9 **Abstract**

10 Nitrous acid (HONO) in the core city of the Central Plains Economic Region was
11 measured using an ambient ion monitor from January 9 to 31, 2019. Measurement time
12 intervals were classified into the following periods in accordance with the daily mean
13 values of PM_{2.5}: clean days (CD), pollution days (PD), and severe pollution days (SPD).
14 The HONO concentrations during CD, PD, and SPD were 1.2, 2.3, and 3.7 ppbv, re-
15 spectively. The contribution of the three sources varied under different pollution levels.
16 The mean values of the net HONO production of the homogeneous reaction ($P_{\text{OH}+\text{NO}}^{\text{net}}$)
17 in CD, PD, and SPD periods were 0.51, 1.03, and 2.18 ppbv h⁻¹, respectively. The
18 average conversions of NO₂ (C_{HONO}) in CD, PD, and SPD periods were
19 0.72×10^{-2} , 0.64×10^{-2} , and 1.54×10^{-2} h⁻¹, respectively, indicating that the
20 heterogeneous conversion of NO₂ was unimportant. Furthermore, the net production of
21 the homogeneous reaction may have been the main factor for the increase in HONO
22 under high-NO_x conditions (i.e., the concentration of NO was higher than that of NO₂)
23 at nighttime. Daytime HONO budget analysis showed that the mean values of the un-
24 known source (P_{unknown}) during CD, PD, and SPD periods were 0.26, 0.40, and 1.83
25 ppbv h⁻¹, respectively. The values of $P_{\text{OH}+\text{NO}}^{\text{net}}$, C_{HONO} , and P_{unknown} in the SPD period
26 were comparatively larger than those in other periods, indicating that HONO partici-
27 pated in many reactions. The proportions of nighttime HONO sources also changed

28 during the entire sampling period. Direct emission and a heterogeneous reaction con-
29 trolled HONO production in the first half of the night and provided a contribution larger
30 than that of the homogeneous reaction. The proportion of homogenization gradually
31 increased in the second half of the night due to the steady increase in NO concentration.
32 The hourly abatement level of HONO abatement pathways, except for OH + HONO,
33 should be at least 1.47 ppbv h⁻¹ in the SPD period. The cumulative frequency distribu-
34 tion of the HONO_{emission}/HONO ratio (less than 20%) was approximately 76.7%, which
35 suggests that direct emission was important. The heterogeneous HONO production in-
36 creased when the relative humidity (RH) increased from 52% to 77%, but it decreased
37 when RH increased further. The average HONO/NO_x ratio (4.9%) was more than twice
38 the assumed globally averaged value (2.0%).

39 1. Introduction

40 Nitrous acid (HONO) is important in the photochemical cycle and can provide
41 hydroxyl radicals (OH):

43 According to measurement and simulation studies (Alicke et al., 2002), the contribution
44 rate of HONO to OH radical concentration can reach 25%–50%, especially when the
45 concentration of OH radicals produced by the photolysis of ozone and formaldehyde is
46 relatively low (two to three hours after sunrise) (Czader et al., 2012). OH radical is also
47 an important oxidant in the atmosphere, and it can react with organic substances, control
48 the oxidation capacity of the atmosphere, and accelerate the formation of secondary
49 aerosols in urban atmosphere (Sörgel et al., 2011). Therefore, reaction changes during
50 pollution can be observed by studying the formation mechanism of HONO.

51 Several instruments have been used to determine ambient HONO concentrations,
52 and these include differential optical absorption spectrophotometer (DOAS) (Winer and
53 Biermann, 1994), long path absorption photometer (LOPAP) (Heland et al., 2001), Ni-
54 tro-MAC (Michoud et al., 2014), stripping coil-UV/vis absorption photometer (SC-AP)

55 (Pinto et al., 2014), and ambient ion monitor (AIM) (VandenBoer et al., 2014). A pre-
56 vious comparison of different instruments showed that SC-AP is compatible with two
57 spectral measurement instruments, namely, LOPAP and DOAS (Pinto et al., 2014).
58 Compared with HONO measured by SC-AP deployed onsite, HONO measured by AIM
59 has a small error and is within the acceptable analytical uncertainty; the results exhib-
60 ited a consistency of nearly 1:1 (VandenBoer et al., 2014). Previous studies have
61 reported that HONO concentrations range from a few pptv in clean remote areas to
62 several ppbv (0.1–2.1 ppbv) in air-polluted urban areas (Hou et al., 2016; Michoud et
63 al., 2014).

64 The sources of HONO are direct emission and homogeneous and heterogeneous
65 reactions (Acker et al., 2005; Grassian, 2001; Kurtenbach et al., 2001). HONO can be
66 directly discharged into the atmosphere during vehicle operation and biomass combus-
67 tion. Through a tunnel experiment, Kurtenbach et al. (2001) discovered that motor
68 vehicles emit a small amount of HONO, and the HONO/NO_x ratio of HONO combus-
69 tion sources (aside from NO_x and other pollutants) accounts for 0.1%–0.8%
70 (Kurtenbach et al., 2001). Another study showed that the homogeneous reaction of NO
71 and OH radicals is the major source of HONO under increased NO concentrations
72 (Spataro et al., 2013). Furthermore, HONO can be absorbed by the OH radical (Alicke,
73 2003; Vogel et al., 2003). Tong et al. (2015) used NO + OH and HONO + OH homoge-
74 neous reactions, to calculate the net generation rate of HONO homogeneous reactions
75 at night (Tong et al., 2015), which are expressed as:

