinese cities, i.e., Changchun,  
100 Shanghai and Guangzhou, and their organic fraction was analyzed using ultra-high-performance  
101 liquid chromatography (UHPLC) coupled with Orbitrap-MS. The Chinese cities of Changchun,  
102 Shanghai and Guangzhou are located in the Northeast, East and Southeast of China, which are  
103 major populated regions in China with a population of 7.5, 24 and 15 million, respectively. The  
104 geographic locations of these three cities cover a large latitude spanning from 23.12°N to 43.53°N  
105 resulting in different meteorological conditions, including intensity and duration of sunlight,  
106 average daily temperature and monsoon climate. In addition, the industrial structure, energy  
107 consumption and energy sources in these three cities are different, such as much more heavy  
108 industries (e.g., coal chemical industry and steelworks) in Northeast China (Zhang, 2008), which  
109 can cause difference in anthropogenic emissions, and can therefore influence the chemical  
110 composition of urban OA. Moreover, OA is strongly affected by residential coal combustion during  
111 winter in Northeast China (Huang et al., 2014; An et al., 2019). Therefore, this study presents a  
112 comprehensive overview of chemical composition of OA in three representative Chinese cities  
113 during pollution episodes, which eventually can improve our understanding of OA effects on  
114 climate and public health and also provide a chemical database for haze mitigation strategies in  
115 China.

## 116 **2. Experimental**

### 117 **2.1 PM<sub>2.5</sub> samples**

118 Three 24-h integrated urban PM<sub>2.5</sub> samples were collected during severe haze pollution events with  
119 daily average PM<sub>2.5</sub> mass concentration higher than 115 µg m<sup>-3</sup> in each of the three Chinese cities:  
120 Changchun (43.54° N, 125.13° E, 1.5 m above the ground), Shanghai (31.30° N, 121.50° E, 20 m  
121 above the ground) and Guangzhou (23.07° N, 113.21° E, 53 m above the ground), which are located  
122 in the Northeast, East and Southeast regions of China, respectively (see Fig. 1). Samples in  
123 Changchun were collected on 4, 24 and 29 of January 2014 with PM<sub>2.5</sub> mass concentrations of

124 185–222  $\mu\text{g m}^{-3}$ , samples in Shanghai were collected on 1, 19 and 20 of January 2014 with  $\text{PM}_{2.5}$   
125 mass concentrations of 159–172  $\mu\text{g m}^{-3}$  and samples in Guangzhou were collected on 5, 6 and 11  
126 of January 2014 with  $\text{PM}_{2.5}$  mass concentrations of 138–152  $\mu\text{g m}^{-3}$ . Further details (e.g., the daily  
127 average concentrations of  $\text{PM}_{2.5}$ ,  $\text{SO}_2$ ,  $\text{NO}_2$ ,  $\text{CO}$  and  $\text{O}_3$ , the average temperature and the daily solar  
128 radiation value during sampling dates) are presented in Table S1, the 48 hours back trajectories of  
129 air arriving at the three sampling sites during the sampling periods are shown in Fig. S1. All  $\text{PM}_{2.5}$   
130 samples were collected on prebaked quartz-fiber filters (20.3×25.4 cm) using a high-volume  $\text{PM}_{2.5}$   
131 sampler at a flow rate of 1.05  $\text{m}^3 \text{min}^{-1}$  (Tisch Environmental, USA) and at each sampling site field  
132 blanks were taken. After sample collection, filters were stored at  $-20\text{ }^\circ\text{C}$  until analysis.

## 133 **2.2 Sample analysis**

134 Detailed description on the filter sample extraction and UHPLC–Orbitrap MS analysis can be found  
135 in our previous studies (Wang et al., 2018; Wang et al., 2019a). Briefly, a part of the filters (around  
136 1.13  $\text{cm}^2$ , corresponding to about 600  $\mu\text{g}$  particle mass in each extracted filter) was extracted three  
137 times with 1.0–1.5 mL of acetonitrile-water (8/2, v/v) in an ultrasonic bath. The extracts were  
138 combined, filtered through a 0.2  $\mu\text{m}$  Teflon syringe filter and evaporated to almost dryness under  
139 a gentle nitrogen stream. Finally, the residue was redissolved in 1000  $\mu\text{L}$  acetonitrile-water (1/9,  
140 v/v) to reach the total particulate mass concentration of around 600  $\mu\text{g mL}^{-1}$  for the following  
141 analysis.

142 Compared to the direct infusion method applied in other UHRMS studies (Lin et al., 2012a; Lin et  
143 al., 2012b; Rincón et al., 2012; Kourtchev et al., 2016; Fleming et al., 2018), the UHPLC technique  
144 was used in this study, which could separate and concentrate the compounds before they entered  
145 the ion source, reducing the ionization suppression and increasing the sensitive of the measurement.  
146 In addition, it can provide separation of some compounds and information of retention time of the  
147 compounds, which is useful for the identification of the compounds and the separation of isomers.  
148 The analytes were separated using a Hypersil Gold column (C18, 50 x 2.0 mm, 1.9  $\mu\text{m}$  particle size)  
149 with mobile phases consisting of (A) 0.04% formic acid and 2% acetonitrile in MilliQ water and  
150 (B) 2% water in acetonitrile. Gradient elution was applied with the A and B mixture at a flow rate  
151 of 500  $\mu\text{L min}^{-1}$  as follows: 0–1.5 min 2% B, 1.5–2.5 min from 2% to 20% B (linear), 2.5–5.5 min  
152 20% B, 5.5–6.5 min from 20% to 30% B (linear), 6.5–7.5 min from 30% to 50% B (linear), 7.5–8.5  
153 min from 50% to 98% B (linear), 8.5–11.0 min 98% B, 11.0–11.05 min from 98% to 2% B (linear),  
154 and 11.05–11.1 min 2% B. The Q Exactive Hybrid Quadrupole-Orbitrap MS was equipped with a  
155 heated ESI source at 120  $^\circ\text{C}$ , applying a spray voltage of  $-3.3\text{ kV}$  and 4.0 kV for negative ESI mode

156 (ESI<sup>-</sup>) and positive ESI mode (ESI<sup>+</sup>), respectively. The mass scanning range was set from m/z 50  
157 to 500 with a resolving power of 70,000 @ m/z 200. The Orbitrap MS was externally calibrated  
158 before each measurement sequence using an Ultramark 1621 solution (Sigma–Aldrich, Germany)  
159 providing mass accuracy of the instrument lower than 3 ppm. Each sample was measured in  
160 triplicate with an injection volume of 10  $\mu$ L.