78 Such calculations have been applied in studies on nighttime sources and daytime budg-
79 ets (Hou et al., 2016; Huang et al., 2017). Finlayson-Pitts et al. (2003) studied mineral
80 dust particles by using isotope-labeled water and revealed the mechanism of the reac-
81 tion between adsorbed NO₂ and H ion dissociated from surface chemically adsorbed
82 H₂O (Finlayson-Pitts et al., 2003):

84 In China, most studies for HONO have concentrated on the Yangtze River Delta, Pearl
85 River Delta and Jing-Jin-Ji region. For example, Hao et al. (2006) reported that field
86 measurement results, especially HONO/NO₂ and relative humidity (RH), have a signif-
87 icant correlation and proved that heterogeneous reactions are an important source of
88 nighttime HONO (Hao et al., 2006). Although the specific chemical mechanisms of
89 heterogeneous reactions remain unknown, the intensity of HONO formation by NO₂
90 can be expressed by the HONO conversion frequency (Alicke et al., 2002; Li et al.,
91 2012). Su et al. (2008a) revealed the importance of the OH radical from HONO during
92 daytime (9:00–15:00 local time) and found that many unknown sources that are closely
93 related to radiation lead to HONO formation (Su et al., 2008a). The researchers sug-
94 gested that the method of budget analysis is crucial for obtaining the missing source.
95 Spataro et al., (2013) measured the HONO level in Beijing’s urban area and discussed
96 the spatiotemporal changes, meteorological effects, and contributions of HONO from
97 different sources. They used the measured HONO data to compare pollution periods in
98 Beijing’s urban and suburban areas. Tong et al. (2015) discovered that the possible
99 mechanisms of HONO formation, namely, direct emission, heterogeneous formation,
100 and homogeneous reaction, differ in the two sites. A few studies (Cui et al., 2018; Hou
101 et al., 2016) compared the characteristics and sources of HONO during severe-pollution
102 and clean periods. Although the definitions of the two periods are different, both can be
103 used to analyze the diurnal variation, source, and daytime budget of HONO during the
104 aggravation of pollution.

105 There is no study of HONO in the Central Plains Economic Region (CPER), with
106 a total population of 0.18 billion by the end of 2011. CPER is the important region for
107 food production and modern agriculture published by the Chinese government
108 (<http://www.ndrc.gov.cn/zcfb/zcfbtz/201212/P020121203614181974825.pdf>), characterizing
109 different influence factors for atmospheric pollution, including economic development
110 level, energy structure, industrial structure, and geographic position (solar radiation)

111 with the Yangtze River Delta, Pearl River Delta and Jing-Jin-Ji region. As the core city
112 of the CPER, Zhengzhou is characterized by severe PM pollution (Jiang et al.,
113 2017;Jiang et al., 2018d), selected in the study. In recent years, comprehensive PM re-
114 search has been conducted on Zhengzhou's chemical characteristics (Jiang et al.,
115 2018b;Li et al., 2019), source apportionment (Jiang et al., 2018c;Jiang et al., 2018e;Liu
116 et al., 2019), health risks (Jiang et al., 2019a;Jiang et al., 2019b), and emission source
117 profiles (Jiang et al., 2018a). However, no study has been performed on the sources and
118 characteristics of HONO in Zhengzhou. Moreover, no synthetic research on different
119 pollution levels in the area is available. In the current study, AIM was used to sample
120 and analyze HONO concentrations. The interactions between HONO and other chemi-
121 cals, such as PM_{2.5}, during pollution were assessed to understand the formation and
122 removal of HONO and the influence on different pollution periods. This investigation
123 of PM_{2.5} and HONO is expected to clarify the sources, sinks, and reactions in fine PM
124 pollution and the importance of systematic research. RH was also analyzed to provide
125 a detailed understanding of HONO generation intensity under different RH conditions.
126 Analysis of the sources of HONO at night provides strong support for conducting
127 HONO budget analysis during daytime. To the best of the authors' knowledge, the for-
128 mation characteristics of HONO at continuous and high time resolutions and different
129 pollution levels have not been studied in Zhengzhou. This work can assist the govern-
130 ments of the CPER in formulating policy to decrease the level of HONO precursors,
131 i.e., NO and NO₂, and HONO direct emission from vehicle.

132 **2. Experiment and methods**

133 **2.1. Sampling site and period**

134 The sampling site is on the rooftop (sixth floor) of a building in Zhengzhou Uni-
135 versity (34°48' N, 113°31' E), which is located in the northwestern part of Zhengzhou,
136 China. The observation height is about 20 m from the ground, and the observation plat-
137 form is relatively open without any tall buildings around. The site is close to the West
138 Fourth Ring Road of Zhengzhou City and about 2 km from Lian Huo Expressway to

139 the north. The measurement period was from January 9 to 31, 2019. Daily data were
140 divided into two periods, namely, daytime (7:00–18:00 local time (Ammann et al.)) and
141 nighttime (19:00–6:00 the next day, LT).