### 161 **2.3 Data processing**

162 A non-target peak picking software (SIEVE<sup>®</sup>, Thermo Fisher Scientific, Germany) was used to find  
163 significant peaks in the LC-MS dataset and to calculate all mathematically possible chemical  
164 formulas for ions signals with a sample-to-blank abundance ratio  $\geq 10$  using a mass tolerance of  $\pm$   
165 2 ppm. The permitted maximum elemental number of atoms was set as follows: <sup>12</sup>C (39), <sup>1</sup>H (72),  
166 <sup>16</sup>O (20), <sup>14</sup>N (7), <sup>32</sup>S (4), <sup>35</sup>Cl (2) and <sup>23</sup>Na (1) (Kind and Fiehn, 2007; Lin et al., 2012a; Wang et  
167 al., 2018). To remove the chemically unreasonable formulas, further constraint was applied by  
168 setting H/C, O/C, N/C, S/C and Cl/C ratios in the ranges of 0.3–3, 0–3, 0–1.3, 0–0.8 and 0–0.8  
169 (Kind and Fiehn, 2007; Lin et al., 2012a; Rincón et al., 2012; Wang et al., 2018; Zielinski et al.,  
170 2018), respectively. For chemical formula C<sub>c</sub>H<sub>h</sub>O<sub>o</sub>N<sub>n</sub>S<sub>s</sub>Cl<sub>x</sub>, the double bond equivalent (DBE) was  
171 calculated by the equation:  $DBE = (2c + 2 - h - x + n) / 2$ . The aromaticity equivalent ( $X_C$ ) as a  
172 modified index for aromatic compounds was obtained using the equation:  $X_C = [3(DBE - (p \times o +$   
173  $q \times n)) - 2] / [DBE - (p \times o + q \times n)]$ , where p and q, respectively, refer to the fraction of oxygen  
174 and sulfur atoms involved in the  $\pi$ -bond structure of a compound. As such the values of p and q  
175 vary between compound categories (Yassine et al., 2014). For example, carboxylic acids and esters  
176 are characterized using p = q = 0.5, while p = q = 1 and p = q = 0 are used for carbonyl and hydroxyl,  
177 respectively. Since it is impossible to identify the structures of the hundreds of formulas observed  
178 in this study, we cannot know the exact values of p and q in an individual compound. Therefore, in  
179 this study, p = q = 0.5 was applied for compounds detected in ESI<sup>-</sup> as carboxylic compounds are  
180 preferably ionized in negative mode. However, because of the high complexity of the mass spectra  
181 in ESI<sup>+</sup>, p = q = 1 was used in ESI<sup>+</sup> to avoid an overestimation of the amount of aromatics.  
182 Moreover, for  $DBE \leq (p \times o + q \times n)$  or  $X_C \leq 0$ ,  $X_C$  was defined as zero. Furthermore, in ESI<sup>-</sup>, for  
183 odd numbers of (p  $\times$  o + q  $\times$  n), the value of (p  $\times$  o + q  $\times$  n) was rounded down to the lower integer.  
184  $X_C \geq 2.50$  and  $X_C \geq 2.71$  have been suggested as unambiguous minimum criteria for the presence  
185 of monoaromatics and polyaromatics, respectively (Yassine et al., 2014).

186 Comparing the peak abundance has been used in recent UHRMS studies (Wang et al., 2017;  
187 Fleming et al., 2018; Song et al., 2018; Ning et al., 2019) to illustrate the relative importance of

188 specific types of compounds. However, it should be noted that different organic compounds have  
189 different signal response in the mass spectrometer due to the differences in ionization and  
190 transmission efficiencies (Schmidt et al., 2006; Leito et al., 2008; Perry et al., 2008; Krueve et al.,  
191 2014). Therefore, uncertainties may exist when comparing the peak areas among compounds. In  
192 this work, we assume that all organic compounds have the same peak abundance response in the  
193 mass spectrometer. The peak abundance-weighted average molecular mass (MM), elemental ratios,  
194 DBE, and Xc for formula  $C_cH_hO_oN_nS_sCl_x$  were calculated using following equations:

$$195 \text{MM}_{\text{avg}} = \sum (\text{MM}_i \times A_i) / \sum A_i$$

$$196 \text{O/C}_{\text{avg}} = \sum (\text{O/C}_i \times A_i) / \sum A_i$$

$$197 \text{H/C}_{\text{avg}} = \sum (\text{H/C}_i \times A_i) / \sum A_i$$

$$198 \text{DBE}_{\text{avg}} = \sum (\text{DBE}_i \times A_i) / \sum A_i$$

$$199 \text{Xc}_{\text{avg}} = \sum (\text{Xc}_i \times A_i) / \sum A_i$$

200 where  $A_i$  is the peak abundance for each individual compound  $i$ .

### 201 **3. Results and discussion**

#### 202 **3.1 General characteristics**

203 The main purpose of this study was to tentatively identify and compare the chemical composition  
204 of organic compounds in the  $\text{PM}_{2.5}$  samples collected in the three Chinese cities: Changchun,  
205 Shanghai and Guangzhou during pollution episodes. To reduce the uncertainty caused by the  
206 variability between the samples collected at each location, only organic compounds measured in  
207 all three samples of each city are used for intercity comparison in this study. The number of organic  
208 compounds and molecular formulas detected in each city, the peak abundance-weighted average  
209 values of molecular mass ( $\text{MM}_{\text{avg}}$ ), elemental ratios, DBE, Xc and the isomer number fraction  
210 (meaning the percentage of formula numbers that have isomers among all assigned formulas) for  
211 each subgroup are listed in Table 1. It should be noted that in this study we focus solely on organic  
212 compounds with elevated signal abundances, and thus, presumably rather high concentrations. In  
213 contrast to our previous study (Wang et al., 2018), compounds with low concentrations were  
214 excluded by increasing the reconstitution volume from 500  $\mu\text{L}$  to 1000  $\mu\text{L}$ , reducing the sample  
215 injection volume from 20  $\mu\text{L}$  to 10  $\mu\text{L}$ , and increasing the sample-to-blank ratio from 3 to 10 during  
216 data processing.

217 Overall, 416–769 (assigned to 272–415 molecular formulas) and 687–2943 (assigned to 383–679  
218 molecular formulas) organic compounds in different samples were determined in ESI<sup>-</sup> and ESI<sup>+</sup>,  
219 respectively. The largest number of organic compounds was observed in Changchun samples in  
220 both ESI<sup>-</sup> and ESI<sup>+</sup>, indicating that OA collected during winter season in Northeast China was  
221 more complex compared to urban OA in East and Southeast China. This increased number of  
222 compounds can possibly be explained by the large residential coal combustion emissions in winter  
223 in North China (Huang et al., 2014; Song et al., 2018; An et al., 2019). In addition, ambient  
224 temperatures were lowest during the sampling period in Changchun (i.e., -14 °C to -9 °C, Table  
225 S1), which likely led to a decreased boundary layer height and therefore enhanced accumulation of  
226 pollutants and enhanced formation of secondary organic aerosol through for example gas-to-  
227 particle partitioning.

228 As shown in Table 1, the abundance-weighted average values of  $MM_{avg}$  and O/C ratio of the total  
229 assigned formulas for Changchun samples detected in negative mode (Changchun<sup>-</sup>) are 169 and  
230 0.58, respectively, which are lower than those for Shanghai<sup>-</sup> ( $MM_{avg} = 176$  and  $O/C = 0.69$ ) and  
231 for Guangzhou<sup>-</sup> ( $MM_{avg} = 183$  and  $O/C = 0.74$ ). On the contrary, the aromaticity equivalent  $X_c$  for  
232 organics detected in Changchun<sup>-</sup>,  $X_c(\text{Changchun}^-) = 2.13$ , is substantially higher than that for  
233 Shanghai<sup>-</sup>,  $X_c(\text{Shanghai}^-) = 1.92$ , and Guangzhou<sup>-</sup>,  $X_c(\text{Guangzhou}^-) = 1.65$ . These observations  
234 indicate that urban OA in Northeast China features a lower degree of oxidation and a higher degree  
235 of aromaticity compared to urban OA in East and Southeast China. Furthermore, the relative peak  
236 abundance fraction of compounds with  $O/C \geq 0.6$ , which are considered as highly oxidized  
237 compounds (Tu et al., 2016), is 31% in Changchun<sup>-</sup>, and higher in Shanghai<sup>-</sup> (46%) and  
238 Guangzhou<sup>-</sup> (51%). The different chemical composition of the samples is probably caused by the  
239 rather low ambient temperatures and decreased photochemical processing of organic compounds  
240 in Northeast China (indicated by the lower solar radiation in Northeast China, see Table S1),  
241 slowing down oxidation processes and leading to a larger number of PAHs, which are mainly  
242 emitted from coal burning (Huang et al., 2014; Song et al., 2018) or by different  
243 biogenic/anthropogenic precursors. In addition, long-range transport of air masses (see the 48 hours  
244 back trajectories in Fig. S1) may have a certain effect on the chemical properties of aerosol samples  
245 collected in the three cities.