142 **2.2. High-time-resolution instruments**

143 AIM (URG-9000D, Thermo, USA), an online ion chromatographic monitoring
144 system for particle and gas components in the atmosphere, was used to measure HONO
145 concentration continuously at a temporal resolution of 1 h. The atmospheric airflow
146 entered the PM_{2.5} cyclone cutting head through the sample tube, and gas–solid separa-
147 tion was performed with a parallel plate denuder with a new synthetic polyamide
148 membrane. The denuder had no moving parts and could be changed without stopping
149 the sampler. The conversion of gas samples from the atmospheric environment is shown
150 in **Fig. S1**. HONO was absorbed by the denuder with an absorption liquid (5.5 mM
151 H₂O₂). **Fig. S2** presents the specific process of gas dissolution in the denuder. The sub-
152 stances that could be oxidized were absorbed by H₂O₂ on the porous membrane surface,
153 but several gases (e.g., O and N) were expelled by the air pump. The abundance of other
154 gaseous acids and bases affected the efficiency of HONO collection by AIM due to the
155 relation between Henry’s law constant and pH. This measurement method and its details
156 have been successfully evaluated in many field studies (Markovic et al., 2012; Tian et
157 al., 2018; Wang et al., 2019). In addition, a QXZ1.0 automatic weather station (Yigu
158 Technologies, China) was used for synchronous observation of meteorological param-
159 eters, including temperature (T), RH, wind direction (WD), and wind speed (WS). O₃,
160 CO, NO, NO_x, NO₂, and PM_{2.5} were measured with a model analyzer (TE, 48i, and 42i,
161 Thermo, USA) and TEOM 1405 PM_{2.5} monitor (Thermo Electron, USA) with a tem-
162 poral resolution of 1 h. Detailed information can be found in the work of (Wang et al.,
163 2019).

164 During the sampling period, all instruments were subjected to strict quality control
165 to avoid possible contamination. The instrument accessories and sampling process were

166 periodically replaced and calibrated, respectively. The instrument parts and consuma-
167 bles should be changed regularly during the observation process, and the sampling flow
168 should be calibrated to reduce the negative effect of accessories on sampling. The mem-
169 brane of the denuder was replaced every six weeks. Standard anion and cation solutions
170 were prepared every two months, and the standard curve was drawn to ensure the ap-
171 propriateness of the correlation coefficient (≥ 0.999) and the accuracy of the sample
172 retention time and response value. The minimum detection limit of AIM was 0.004
173 ppbv. Other detailed information can be found in the work of (Wang et al., 2019).

174 **3. Results and Discussion**

175 **3.1. Temporal variations of meteorological parameters and pollutants**

176 The daily changes in meteorological parameters and $\text{PM}_{2.5}$ are shown in **Fig. 1**. In
177 accordance with the daily average concentration level of $\text{PM}_{2.5}$, the analysis and meas-
178 urement process was divided into three periods (clean days [CD], pollution days [PD],
179 and severe pollution days [SPD]). The days wherein the daily averages of $\text{PM}_{2.5}$ were
180 lower than the second grade in China National Ambient Air Quality Standards
181 (CNAAQs) ($75 \mu\text{g m}^{-3}$) (Zhang et al., 2019) represented CD (January 9, 16, 17, 21, 22,
182 23, 26, and 31), with RH ranging from 4.6% to 78.9% and WS ranging from 0 m s^{-1} to
183 4.2 m s^{-1} . The days wherein the daily averages of $\text{PM}_{2.5}$ were between 75 and $115 \mu\text{g}$
184 m^{-3} represented PD (January 10, 15, 18, 20, 25, 27, and 28), with RH ranging from
185 17.1% to 86.3% and WS ranging from 0 m s^{-1} to 4.6 m s^{-1} . The days wherein the daily
186 averages of $\text{PM}_{2.5}$ were higher than $115 \mu\text{g m}^{-3}$ represented SPD (January 11, 12, 13,
187 14, 19, 24, 29 and 30), with RH ranging from 30.3% to 96.1% and WS ranging from
188 0 m s^{-1} to 3.5 m s^{-1} . Northwest or east wind was observed in most of the observation
189 periods, except for January 21–22. The WD was north, WS was high, the $\text{PM}_{2.5}$ con-
190 centration decreased rapidly, and the effect of pollution removal was evident. **Table 2**
191 lists the data statistics of HONO, $\text{PM}_{2.5}$, NO_2 , NO, NO_x , HONO/ NO_2 , HONO/ NO_x , O_3 ,
192 CO, T, RH, WS, and WD during the measurement period together with their mean value
193 \pm standard deviation. The meteorological parameters in **Table 2** show that the average

194 RH in CD, PD, and SPD periods was 32.8%, 48.6%, and 68.3%, respectively. In SPD,
195 RH was high and WD was low (mean value of 0.4 m s^{-1}).

196 In accordance with the data on trace gases, the average HONO values in CD, PD,
197 and SPD were 1.1, 2.3, and 3.7 ppbv, respectively. The mean values of NO_2 were 24.6,
198 33.2, and 41.7 ppbv (46.2 , 62.7 , and $78.4 \mu\text{g m}^{-3}$ lower than the first grade in CNAAQs
199 [$80 \mu\text{g m}^{-3}$]), respectively. The mean values of CO were 0.8, 1.3, and 1.8 ppmv (0.9 ,
200 1.5 , and 2.1 mg m^{-3} lower than the first grade in CNAAQs [4 mg m^{-3}]), respectively.
201 The variations of the average HONO, $\text{PM}_{2.5}$, NO_2 , and CO in the three periods were
202 similar. The mean values in the SPD period were the largest, and those in the CD period
203 were the smallest. The highest mean value of O_3 occurred in the CD period, similar to
204 previous observations (Hou et al., 2016; Huang et al., 2017; Zhang et al., 2019).