246 Figure 1 shows the reconstructed mass spectra of organic compounds detected in ESI<sup>-</sup> and ESI<sup>+</sup>.  
247 A major fraction organic species detected in ESI<sup>-</sup> are attributed to CHO<sup>-</sup> and CHON<sup>-</sup>, accounting  
248 for 30–42% and 39–55% in terms of peak abundance, respectively, and comprising 39–45% and  
249 23–33% in terms of peak numbers, respectively. This is consistent with previous studies on Chinese

250 urban OA by Wang et al. (2017 and 2018) and Brüggemann et al. (2019). Comparing the organic  
251 compounds detected in ESI<sup>-</sup> for the three cities, 120 formulas were observed in all cities as  
252 common formulas (which refer to the compounds detected in all cities with the same molecular  
253 formulas and with the same retention times (retention time difference  $\leq 0.1$  min)) (Fig. 2a),  
254 accounting for 29–44% and 57–71% of all assigned formulas in terms of formula numbers and  
255 peak abundance, respectively. Despite the above-mentioned differences in chemical composition  
256 for OA from Changchun compared to OA from Shanghai and Guangzhou, these results demonstrate  
257 that still a large number of common organic compounds exist in Chinese urban OAs collected in  
258 different cities, in particular for organics with higher signal abundances. Furthermore, as shown by  
259 the pie chart in Fig. 2b, these common formulas are dominated by CHON<sup>-</sup> and CHO<sup>-</sup>, accounting  
260 for 62% and 30% of the total common formulas in terms of peak abundance, respectively.

261 As it is commonly known, ESI exhibits different ionization mechanisms in negative and positive  
262 ionization modes. While ESI<sup>-</sup> is especially sensitive to deprotonatable compounds (e.g., organic  
263 acids), ESI<sup>+</sup> is more sensitive to protonatable compounds (e.g., organic amines) (Ho et al., 2003).  
264 Due to the different ionization mechanisms, clear differences were observed in the mass spectra  
265 (Fig. 1) and chemical characteristics (Table 1) from ESI<sup>-</sup> and ESI<sup>+</sup> measurements. For example,  
266 CHO compounds were preferentially detected in ESI<sup>-</sup>, accounting for a relatively large fraction of  
267 30–42% of all detected compounds in terms of peak abundance, compared to merely 4–13% for  
268 such CHO compounds in ESI<sup>+</sup>. In contrast, CHN compounds were only observed in ESI<sup>+</sup>, yielding  
269 a rather large peak abundance fraction of 40–71%. In particular, as can be seen in Fig.1, several  
270 peaks of CHN<sup>+</sup> compounds in Shanghai<sup>+</sup> and Guangzhou<sup>+</sup> have much higher abundance compared  
271 to other organic species, probably due to their high concentrations and/or high ionization  
272 efficiencies in the positive mode. This observation indicates that most CHO compounds with high  
273 concentrations are probably organic acids, whereas the majority of CHN compounds likely belong  
274 to the group of organic amines, which is in good agreement with previous studies (Lin et al., 2012a;  
275 Wang et al., 2017; Wang et al., 2018). Organic compounds in ESI<sup>+</sup> are dominated by CHN<sup>+</sup> and  
276 CHON<sup>+</sup> compounds in terms of both peak numbers and peak abundance and these compounds are  
277 characterized by rather high H/C ratio and low O/C ratios (Table 1), indicating a low degree of  
278 oxidation. The Venn diagram presented for ESI<sup>+</sup> measurements in Fig. 2a shows that out of a total  
279 of 383–679 formulas, 129 formulas were found in samples from all three cities. Such common  
280 formulas, thus, account for 19–34% and 30–75% of all assigned formulas in terms of formula  
281 numbers and peak abundance, respectively. Among these common formulas, CHN<sup>+</sup> and CHON<sup>+</sup>  
282 exhibit the highest abundance fractions of 72% and 26%, respectively (Fig. 2b).

283 In the following, we will compare and discuss the chemical properties in detail for the three cities,  
284 including degrees of oxidation, unsaturation and aromaticity of each organic compound class (i.e.,  
285 CHO, CHON, CHN, CHOS and CHONS). It should be noted that the chlorine-containing  
286 compounds were not discussed in this study due to the very low MS signal abundance. In addition,  
287 since peak abundances for the formula can vary by orders of magnitude, the area of the circles  
288 presented in the Figure 3 and Figures 5–7 is proportional to the fourth root of the peak abundance  
289 of each formula to reduce the size difference of the circles. For a more detailed comparison, figures  
290 with the circle size related to the absolute peak abundances are presented in the SI.

### 291 **3.2 CHO compounds**

292 CHO compounds have been widely observed in urban OA, accounting for a substantial fraction  
293 (8–67%) of OA (Rincón et al., 2012; Tao et al., 2014; Wang et al., 2017; Wang et al., 2018).  
294 Previous studies have shown that a large fraction of CHO compounds in urban OA is composed of  
295 organic acids, containing deprotonatable carboxyl functional groups, which are detected  
296 preferentially in negative ionization mode when using ESI–MS. As shown in Table 1, a total of  
297 346, 164, and 196 CHO– compounds were detected in ESI– in the OA samples collected in  
298 Changchun, Shanghai and Guangzhou, accounting for 30%, 40% and 42% of the overall peak  
299 abundance in each sample, respectively. Out of all assigned formulas, 47 common CHO– formulas  
300 were observed for all sites, accounting for 35–52% and 42–68% of all identified CHO– formulas  
301 in terms of formula numbers and peak abundance, respectively.

302 Despite this similarity, OA samples from Changchun– (i.e. in negative ionization mode) exhibit  
303 certain differences compared to samples from Shanghai– and Guangzhou–. The average H/C  
304 values for CHO– compounds are in a similar range for the three locations (i.e., 0.96–1.10), however,  
305 the average O/C values for O/C(Shanghai–) = 0.59 and O/C(Guangzhou–) = 0.65 are rather high  
306 compared to the average O/C ratio for Changchun–, O/C(Changchun–) = 0.41. Furthermore, the  
307 relative peak abundance fraction of CHO– compounds with O/C ≥ 0.6, which are considered as  
308 highly oxidized compounds (Tu et al., 2016), is 14% in Changchun and somewhat higher in  
309 Shanghai– (34%) and Guangzhou– (45%). Altogether, these results indicate that CHO– compounds  
310 in urban OA from East and Southeast China experienced more intense oxidation and aging  
311 processes and/or were affected to a larger degree by biogenic sources.