205 **Fig. 2** shows the concentration changes in HONO and gas species throughout the
206 measurement period. The HONO concentrations ranged from 0.2 ppbv to 14.8 ppbv
207 and had an average of 2.5 ppbv, which is higher than the average values of 0.6
208 (Rappenglück et al., 2013), 1.5 (Hou et al., 2016), and 1.0 ppbv (Huang et al., 2017) in
209 previous urban studies. The diurnal variations of HONO, NO, NO_2 , O_3 , HONO/ NO_2 ,
210 and HONO/ NO_x are illustrated in **Fig. 3**. After sunset, the HONO concentrations in CD,
211 PD, and SPD began to accumulate due to the attenuation of solar radiation and the
212 stabilization of the boundary layer (Cui et al., 2018). The maximum values of 1.7,
213 4.1, and 6.9 ppbv were reached in the morning (08:00–10:00 LT) in CD, PD, and SPD,
214 respectively. After sunrise, the HONO concentration decreased because of the increased
215 solubility and rapid photolysis then remained at a low level before sunset (14:00–16:00
216 LT). The diurnal variations of HONO during the measurement were similar in the three
217 periods, as shown in **Fig. S3**. The NO and NO_2 concentration increased in the morning
218 rush hours, decreased rapidly afterward, and remained low in the afternoon. After sun-
219 set, the concentrations of NO and NO_2 began to increase again and remained at a high
220 level after midnight until sunrise. Furthermore, the diurnal variation of NO in the CD
221 period was similar to that of NO_2 . The peak was reached at around 09:00 LT due to

222 vehicle emission in the morning rush hours, and the lowest value was observed at
223 around 16:00 LT. After 18:00 LT, the boundary layer height decreased in the evening
224 rush hours, resulting in an increase in NO and NO₂ concentrations (Hendrick et al.,
225 2014). O₃ showed a diurnal cycle and had maximum values in CD, PD, and SPD peri-
226 ods in the afternoon. The HONO/NO₂ ratio is commonly used to estimate the formation
227 of HONO in NO₂ transformation (Wang et al., 2013). Compared with HONO formation,
228 NO₂ transformation is less affected by diffusion during atmospheric migration (Li et
229 al., 2012). The HONO/NO₂ ratio in the CD period began to increase after sunset and
230 reached its peak at night. Then, it decreased in the morning as a result of the enhance-
231 ment of NO₂ emission and photolysis of HONO. However, the mean value of
232 HONO/NO₂ in PD and SPD periods gradually increased from nighttime and eventually
233 reached the maximum values of 14.3% and 18.9% at 09:00 and 10:00 LT, respectively.
234 This result indicates that the strength of the heterogeneous reaction increased slightly
235 with the exacerbation of pollution. The HONO/NO₂ ratio showed a diurnal cycle with
236 a low level in the afternoon and a high level after sunset due to the heterogeneous reac-
237 tion of NO₂ on the ground and aerosol surface (Su et al., 2008b). For comparison, the
238 daytime and nighttime HONO, HONO/NO₂, and HONO/NO_x mean values in other
239 cities around the world are listed in **Table 1**. The values of HONO, HONO/NO₂, and
240 HONO/NO_x in Zhengzhou are relatively higher than those in other parts of the world.

241 **3.2. Nocturnal HONO sources and formation**

242 **3.2.1. Homogeneous reaction of NO and OH**

243 The homogeneous reaction of NO and OH (R2 and R3) is the main pathway of
244 HONO formation in the gas phase. Spataro et al. (2013) found that the formation mech-
245 anism leads to an increase in HONO in high-pollution areas with an increase in NO at
246 night (Spataro et al., 2013). $P_{\text{OH}+\text{NO}}^{\text{net}}$ can be understood as the net hourly HONO pro-
247 duction amount of homogeneous reaction and is calculated as

$$248 \quad P_{\text{OH}+\text{NO}}^{\text{net}} = k_{\text{OH}+\text{NO}} [\text{OH}][\text{NO}] - k_{\text{OH}+\text{HONO}} [\text{OH}][\text{HONO}] \quad (2)$$

249 At T=298 K and P=101 kPa, the rate constants of $k_{\text{OH}+\text{NO}}$ and $k_{\text{OH}+\text{HONO}}$ are

250 9.8×10^{-12} and 6.0×10^{-12} $\text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$, respectively. [OH] is the concentration of
251 OH radicals that cannot be obtained in the measurement. Therefore, in reference to
252 Beijing, the average value of OH measured in Zhengzhou at night can be assumed to
253 be 1.0×10^6 $\text{cm}^3 \text{molecule}^{-1}$ (Lelieveld et al., 2016). $P_{\text{OH}+\text{NO}}^{\text{net}}$ primarily depends on the
254 concentrations of NO and HONO because the reaction rates of $\text{kOH}+\text{NO}$ and $\text{kOH}+\text{HONO}$
255 are close. **Fig. 4** shows the nocturnal variations of $P_{\text{OH}+\text{NO}}^{\text{net}}$, NO, and HONO during CD,
256 PD, and SPD periods. When the NO levels were high, the variations of $P_{\text{OH}+\text{NO}}^{\text{net}}$ fol-
257 lowed those of NO during the three periods (Atkinson et al., 2004). The mean value of
258 $P_{\text{OH}+\text{NO}}^{\text{net}}$ was 1.31 ppbv h^{-1} , and the specific values in CD, PD, and SPD periods were
259 0.51 , 1.03 , and 2.18 ppbv h^{-1} , respectively.