312 Similarly, as shown in Fig. 3, the abundance-weighted average molecular formulas for CHO–  
313 compounds in Changchun–, Shanghai– and Guangzhou– are  $C_{8.58}H_{7.86}O_{3.22}$  ( $MM_{avg}(\text{Changchun–})$   
314 = 162),  $C_{8.01}H_{7.27}O_{4.22}$  ( $MM_{avg}(\text{Shanghai–})$  = 171) and  $C_{7.70}H_{8.04}O_{4.48}$  ( $MM_{avg}(\text{Guangzhou–})$  = 172),

315 respectively. Again, these average formulas show that CHO<sup>-</sup> in Shanghai<sup>-</sup> and Guangzhou<sup>-</sup>  
316 experienced more intense oxidation processes and/or were affected to a larger degree by biogenic  
317 precursors, indicated by the larger abundance-weighted  $MM_{avg}$  with a higher degree of oxygenation.  
318 In contrast, CHO<sup>-</sup> compounds from OA samples in Changchun<sup>-</sup> exhibit a lower abundance-  
319 weighted  $MM_{avg}$  with a decreased oxygen content.

320 Besides oxygenation, the aromaticity of the detected CHO<sup>-</sup> compounds exhibits remarkable  
321 differences in these three cities. In all cities, the CHO<sup>-</sup> compounds with high peak abundance were  
322 mainly assigned to monoaromatics with  $2.5 \leq X_c < 2.7$  (purple circles in Fig. 3) in the region of  
323 7–12 carbon atoms per compound and DBE values of 5–7. The relative peak abundance fraction  
324 of monoaromatics in total CHO<sup>-</sup> compounds is 67% in Changchun, which is higher compared to  
325 64% in Shanghai and 49% in Guangzhou. In addition, 14% of CHO<sup>-</sup> compounds in Changchun  
326 were identified as polyaromatic compounds with  $X_c \geq 2.7$  (red circles in Fig. 3), which is higher  
327 than the 8% in Shanghai and 4% in Guangzhou. These observations indicate that CHO<sup>-</sup> compounds  
328 in the three Chinese cities are highly affected by aromatic precursors (e.g., benzene, toluene and  
329 naphthalene), in particular for the Changchun aerosol samples.

330 Besides the monoaromatics and polyaromatics, the rest of the detected CHO<sup>-</sup> compounds were  
331 assigned to aliphatic compounds with an  $X_c$  lower than 2.5 (grey circles in Fig. 3). Interestingly,  
332 these aliphatic compounds account for about 47% of all CHO<sup>-</sup> compounds for Guangzhou<sup>-</sup>  
333 samples in terms of peak abundance, whereas samples from Changchun<sup>-</sup> and Shanghai<sup>-</sup> exhibit  
334 only rather small fractions of such CHO<sup>-</sup> compounds, i.e., 19% and 28%, respectively. Such  
335 aliphatic compounds are commonly derived from biogenic precursors (Kourtchev et al., 2016) and  
336 vehicle emission (Tao et al., 2014; Wang et al., 2017) and/or generated by intense oxidation  
337 processes of aromatic precursors, indicating the different biogenic and anthropogenic emission  
338 sources and chemical reaction processes for OAs in the three cities.

339 In addition, through the analysis of individual formulas, we find that for the Changchun<sup>-</sup> samples,  
340 formulas of  $C_8H_6O_4$ ,  $C_7H_6O_2$ ,  $C_7H_6O_3$ ,  $C_8H_8O_2$ , and  $C_8H_8O_3$  with DBE values of 6, 5, 5, 5, and 5  
341 dominate the assigned CHO formulas with respect to peak abundance. According to previous  
342 studies,  $C_8H_6O_4$ ,  $C_7H_6O_2$  and  $C_7H_6O_3$  are suggested to be phthalic acid, benzoic acid and  
343 monohydroxy benzoic acid, respectively, which are derived from naphthalene (Kautzman et al.,  
344 2010; Riva et al., 2015; Wang et al., 2017; He et al., 2018; Huang et al., 2019).  $C_8H_8O_2$  is likely 4-  
345 hydroxy acetophenone, which could be derived from estragole (Pereira et al., 2014), while  $C_8H_8O_3$   
346 is suggested to be either 4-methoxybenzoic acid generated from estragole (Pereira et al., 2014) or

347 vanillin emitted from biomass burning (Li et al., 2014). For the Shanghai- samples, besides  $C_8H_6O_4$ ,  
348  $C_7H_6O_3$  and  $C_7H_6O_2$ , formulas of  $C_6H_8O_7$  and  $C_9H_8O_4$  with DBE values of 3 and 6 were observed  
349 with high peak abundances.  $C_6H_8O_7$  was identified as citric acid in the pollen sample and mountain  
350 particle sample in previous studies (Fu et al., 2008; Wang et al., 2009; Jung and Kawamura, 2011),  
351 and  $C_9H_8O_4$  are probably homophthalic acid derived from e.g. estragole (Pereira et al., 2014). For  
352 the Guangzhou- samples, besides the formulas of  $C_8H_6O_4$  and  $C_6H_8O_7$  discussed above,  $C_4H_6O_4$   
353 and  $C_4H_6O_5$  with low DBE values of two were detected with high abundances and are suggested to  
354 be succinic acid and malic acid, respectively (Claeys et al., 2004; Wang et al., 2017).

### 355 3.3 CHON compounds

356 A large amount of nitrogen-containing organic compounds was detected in these three cities,  
357 accounting for 39–55% and 25–47% of total peak abundance detected in ESI- and ESI+,  
358 respectively. Out of all assigned formulas, 45 common CHON- and 62 common CHON+ formulas  
359 were observed in all cities, accounting for 65–82% and 25–44% of all CHON compounds detected  
360 in ESI- and ESI+ in terms of peak abundance, respectively. It indicates that a large amount of  
361 CHON compounds in all three Chinese cities show similar properties of chemical composition.

362 The CHON compounds were further classified into different subgroups according to their O/N  
363 ratios (Fig. 4 for CHON- and Fig. S3 for CHON+) or according to the number of nitrogen atoms  
364 in their molecular formulas (see Fig. S4 for CHON- and S5 for CHON+). As shown in Fig. 4, the  
365 majority (84–96% in terms of peak abundance) of CHON- compounds exhibited O/N ratios  $\geq 3$ ,  
366 allowing the assignment of one nitro ( $-NO_2$ ) or nitrooxy ( $-ONO_2$ ) group for these formulas, which  
367 are preferentially ionized in ESI- mode (Lin et al., 2012b; Wang et al., 2017; Song et al., 2018;  
368 Wang et al., 2018). CHON- formulas with O/N ratios  $\geq 4$  suggest the presence of further  
369 oxygenated functional groups, such as a hydroxyl group ( $-OH$ ) or a carbonyl group ( $C=O$ ). In  
370 terms of peak abundance, 59% of CHON- compounds observed in Guangzhou- exhibited formulas  
371 with O/N ratios  $\geq 4$ , which is higher than 51% in Changchun- and 45% in Shanghai-, indicating  
372 that CHON- compounds in Southeast China show a higher degree of oxidation compared to those  
373 in Northeast and East China. Not surprisingly, CHON+ compounds generally exhibit lower O/N  
374 ratios (Fig. S3), as they probably contain reduced nitrogen functional group (e.g., amines) which  
375 are preferably detected in ESI+. As shown in Fig. S3, CHON+ compounds with O/N ratio of 1 are  
376 dominant in Changchun+, whereas CHON+ compounds in Shanghai+ and Guangzhou+ show a  
377 broader range of O/N ratios from 1 to 3. Moreover, the average O/C ratios (0.27–0.45) in Shanghai+  
378 and Guangzhou+ (Table 1) are much greater than that (0.19) in Changchun+. Consistent with the

379 observations for CHO compounds, these results indicate again that CHON<sup>+</sup> compounds in the OA  
380 of East and Southeast China experienced more intensive photooxidation and/or were affected to a  
381 larger degree by biogenic precursors.

382 Figure 5 shows the DBE versus C number of CHON<sup>-</sup> compounds for the three cities. The majority  
383 of CHON<sup>-</sup> compounds lie in the region of 5–15 C atoms and 3–10 DBEs. 67% of CHON<sup>-</sup>  
384 compounds in terms of peak abundance were assigned to mono or polyaromatics in Shanghai<sup>-</sup>,  
385 which is higher than 52% in Guangzhou<sup>-</sup> and 55% in Changchun<sup>-</sup>. It indicates that CHON<sup>-</sup>  
386 compounds are dominated with aromatic compounds in all cities, while relatively higher peak  
387 abundance weighted fraction of aromatic CHON<sup>-</sup> compounds were observed in Shanghai. The  
388 peak abundance-weighted average molecular formulas for CHON<sup>-</sup> compounds in Changchun<sup>-</sup>,  
389 Shanghai<sup>-</sup> and Guangzhou<sup>-</sup> are  $C_{7.10}H_{6.76}O_{3.56}N_{1.03}$ ,  $C_{7.07}H_{6.03}O_{3.80}N_{1.24}$  and  $C_{7.12}H_{6.36}O_{3.99}N_{1.24}$ ,  
390 respectively, showing that CHON<sup>-</sup> formulas in Shanghai<sup>-</sup> and Guangzhou<sup>-</sup> contain more O and  
391 N atoms on average than those for Changchun<sup>-</sup>. Formulas of  $C_6H_5O_3N_1$ ,  $C_6H_5O_4N_1$ ,  $C_7H_7O_3N_1$ ,  
392  $C_7H_7O_4N_1$ ,  $C_8H_9O_3N_1$ , and  $C_8H_9O_4N_1$  were detected with the highest abundance in all cities. These  
393 molecular formulas are in line with nitrophenol or nitrocatechol analogs, which have been identified  
394 in a previous urban OA study (Wang et al., 2017). Furthermore, these nitrooxy-aromatic  
395 compounds were shown to enhance light absorbing properties of OA (Laskin et al., 2015; Lin et al.,  
396 2015). In addition, it should be noted that the X<sub>c</sub> values for  $C_6H_5O_4N_1$ ,  $C_7H_7O_4N_1$  and  $C_8H_9O_4N_1$   
397 were calculated to be lower than 2.5, suggesting that the fraction of aromatics in CHON<sup>-</sup>  
398 compounds was underestimated. This is because that for nitrocatechol analogs with formulas of  
399  $C_6H_5O_4N_1$ ,  $C_7H_7O_4N_1$  and  $C_8H_9O_4N_1$ , only one oxygen atom is involved in the  $\pi$ -bond structure  
400 corresponding to the p value of 0.25 in the X<sub>c</sub> calculation equation, which is lower than the p value  
401 of 0.5 applied for the X<sub>c</sub> calculation in this study. The diagram of DBE versus C number for  
402 CHON<sup>+</sup> compounds observed in the three locations (presented in Fig. S7 in SI) shows that more  
403 aromatic CHON<sup>+</sup> compounds with relatively lower degree of oxidation were assigned in  
404 Changchun<sup>+</sup> samples compared to Shanghai<sup>+</sup> and Guangzhou<sup>+</sup> samples.

### 405 **3.4 CHN<sup>+</sup> compounds**

406 696 CHN<sup>+</sup> compounds were detected in Changchun<sup>+</sup> samples in ESI<sup>+</sup>, which is higher than in  
407 Shanghai<sup>+</sup> (253) and Guangzhou (205). These CHN<sup>+</sup> compounds are likely assignable to amines  
408 according to previous studies (Rincón et al., 2012; Wang et al., 2017; Wang et al., 2018). The  
409 number of CHN<sup>+</sup> compounds accounts for 24%, 36% and 30% of the total organic compounds in  
410 Changchun<sup>+</sup>, Shanghai<sup>+</sup> and Guangzhou<sup>+</sup>, respectively, whereas the peak abundance of these

411 compounds accounts for 40%, 71% and 62%, respectively. The majority (> 97% in terms of peak  
412 abundance) of CHN<sup>+</sup> compounds have one or two nitrogen atoms in their molecular formulas (see  
413 Fig. S9). Comparing the CHN<sup>+</sup> compounds for the three cities, 51 common CHN<sup>+</sup> formulas were  
414 observed in all cities, which contribute to as much as 43–89% of the total abundance of CHN<sup>+</sup>  
415 formulas. This large percentage indicates that CHN<sup>+</sup> compounds with presumably high  
416 concentrations in Changchun<sup>+</sup>, Shanghai<sup>+</sup> and Guangzhou<sup>+</sup> exhibit similar chemical composition.  
417 However, again OA samples from Changchun show some distinct differences to samples from  
418 Guangzhou and Shanghai.

419 A van Krevelen diagram of CHN<sup>+</sup> compounds detected in the three samples is shown in Fig. 6,  
420 illustrating H/C ratios as a function of N/C ratio. In this plot, major parts of the CHN<sup>+</sup> compounds  
421 are found in a region, which is constraint by H/C ratios between 0.5 and 2 and N/C ratios lower  
422 than 0.5. Moreover, the pie charts show that the majority (83–87% in terms of peak abundance and  
423 72–90% in terms of peak numbers) of these CHN<sup>+</sup> compounds can be assigned to mono- and  
424 polyaromatics with  $X_c \geq 2.5$ . In addition, as shown in Table 1, the average DBE and  $X_c$  values of  
425 CHN<sup>+</sup> compounds are the highest among all organic species. These observations imply that CHN<sup>+</sup>  
426 compounds exhibit the highest degree of aromaticity of all organics in the Chinese urban OA  
427 samples, which is consistent with previous studies (Lin et al., 2012b; Rincón et al., 2012; Wang et  
428 al., 2018). Polyaromatic compounds with  $X_c \geq 2.7$  are displayed in the lower left corner of the  
429 van Krevelen diagram, accounting for 41% in terms of peak abundance (48% in terms of peak  
430 numbers) of CHN<sup>+</sup> compounds detected in Changchun<sup>+</sup>, but merely for 9–10% in terms of peak  
431 abundance (27–31% in terms of peak numbers) in Shanghai<sup>+</sup> and Guangzhou<sup>+</sup>. For example,  
432 formulas of C<sub>11</sub>H<sub>11</sub>N<sub>1</sub> ( $X_c = 2.7$ ), C<sub>10</sub>H<sub>9</sub>N<sub>1</sub> ( $X_c = 2.7$ ), and C<sub>12</sub>H<sub>13</sub>N<sub>1</sub> ( $X_c = 2.7$ ), which are assigned  
433 to be naphthalene core structure-containing compounds, have relatively higher abundance in  
434 Changchun<sup>+</sup> than in Shanghai<sup>+</sup> and Guangzhou<sup>+</sup>. Moreover, the average DBE and  $X_c$  values of  
435 CHN<sup>+</sup> compounds (see Table 1) in Changchun<sup>+</sup> are substantially higher than those in Shanghai<sup>+</sup>  
436 and Guangzhou<sup>+</sup>, further indicating that CHN<sup>+</sup> compounds in Changchun<sup>+</sup> show a higher degree  
437 of aromaticity, which can be caused by large coal combustion emissions in the winter in Changchun.  
438 Remarkably, as can be seen in Fig. 6, the abundance of CHN<sup>+</sup> compounds in Changchun<sup>+</sup>  
439 distributes evenly among different individual CHN<sup>+</sup> compounds, while in Shanghai<sup>+</sup> and  
440 Guangzhou<sup>+</sup> they are dominated by the formula of C<sub>10</sub>H<sub>14</sub>N<sub>2</sub> (the biggest purple circle in Fig. 6)  
441 with DBE value of 5, which probably has high concentration and/or high ionization efficiency in  
442 the positive ESI mode. According to a previous smog chamber study (Laskin et al., 2010), most  
443 CHN<sup>+</sup> aromatics are probably generated from biomass burning through the addition of reduced

444 nitrogen (e.g., NH<sub>3</sub>) to the organic molecules via imine formation reaction, indicating that biomass  
445 burning probably made a certain contribution to the formation of CHN<sup>+</sup> compounds observed in  
446 the three urban OA samples in our study.