260 $P_{\text{OH}+\text{NO}}^{\text{net}}$ varied from 0.04 ppbv h^{-1} to 1.89 ppbv h^{-1} during the CD period. The
261 mean value of $P_{\text{OH}+\text{NO}}^{\text{net}}$ increased before midnight, decreased after midnight, and in-
262 creased slightly at 3 am. In the PD period, $P_{\text{OH}+\text{NO}}^{\text{net}}$ ranged from 0.26 ppbv h^{-1} to 1.74
263 ppbv h^{-1} . The situation was similar to that in the CD period, except that the value re-
264 mained almost constant. In addition, the contribution of HONO from homogeneous
265 reaction during the SPD period was larger than those in the CD and PD periods, and the
266 level of $P_{\text{OH}+\text{NO}}^{\text{net}}$, with an average value of 2.18 ppbv h^{-1} , was equal to the value in a
267 previous study (2.18 ppbv h^{-1} in Beijing) (Tong et al., 2015). From 19:00 LT to 03:00
268 LT, the mean value of $P_{\text{OH}+\text{NO}}^{\text{net}}$ increased from 0.59 ppbv h^{-1} to 3.60 ppbv h^{-1} . HONO
269 increased from 2.84 ppbv to 4.59 ppbv and subsequently decreased to 4.43 ppbv . By
270 integrating $P_{\text{OH}+\text{NO}}^{\text{net}}$ during the eight hours, the homogeneous reaction can provide an
271 accumulated HONO formation of at least 13.41 ppbv (i.e., $0.59 + 0.79 + 1.01 + 1.03 +$
272 $1.38 + 2.21 + 2.80 + 3.60 \text{ ppbv}$). However, the mean accumulation value of measured
273 HONO in this nighttime period was merely 1.59 ppbv . With the increase in pollution
274 level, the HONO accumulation time at nighttime increased. This result indicates that
275 first, the homogeneous reaction of $\text{OH} + \text{NO}$ is sufficient to augment HONO in the first
276 half of the night, although NO_2 transformation and other sources may still exist. When
277 the concentration of NO is relatively high, the net production generated by $\text{OH} + \text{NO}$

278 may be the leading factor for the increase in HONO at night (Tong et al., 2015). Second,
279 the hourly abatement level of HONO abatement pathways, except OH + HONO, should
280 be at least 1.47 ppbv h^{-1} (i.e., $13.41 - 1.59 \text{ ppbv} / 8 \text{ h}$). The contributions of other
281 HONO abatement pathways in the current work even exceeded the formation of hetero-
282 geneous reactions, similar to a previous study (Spataro et al., 2013).

283 3.2.2. Direct emission

284 At present, no HONO emission inventory or emission factor database for Zheng-
285 zhou is available. As a result, estimating any HONO from direct emission is difficult.
286 In the current study, directly emitted HONO could have been generated by vehicle ex-
287 haust and biomass combustion because no pollution source was near the measurement
288 site. Hence, only night data (17:00–06:00 LT) were considered to avoid the problem of
289 instant photolysis of directly emitted HONO. In a previous study, the HONO/NO_x ratio
290 from tunnel measurement was set to 0.65% to estimate an upper limit of HONO emitted
291 by traffic near the site (Kurtenbach et al., 2001). The minimum value of HONO/NO_x
292 in the SPD period in the current work was 1.5%, which is slightly higher than the value
293 measured in the abovementioned study. Directly emitted HONO at night was not trans-
294 formed immediately. The HONO concentrations corrected by direct emissions are given
295 as

$$296 \quad [\text{HONO}]_{\text{correct}} = [\text{HONO}] - [\text{HONO}]_{\text{emission}} = [\text{HONO}] - 0.0065 \times [\text{NO}_x], \quad (2)$$

297 where $[\text{HONO}]_{\text{emission}}$, $[\text{NO}_x]$, and 0.0065 are direct emission HONO concentration,
298 NO_x concentration, and HONO/NO₂ direct emission ratio, respectively. The direct
299 emission contribution was estimated by comparing the direct emission HONO with the
300 observed HONO. The ranges of HONO_{emission}/HONO in CD, PD, and SPD periods were
301 2%–52%, 6%–34%, and 2%–41%, respectively, and the mean values were 17%, 16%,
302 and 16%, respectively. The frequency distribution of the HONO_{emission}/HONO ratio at
303 nighttime is shown in **Fig. 5**. For this upper limit estimation, the frequency distribution
304 of HONO_{emission}/HONO (less than 20%) was approximately 76.7%. Hence, direct emis-
305 sion may not be the main reason for the high growth of HONO levels. Compared with

306 the direct emission of other sites, that of the measurement site accounted for a lower
307 proportion possibly because the site is relatively far from the highway in the campus.