### 447 **3.5 CHOS<sup>-</sup> compounds**

448 In this study, 75–155 CHOS<sup>-</sup> compounds were observed, accounting for 10%, 12% and 14% of  
449 the total peak abundance of all organics in Changchun<sup>-</sup>, Shanghai<sup>-</sup> and Guangzhou<sup>-</sup>, respectively.  
450 Around 89–96% of these CHOS<sup>-</sup> compounds were found to fulfill the O/S ≥ 4 criterion allowing  
451 the assignment of at least one –OSO<sub>3</sub>H functional group, and thus, a tentative classification to  
452 organosulfates (OSs) (Lin et al., 2012a; Lin et al., 2012b; Tao et al., 2014; Wang et al., 2016; Wang  
453 et al., 2017; Wang et al., 2018; Wang et al., 2019a). OSs were shown to affect the surface activity  
454 and hygroscopic properties of the aerosol particles, leading to potential impacts on climate (Hansen  
455 et al., 2015; Wang et al., 2019a). Out of all formulas, 23 common CHOS<sup>-</sup> formulas were detected  
456 for the three sample locations, accounting for 28%, 58% and 52% of the CHOS<sup>-</sup> peak abundance  
457 in Changchun<sup>-</sup>, Shanghai<sup>-</sup> and Guangzhou<sup>-</sup>, respectively. However, 40 common CHOS<sup>-</sup>  
458 formulas were found between Shanghai<sup>-</sup> and Guangzhou<sup>-</sup>, accounting for 60–65% and 78–81%  
459 in terms of the CHOS<sup>-</sup> formula numbers and peak abundance, respectively. This indicates that the  
460 chemical composition of the major CHOS<sup>-</sup> compounds of Shanghai<sup>-</sup> and Guangzhou<sup>-</sup> are quite  
461 similar, while they show substantial chemical differences for samples from Changchun<sup>-</sup>.

462 Figure 7 shows the DBEs as a function of carbon number for all CHOS<sup>-</sup> compounds detected for  
463 the three cities. The CHOS<sup>-</sup> compounds exhibit a DBE range from 0 to 10 and carbon number  
464 range of 2–15. However, the majority of CHOS<sup>-</sup> compounds with elevated peak abundances  
465 concentrate in a region with rather low DBE values of 0–5. The average H/C ratios of CHOS<sup>-</sup>  
466 compounds are in the range of 1.56–1.85, and thus, higher than for any other compound class,  
467 whereas the average DBE values of 1.71–2.55 are the lowest among all classes. This indicates that  
468 CHOS<sup>-</sup> compounds in the OA from the three Chinese cities are characterized by a low degree of  
469 unsaturation. Moreover, the pie charts in Fig. 7 show that aliphatic compounds with X<sub>c</sub> ≤ 2.5 are  
470 dominant in CHOS<sup>-</sup> compounds with a fraction of 96–99% in terms of peak abundance, which is  
471 substantially higher than that (13–48%) for CHO, CHON and CHN species. Aliphatic CHOS<sup>-</sup>  
472 compounds with C ≤ 10 can be formed from biogenic and/or anthropogenic precursors (Hansen  
473 et al., 2014; Glasius et al., 2018; Wang et al., 2019a), such as C<sub>2</sub>H<sub>4</sub>O<sub>6</sub>S<sub>1</sub> (derived from glyoxal)  
474 (Lim et al., 2010; McNeill et al., 2012), C<sub>3</sub>H<sub>6</sub>O<sub>6</sub>S<sub>1</sub> (derived from isoprene) (Surratt et al., 2007) and  
475 C<sub>8</sub>H<sub>16</sub>O<sub>4</sub>S<sub>1</sub> (derived from α-pinene). However, more CHOS<sup>-</sup> compounds with C > 10 and with

476 DBEs lower than 1 are observed in Changchun-, such as  $C_{14}H_{28}O_5S_1$ ,  $C_{13}H_{26}O_5S_1$ ,  $C_{12}H_{24}O_5S_1$ ,  
477  $C_{11}H_{22}O_5S_1$  and  $C_{11}H_{20}O_6S_1$ . These high-carbon-number-containing CHOS- compounds are likely  
478 formed from long-alkyl-chain compounds with less oxygenated functional groups, which were  
479 previously suggested to be emitted from traffic (Tao et al., 2014) or derived from sesquiterpene  
480 emissions (Brüggemann et al., 2019). However, as sesquiterpene emissions can be expected to be  
481 very low in wintertime at Changchun, the presence of these compounds further underlines the  
482 strong impact of anthropogenic emissions on CHOS- formation in Changchun-. In this study,  
483 (O-3S)/C ratio was used instead of traditional O/C ratio to present the oxidation state of CHOS-  
484 compounds, since the sulfate functional group contains three more oxygen atoms than common  
485 oxygen-containing groups (e.g., hydroxyl and carbonyl), which makes no contribution to the  
486 oxidation state of the carbon backbone of the CHOS- compounds. Comparing average values for  
487 H/C, (O-3S)/C and DBEs of CHOS- for the three sample locations (see Table 1), we find that the  
488 H/C ratios (1.85) and (O-3S)/C ratios (0.61-0.71) for Shanghai- and Guangzhou- samples are  
489 larger than those for Changchun- samples (H/C = 1.56 and (O-3S)/C = 0.52), whereas the DBE  
490 values (1.71-1.79) in Shanghai- and Guangzhou- are lower than those for Changchun- (2.55).  
491 These observations indicate that CHOS- compounds in urban OA from Northeast China are less  
492 oxidized but more unsaturated compared to those in East and Southeast China, likely due to  
493 enhanced emissions from residential heating during winter in North China.

### 494 **3.6 CHONS compounds**

495 4-5% of the total organics detected in ESI- were identified as CHONS- compounds in terms of  
496 peak abundance. In contrast, CHONS+ compounds account merely for 0.3-1% of all organics  
497 detected in ESI+. The average  $MM_{avg}$  of the CHONS- compounds for the three sample locations  
498 ranges from 214 to 293 Da, generally showing larger molecular masses than compounds of any  
499 other class because of the likely presence of both nitrate and sulfate functional groups. In total, only  
500 5 common CHONS- formulas were detected for all three sample locations, accounting for 4%, 21%  
501 and 20% of the CHONS- peak abundance in Changchun-, Shanghai- and Guangzhou-  
502 respectively. As already observed for other compound classes, these percentages imply that the  
503 CHONS- compounds in urban OA of Shanghai- and Guangzhou- exhibit a rather similar chemical  
504 composition, whereas such compounds are different for Changchun-.

505 In the OA samples of Shanghai- and Guangzhou-, 78-87% of CHONS- compounds in terms of  
506 peak abundance have 7 or more O atoms in their formulas, allowing the assignment of one -OSO<sub>3</sub>H  
507 and one -NO<sub>3</sub> functional groups in the molecular structures, thus, classifying them as potential

508 nitrooxy-organosulfates. In contrast to Shanghai- and Guangzhou-, only 26% of CHONS-  
509 compounds were assigned to such nitrooxy-organosulfates for Changchun-, indicating that most  
510 of the N atoms in the CHONS- compounds are present in a reduced oxidation state, e.g., in the  
511 form of amines. The average DBE and Xc values of CHONS- compounds in Shanghai- and  
512 Guangzhou- are 3.3–3.45 and 0.43–0.44, respectively. Again these values differ for the  
513 Changchun- samples with an increased average DBE of 3.75 and an average Xc of 1.06, indicating  
514 that CHONS- compounds in Changchun- possess on average a higher degree of unsaturation and  
515 aromaticity compared to such compounds in Shanghai- and Guangzhou- samples. Interestingly,  
516 the compound with formula  $C_{10}H_{17}O_7NS$  has the highest relative peak abundance (32%) in  
517 Shanghai- and Guangzhou-, whereas in Changchun- the compound with formula  $C_2H_3O_4NS$  is  
518 dominant.  $C_{10}H_{17}O_7NS$  has previously been identified as mononitrate organosulfate generated from  
519  $\alpha/\beta$ -pinene (Iinuma et al., 2007; Surratt et al., 2008; Lin et al., 2012b; Wang et al., 2017), while  
520  $C_2H_3O_4NS$  may be assigned as a cyanogroup-containing sulfate. This observation is comparable to  
521 our previous study (Wang et al., 2019a), which found that  $C_{10}H_{17}O_7NS$  was dominant for CHONS-  
522 compounds in low-concentration aerosol samples collected in Beijing (China) and Mainz  
523 (Germany). Consistently, a  $C_2H_3O_4NS$  compound had the highest abundance among CHONS-  
524 compounds in polluted Beijing aerosol samples. This agreement can be explained by the adjacent  
525 locations of Beijing (39.99° N, 116.39° E) and Changchun (43.54° N, 125.13° E) and similar  
526 residential heating patterns by coal combustion during wintertime. In conclusion, these results  
527 further demonstrate that the precursors for CHONS- compounds in Shanghai- and Guangzhou-  
528 are different from those in Changchun-, which is probably due to differences in anthropogenic  
529 emissions.

#### 530 **4 Conclusion**

531 The molecular composition of the organic fraction of  $PM_{2.5}$  samples collected in three Chinese  
532 megacities (Changchun, Shanghai and Guangzhou) was investigated using a UHPLC-Orbitrap  
533 mass spectrometer. In total, 416–769 (ESI-) and 687–2943 (ESI+) organic compounds were  
534 observed and separated into five subgroups: CHO, CHN, CHON, CHOS and CHONS. Specifically,  
535 120 common formulas were detected in ESI- and 129 common formulas in ESI+ for all sample  
536 locations, accounting for 57–71% and 30–75% in terms of peak abundance, respectively. Overall,  
537 we found that urban OA in Changchun, Shanghai and Guangzhou shows a quite similar chemical  
538 composition for organic compounds of high concentrations. The majority of these organic species  
539 was assigned to mono-aromatic or poly-aromatic compounds, indicating that anthropogenic  
540 emissions are the major source for urban OA in all three cities.

541 Despite the chemical similarity of the three sample locations for organic compounds in urban OA,  
542 remarkable differences were found in chemical composition of the remaining particle constituents,  
543 in particular for OA samples from Changchun. In general, a larger amount of polyaromatics was  
544 observed for Changchun samples, most likely due to emissions from coal combustion during  
545 wintertime residential heating period. Moreover, the peak abundance-weighted average DBE and  
546 average Xc values of the total organic compounds in Changchun were found to be larger than those  
547 for Shanghai and Guangzhou, showing that organic compounds in Changchun possess a higher  
548 degree of unsaturation and aromaticity. For average H/C and O/C ratios a similar trend was  
549 observed. While average H/C and O/C ratios detected in ESI<sup>-</sup> were found to be highest for  
550 Guangzhou samples, relatively lower values were observed for Shanghai and Changchun samples,  
551 indicating that OA collected in lower latitude regions of China experiences more intense  
552 photochemical oxidation processes and/or are affected to a larger degree by biogenic sources.

## 553 **5 Limitations**

554 In this study, we used the peak abundance-weighted method to illustrate the difference in chemical  
555 formulas assigned by Orbitrap mass spectrometry. This comparison was made based on the  
556 assumption that the measured organic compounds have same peak abundance response in the mass  
557 spectrometer. However, this assumption can bring some uncertainties because the ionization  
558 efficiencies vary between different compounds (Schmidt et al., 2006; Leito et al., 2008; Perry et al.,  
559 2008; Krueve et al., 2014). For example, the ionization efficiencies of nitrophenol species detected  
560 in negative ESI mode can vary by a large degree depending on the position of the substituents at  
561 the nitrobenzene ring (Schmidt et al., 2006; Krueve et al., 2014) and the ionization efficiencies of  
562 carboxylic acids can also vary by several orders of magnitude depending on the structures (Krueve  
563 et al., 2014). Nonetheless, it is a challenging analytical task to identify and quantify all compounds  
564 in ambient OA due to the high chemical complexity of OA and the limits in authentic standards of  
565 OA. Despite the inherent uncertainties, the peak abundance-weighted comparison of molecular  
566 formulas provides an overview of the difference in chemical composition of OA in these three  
567 representative Chinese cities. In particular, the chemical formulas assigned in this study can be  
568 validated in future studies by authentic standards and the difference in ionization efficiencies can  
569 be further evaluated.

570

571 **Author contributions.** RJH, TH and KW conducted the study design. LY, HN, JG and MW  
572 collected the PM<sub>2.5</sub> filter samples. KW and YZ carried out the experimental work and data analysis.

573 KW wrote the manuscript. KW, TH, RJH, M. Brüggemann, YZ, JH, M. Bilde and MG interpreted  
574 data and edited the manuscript. All authors commented on and discussed the manuscript.

575 **Competing interests.** The authors declare that they have no conflict of interest.

576 **Acknowledgements.** This study was supported by the National Natural Science Foundation of  
577 China (NSFC, Grant No. 41925015, No. 91644219 and No. 41877408), the Chinese Academy of  
578 Sciences (No. ZDBS-LY-DQC001), the National Key Research and Development Program of  
579 China (No. 2017YFC0212701), and the German Research Foundation (Deutsche  
580 Forschungsgemeinschaft, DFG) under Grant No. INST 247/664-1 FUGG. K. Wang and Y. Zhang

881 \*The values in brackets indicate the number of unique molecular formulas. \*\*The values in brackets indicate the  
 882 (O-3S)/C and (O-3S-2N)/C ratios for CHOS and CHONS compounds, respectively, detected in ESI- mode

883

884

885 Figure 1. Mass spectra of detected organic compounds reconstructed from extracted ion  
 886 chromatograms in ESI- and ESI+. The horizontal axis refers to the molecular mass (Da) of the  
 887 identified species. The vertical axis refers to the relative peak abundance of each individual  
 888 compound to the compound with the greatest peak abundance. The pie charts show the percentage  
 889 of each organic compound subgroup (i.e. CHO, CHON, CHOS, CHONS and CHN) in each sample  
 890 in terms of peak abundance. The map in the lower right corner shows the locations of these three  
 891 megacities in China.