308 **3.2.3. Heterogeneous conversion of NO₂ to HONO**

309 NO₂ is an important precursor for HONO formation. In addition, recent
310 field measurements in many urban locations have shown that a positive cor-
311 relation exists between HONO and NO₂ (Cui et al., 2018; Hao et al.,
312 2006; Huang et al., 2017; Zhang et al., 2019), suggesting they have a com-
313 mon source. Moreover, (Acker et al., 2005) reported that different
314 meteorological conditions may lead to significant differences in the rela-
315 tionship between the source and receptor, and these differences lead to
316 various types of correlation. During the measurement period, the
317 HONO/NO₂ ratio varied between 1.3% and 59.0%, with an average of 7.6%,
318 which is slightly higher than the 6.2% average in a previous study (Cui et
319 al., 2018). The HONO/NO₂ ratio calculated in this work is much larger than
320 that calculated for direct emission (< 1%) (Kurtenbach et al., 2001), suggesting
321 that heterogeneous reactions may be a more important pathway for HONO
322 production than direct emissions. With regard to the heterogeneous conver-
323 sion of NO₂, several studies (An et al., 2012; Shen and Zhang, 2013) have
324 reported that the surface of soot particles is the medium. The contribution
325 of soot surface to HONO production is usually much lower than expected
326 because the uptake efficiency of NO₂ decreases with the prolonged reaction
327 time caused by surface deactivation. The aerosol surface is an important
328 medium for the heterogeneous transformation from NO₂ to HONO (Liu et
329 al., 2014). The mass concentration of aerosols was used as an alternative to
330 identify the influence of aerosols in this study because the surface density of
331 aerosols could not be obtained.

332 The correlations between PM_{2.5} and HONO/NO₂ ratio in CD, PD, and
333 SPD periods are shown in **Fig. 6**. With the exacerbation of the PM_{2.5} level,

334 the average value of HONO/NO₂ gradually increased, indicating that the
335 aerosol surface occupied an important position in the heterogeneous trans-
336 formation. Comparison of HONO/NO₂ and HONO with PM_{2.5} showed that
337 the correlation between HONO/NO₂ and PM_{2.5} ($R^2=0.23$) was weaker than
338 that between HONO and PM_{2.5} ($R^2=0.55$) in the entire period. The main
339 source of HONO could not have been the transformation of NO₂. Notably,
340 the HONO correlation in the PD period was significantly stronger than that
341 in the two other periods. This result proves that HONO-related reactions
342 occurred more frequently during this period. The increased HONO in ambi-
343 ent air during the pollution period could have been caused by the
344 comparatively high loading and large particle surface (Cui et al., 2018).
345 Similar phenomena have been observed in a correlation study on CO and
346 HONO wherein CO was used as a tracer for traffic-induced emissions and
347 tested by considering the correlation between HONO and CO over an iden-
348 tical time interval (Qin et al., 2009). The correlation coefficient between
349 HONO and CO was relatively moderate ($R^2=0.43$), indicating that HONO
350 and CO processes affected most cases.

351 The absorbed water influenced the heterogeneous formation (Stutz et
352 al., 2004). The influence of RH on the heterogeneous conversion is shown
353 in **Fig. 6(d)**. When RH was less than 52%, the HONO/NO₂ ratio slowly in-
354 creased. When RH was greater than 52% but less than 77%, the HONO/NO₂
355 ratio began to increase rapidly with RH. The HONO/NO₂ ratio decreased
356 when RH was further increased. Similar variation patterns have been ob-
357 tained in previous studies (Huang et al., 2017; Qin et al., 2009; Tong et al.,
358 2015). Surface adsorbed water functions not only as sources but also as
359 sinks of HONO by affecting the hydrolysis of NO₂ and the sedimentation of
360 HONO to generate HONO (Ammann et al., 1998). When RH ranged from 52%

361 to 77%, the moisture effect of HONO was more severe than that of sedi-
362 mentation. This phenomenon confirms that RH improved the conversion
363 efficiency (Stutz et al., 2004). However, the surface reached saturation when
364 RH was greater than 77%. The excess water restricted NO₂ transformation
365 (Wojtal et al., 2011). The absorption and dissolution of HONO by the satu-
366 rated surface water layer caused HONO/NO₂ ratio to decrease drastically.

367 The study of the correlation between HONO_{correct} and NO₂ at nighttime
368 is shown in **Fig. S4**. HONO_{correct} was used in the calculation to exclude the
369 influence of direct emission on NO₂ conversion. The nocturnal variations
370 of HONO_{correct}, NO₂, and HONO_{correct}/NO₂ ratios in the CD, PD, and SPD
371 periods are presented in **Fig. 7**. In general, the HONO_{correct}/NO₂ ratio
372 reached its maximum at or before midnight but decreased after midnight. In
373 the PD and SPD periods, HONO was generated by heterogeneous reaction
374 (R4), and NO₂ decreased. The production of HONO was equal to its loss
375 (mainly night deposition), and HONO concentration reached a relatively
376 stable state (Stutz, 2002). The weak correlation between nighttime
377 HONO/NO₂ and PM_{2.5} can be reasonably explained by the stable HONO_{cor-}
378 _{rect}/NO₂ ratio after midnight (Qin et al., 2009). A previous study (Xu et al., 2015)
379 found that a low HONO_{correct} in the first half of the night (19:00–00:00 LT)
380 indicates an important contribution of automobile exhaust emissions, and a
381 low HONO_{correct} in the second half of the night means heterogeneous reac-
382 tions dominate. Therefore, the heterogeneous reaction conversion rate of
383 HONO was calculated in then current study by using the data of HONO_{correct}.

384 The conversion rate of HONO (C_{HONO}) is usually used as an indicator
385 to test the efficiency of NO₂ heterogeneous reactions. Total HONO_{correct} was
386 assumed to be generated by the heterogeneous transformation of NO₂. The
387 formula for the conversion rate of NO₂ (C_{HONO}) is as follows (Su et al.,
388 2008a; Xu et al., 2015):

$$C_{\text{HONO}} = ([\text{HONO}_{\text{correct}}]_{t_2} - [\text{HONO}_{\text{correct}}]_{t_1}) / (t_2 - t_1) [\text{NO}_2], \quad (3)$$

389 where $[\text{NO}_2]$ is the average concentration of NO_2 within the t_2-t_1 time in-
390 terval (1 h). In this study, the average conversion rate of NO_2 was 1.02×10^{-2}
391 h^{-1} . The mean values of C_{HONO} in the CD, PD, and SPD periods were
392 0.72×10^{-2} , 0.64×10^{-2} , and $1.54 \times 10^{-2} \text{ h}^{-1}$, respectively. The conversion rates
393 in this study were 0.58×10^{-2} and $1.46 \times 10^{-2} \text{ h}^{-1}$ higher than those of Beijing
394 I (polluted) and II (heavily polluted) periods, respectively. The improve-
395 ment of the conversion rate demonstrates that NO_2 had high reaction
396 efficiency through the process from NO_2 to HONO in the aggravation of
397 pollution, which could have led to the high utilization efficiency of the aer-
398 osol surface due to good particle surface properties (e.g., surface type and
399 moisture).

401 3.3. Daytime HONO budget

402 $\frac{d \text{HONO}}{dt}$ represents the observed variations of hourly HONO concen-
403 trations, for which we can use $\Delta \text{HONO} / \Delta t$ instead. P_{unknown} is the production
404 rate by an unknown daytime HONO source. $P_{\text{OH}+\text{NO}}$ is the rate of reaction of
405 NO and OH . P_{emi} represents the direct emission rate of HONO from combus-
406 tion processes. The heterogeneous transformation mechanism was assumed
407 to be the same for day and night. Therefore, the daytime heterogeneous
408 productivity ($P_{\text{het}} = C_{\text{HONO}} \times [\text{NO}_2]$) was calculated with the nighttime mean
409 values of C_{HONO} in the different periods. $L_{\text{OH}+\text{HONO}}$ is the rate of the reaction
410 between OH and HONO (R3). The calculation formulas of $P_{\text{OH}+\text{NO}}$ and
411 $L_{\text{OH}+\text{HONO}}$ have been provided in Section 3.2.1. Upon sunlight irradiation, an
412 OH radical and NO were formed as R1. L_{photo} represents the photolysis loss
413 rate of HONO ($L_{\text{photo}} = J_{\text{HONO}} \times [\text{HONO}]$). The photolysis frequency and OH
414 radical concentration could not be directly measured in this study. Therefore,
415 the tropospheric ultraviolet and visible (TUV) transfer model of the Na-
416 tional Center for Atmospheric Research

417 (http://cprm.acom.ucar.edu/Models/TUV/Interactive_TUV/) (Hou et al.,
418 2016) was used to calculate the J_{HONO} value. The concentration of OH radi-
419 cals was calculated with the formulas of NO_2 , O_3 , and $J_{\text{O}^1\text{D}}$ (Rohrer and
420 Berresheim, 2006). Aerosol effects were considered by using aerosol optical
421 thickness (AOD), single scattering albedo (SSA), and Angstrom exponent
422 as inputs in the TUV model. Typical AOD, SSA, and Angstrom exponent
423 values of 1.32, 0.9, and 1.3, respectively, were adopted for the PD and SPD
424 periods. In the CD period, the respective values were 0.66, 0.89, and 1.07
425 (Che et al., 2015; Cui et al., 2018; Hou et al., 2016). The average profiles of
426 J_{HONO} and $J_{\text{O}^1\text{D}}$ concentrations in the CD, PD, and SPD periods are shown in
427 **Fig. 8**. The mean values of J_{HONO} and OH radical concentration in the CD,
428 PD, and SPD periods were 5.93×10^{-4} , 3.79×10^{-4} , and 3.79×10^{-4} cm^3 mole-
429 $\text{cule}^{-1} \text{ s}^{-1}$ and 4.10×10^6 , 2.93×10^6 , and 3.76×10^6 cm^3 molecule $^{-1} \text{ s}^{-1}$, re-
430 spectively. The results of the calculated OH radicals ranged from $(0.58-11.49) \times 10^6$
431 cm^3 molecule $^{-1} \text{ s}^{-1}$, and the mean value was 3.57×10^6 cm^3 molecule $^{-1} \text{ s}^{-1}$ at noon in
432 Zhengzhou.