892

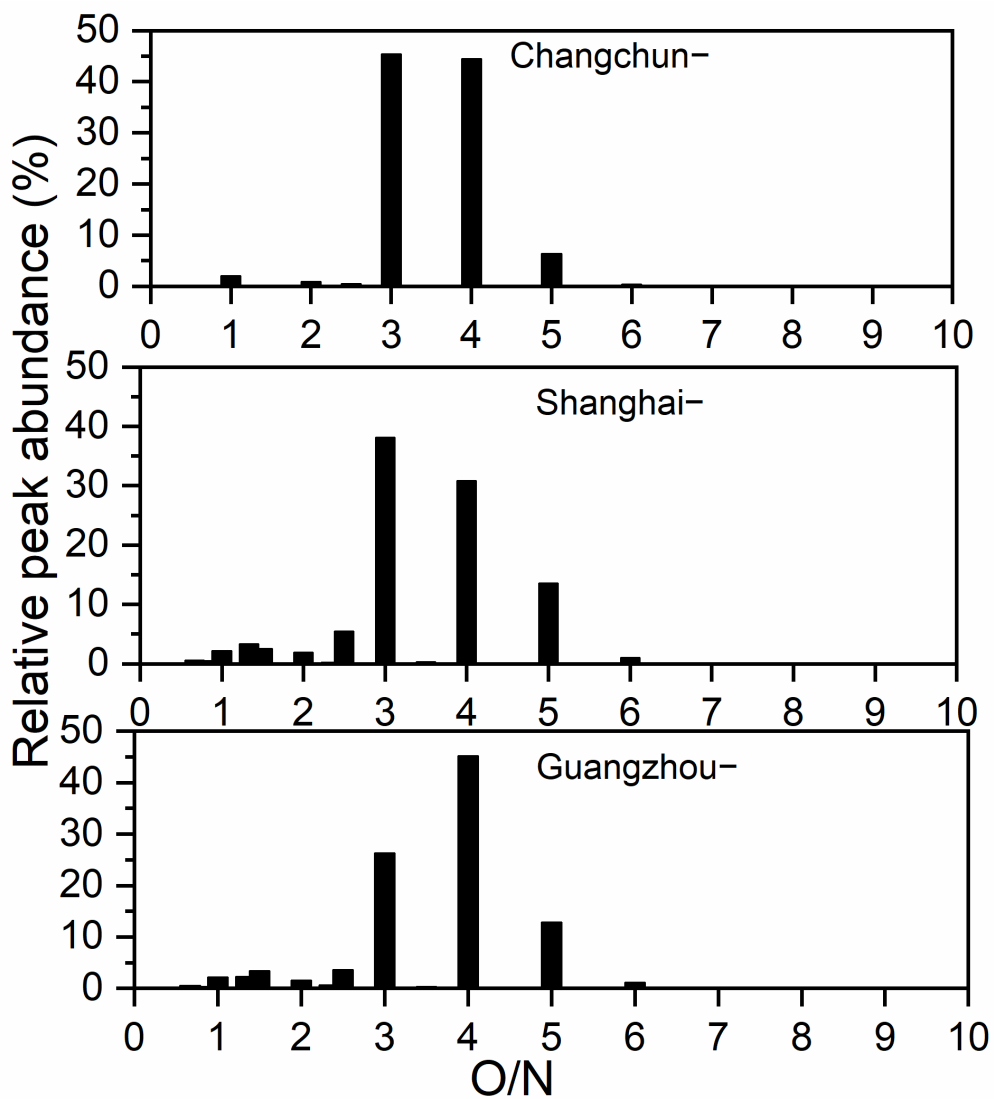

893

894 Figure 2. (a) Venn diagrams showing the number distribution of all molecular formulas detected in  
 895 ESI<sup>-</sup> and ESI<sup>+</sup> for all sample locations. The overlapping molecular formulas refer to the  
 896 compounds detected in each city with the same molecular formulas and with the same retention  
 897 times (retention time difference  $\leq 0.1$  min). (b) Peak abundance contribution of each elemental  
 898 formula category to the total common formulas.

899

900 Figure 3. Double bond equivalent (DBE) versus carbon number for all CHO- compounds for all  
 901 sample locations. The molecular formula represents the abundance-weighted average CHO-  
 902 formula and the area of the circles is proportional to the fourth root of the peak abundance of an  
 903 individual compound (a diagram with circle areas related to the absolute peak abundances is  
 904 presented in Fig. S2). The color bar denotes the aromaticity equivalent (gray with  $X_c < 2.50$ , purple  
 905 with  $2.50 \leq X_c < 2.70$  and red with  $X_c \geq 2.70$ ). The pie charts show the percentage of each  $X_c$   
 906 category (i.e., gray color-coded compounds, purple color-coded compounds and red color-coded  
 907 compounds) in each sample in terms of peak abundance.

908

909 Figure 4. Classification of CHON<sup>-</sup> compounds into different subgroups according to O/N ratios in  
 910 their formulas. The y-axis indicates the relative contribution of each specific O/N ratio subgroup to  
 911 the sum of peak abundances of CHON<sup>-</sup> compounds.

912

913 Figure 5. Double bond equivalent (DBE) versus carbon number for all CHON-  
 914 sample locations. The molecular formula represents the abundance-weighted average CHON-  
 915 formula and the area of circles is proportional to the fourth root of the peak abundance of an  
 916 individual compound (a diagram with circle areas related to absolute peak abundances is presented  
 917 in Fig. S6). The color bar denotes the aromaticity equivalent (gray with  $X_c < 2.50$ , purple with  $2.50$   
 918  $\leq X_c < 2.70$  and red with  $X_c \geq 2.70$ ). The pie charts show the percentage of each  $X_c$  category (i.e.,  
 919 gray color-coded compounds, purple color-coded compounds and red color-coded compounds) in  
 920 each sample in terms of peak abundance.

921

922 Figure 6. Van Krevelen diagrams for CHN+ compounds in Changchun, Shanghai and Guangzhou  
 923 samples. The area of circles is proportional to the fourth root of the peak abundance of an individual  
 924 compound (a diagram with circle areas related to absolute peak abundances is presented in Fig.  
 925 S10) and the color bar denotes the aromaticity equivalent (gray with  $X_c < 2.50$ , purple with  $2.50 \leq$   
 926  $X_c < 2.70$  and red with  $X_c \geq 2.70$ ). The pie charts show the percentage of each  $X_c$  category (i.e.,  
 927 gray color-coded compounds, purple color-coded compounds and red color-coded compounds) in  
 928 each sample in terms of peak abundance.

929

930 Figure 7. Double bond equivalent (DBE) versus carbon number for all CHOS- compounds for all  
 931 sample locations. The molecular formula represents the abundance-weighted average CHOS-  
 932 formula and the area of circles is proportional to the fourth root of the peak abundance of an  
 933 individual compound (a diagram with circle areas related to absolute peak abundances is presented  
 934 in Fig. S11). The color bar denotes the aromaticity equivalent (gray with  $X_c < 2.50$ , purple with  
 935  $2.50 \leq X_c < 2.70$  and red with  $X_c \geq 2.70$ ). The pie charts show the percentage of each  $X_c$  category  
 936 (i.e., gray color-coded compounds, purple color-coded compounds and red color-coded compounds)  
 937 in each sample in terms of peak abundance.