433 By studying the source and reduction, the daytime HONO budget was analyzed
434 with Eq. (4) (Su et al., 2008b).

$$435 \quad \frac{d \text{HONO}}{d t} = \text{sources} - \text{sinks}$$
$$436 \quad = (\text{P}_{\text{unknown}} + \text{P}_{\text{OH}+\text{NO}} + \text{P}_{\text{emi}} + \text{P}_{\text{het}}) - (\text{L}_{\text{OH}+\text{HONO}} + \text{L}_{\text{photo}}) \quad (4)$$

$$437 \quad \text{P}_{\text{OH}+\text{NO}} = k_{\text{OH}+\text{NO}} [\text{OH}] [\text{NO}] \quad (5)$$

$$438 \quad \text{L}_{\text{OH}+\text{HONO}} = k_{\text{OH}+\text{HONO}} [\text{OH}] [\text{HONO}] \quad (6)$$

439 Each production and loss rate of daytime HONO during CD, PD, and
440 SPD periods are illustrated in **Fig. 8** together with $d\text{HONO}/dt$. $\text{P}_{\text{unknown}}$ was
441 at a high level before midday. $\text{P}_{\text{unknown}}$ approached 0 ppbv after midday. In
442 the CD, PD, and SPD periods, the mean values of $\text{P}_{\text{unknown}}$ were 0.26, 0.40,
443 and 1.83 ppbv h^{-1} , respectively; the mean values of $\text{P}_{\text{OH}+\text{NO}}$ were 1.14, 2.07, and
444 4.03 ppbv h^{-1} , respectively; the mean values of P_{emi} were 0.17, 0.30, and 0.43

445 ppbv h^{-1} , respectively; and the mean values of P_{het} were 0.14, 0.18, and 0.55
446 ppbv h^{-1} , respectively. The midday time P_{unknown} (1.83 ppbv h^{-1}) calculated in Zheng-
447 zhou during the winter haze pollution period was close to the result obtained from
448 Beijing's urban area (Hou et al., 2016) (1.85 ppbv h^{-1}). The P_{unknown} contribution to
449 daytime HONO sources in CD, PD, and SPD periods accounted for 15%, 14%, and
450 28% of the HONO production rate ($P_{\text{unknown}} + P_{\text{OH+NO}} + P_{\text{emi}} + P_{\text{het}}$), respectively. Previ-
451 ous studies (Spataro et al., 2013; Yang et al., 2014) have shown that meteorological
452 conditions, such as solar radiation and WS, can affect unknown sources. The low
453 P_{unknown} contribution of daytime HONO concentration may be related to the low solar
454 radiation and low wind speed during severe pollution. Although the values of $P_{\text{OH+NO}}$
455 had high uncertainty because of the NO concentrations, $P_{\text{OH+NO}}$ contributed the most to
456 HONO production during daytime. In addition to the photolysis of HONO and the ho-
457 mogeneous reaction of HONO and OH, one or more important sinks might exist to
458 control the variation between the sources and sinks of the daytime HONO during com-
459 plex contamination. However, further research is needed to analyze the unknown
460 sources of daytime HONO.

461 **4. Conclusions**

462 Ambient HONO measurement using AIM with other atmospheric pollutants and
463 meteorological parameters was conducted in the CPER. The HONO concentrations dur-
464 ing the entire measurement varied from 0.2 ppbv to 14.8 ppbv, with an average of 2.5
465 ppbv. The HONO concentrations in the CD, PD, and SPD periods were 1.1, 2.3, and
466 3.7 ppbv, respectively, and the HONO/NO₂ ratios were 4.7%, 7.1%, and 9.4%, respec-
467 tively. HONO concentration was a combined action of direct emission and
468 heterogeneous reaction, and the contributions of the two were higher than that of ho-
469 mogeneous reaction in the first half of the night. However, the proportion of
470 homogenization gradually increased in the second half of the night due to the steady
471 increase in NO concentration. The hourly abatement level of other HONO abatement
472 pathways aside from OH + HONO should be at least 1.47 ppbv h^{-1} in the SPD period.

473 The sum of the frequency distributions of the $\text{HONO}_{\text{emission}}/\text{HONO}$ ratio less than 20%
474 was approximately 76.7%, indicating that the direct emission of HONO was the main
475 source of the observed HONO level at night. The mean values of $\text{HONO}_{\text{emission}}/\text{HONO}$
476 in the CD, PD, and SPD periods were 17%, 16%, and 16%, respectively. This phenom-
477 enon means that the policy of restricting motor vehicles published by the local
478 government in January 2019 had a good effect on decreasing HONO emissions. In ad-
479 dition, when RH increased from 52% to 77%, the heterogeneous HONO production
480 increased, but it decreased when RH increased further due to the effect of surface water.
481 The contribution of the three sources varied with different pollution levels. The mean
482 values of C_{HONO} in the CD, PD, and SPD periods were 0.72×10^{-2} , 0.64×10^{-2} ,
483 and $1.54 \times 10^{-2} \text{ h}^{-1}$, respectively. At nighttime in the SPD period, the heterogene-
484 ous conversion of NO_2 appeared to be unimportant. Furthermore, the net production
485 generated by homogeneous reaction may be the leading factor for the increase in HONO
486 under high- NO_x conditions (i.e., the concentration of NO was relatively higher than
487 that of NO_2) at nighttime. The mean value of $P_{\text{OH}+\text{NO}}^{\text{net}}$ in the CD, PD, and SPD periods
488 were 0.51, 1.03, and 2.18 ppbv h^{-1} , respectively. Daytime HONO budget analysis
489 showed that the mean values of P_{unknown} in the CD, PD, and SPD periods were 0.26,
490 0.40, and 1.83 ppbv h^{-1} , respectively. Although the values of $P_{\text{OH}+\text{NO}}$ had high uncer-
491 tainty because of the variation of NO concentrations, $P_{\text{OH}+\text{NO}}$ contributed the most to
492 HONO production during daytime. After the analysis, C_{HONO} , $P_{\text{OH}+\text{NO}}^{\text{net}}$, and P_{unknown} in
493 the SPD period were larger than those in the other periods, indicating that HONO par-
494 ticipated in many reactions.
