Abstract. Photosensitizing compounds containing brown carbon can absorb UV light and transfer that energy to low volatile organic compounds at the surface of aqueous particles. To better understand the reactivity and photochemical aging processes of organic coating on the aqueous aerosol surface, we have simulated the photosensitized reaction of organic films made of several long chain fatty acids in a Langmuir trough in the presence or absence of irradiation. Several chemicals (imidazole-2-carboxaldehyde and humic acid), PM_{2.5} samples collected from the field and secondary organic aerosols samples generated from a simulation chamber were used as photosensitizers to be involved in the photochemistry of the organic films. Stearic acid, elaidic acid, oleic acid and two different phospholipids with the same carbon chain length and different degrees of saturation i.e., 1,2-distearoyl-sn-glycero-3-phosphocholine (DSPC) and 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC) were chosen as the common organic film-forming species in this analysis. The double bond (*trans* and *cis*) in unsaturated organic compounds has an effect on the surface area of the organic monolayer. The OA monolayer possessing a *cis* double bond in an alkyl chain is more expanded than EA monolayers on artificial seawater that contain a photosensitizer. Monitoring the change in the relative area of DOPC monolayers has shown that DOPC does not react with photosensitizers under dark conditions. Instead, the photochemical reaction initiated by the excited photosensitizer and molecular oxygen can generate hydroperoxidation in the DOPC monolayers, accompanied by an increase in the molecular area. The DSPC monolayers did not yield any photochemical oxidized products under the same conditions. The spectra measured with polarization modulation-infrared reflection absorption spectroscopy (PM-IRRAS) were also consistent with the results of a surface pressure-area isotherm. Here, a reaction mechanism explaining these observations is presented and discussed. The results will contribute to our understanding of the processing of organic aerosol aging that controls the aerosol composition.

1 Introduction

In the marine environment, the degradation of bacteria and diatoms can produce lipids, such as phospholipids, triacylglycerides, and glycolipids, which are the lipid-containing cellular components of microorganisms (Jeffrey, 1966). Phospholipids can either be transported from seawater into sea spray aerosol (SSA) or further transformed into fatty acids through heterotrophic breakdown. Long chain saturated fatty acids, such as palmitic acid and stearic acid, correspond to major constituents of the sea surface microlayer and are also detected in marine aerosols (Marty et al., 1979; Slowey et al., 1962; Wu et al., 2015). Unsaturated fatty acids with carbon chain lengths of 18-22 carbons also dominate the composition of seawater samples (Jeffrey, 1966; Osterroht, 1993). Oleic acid and elaidic acid were the most abundant unsaturated acids in seawater (Osterroht, 1993). The abundance of saturated fatty acids in PM₁₀ samples collected from the southeast coast of China was significantly higher than unsaturated fatty acids due to their enhanced photochemical stabilities and extensive atmospheric sources (Wu et al., 2015). In addition to biogenic sources, stearic acid, oleic acid and elaidic acid detected in PM₁₀ are primarily emitted from anthropogenic sources such as cooking, biomass burning and vehicle exhaust in urban areas. The sum concentration of linoleic acid and oleic acid can reach up to 10-38% of the total concentration of organic acids found in cooking emissions (Yang et al., 2013).

“Brown carbon” (BrC) refers to the type of light-absorbing organic aerosol material that efficiently absorbs radiation from visible to ultraviolet wavelengths in the atmosphere (Laskin et al., 2015; Andreae and Gelencser, 2006; Poschl, 2005). The fully dissolved organic fraction of BrC is referred to as water-soluble organic carbon (WSOC), while colloidal aggregates belong to water-insoluble organic carbon (WIOC). BrC can be generated from primary source, such as fossil fuel combustion and biomass burning. Multiple atmospheric reactions between gas and particle or aqueous phase also lead to secondary BrC production. Aerosol flow tube experiments suggest that the exposure of SOA particles produced from biogenic alkenes to gaseous ammonia could increase the complex refractive index (Flores et al., 2014). The addition of amino acids or ammonium ions to limonene SOA was also shown to produce BrC, which strongly absorbed visible light and fluoresced at visible and ultraviolet wavelengths (Bones et al., 2010). Typical BrC is a mixture of a large number of strongly absorbing chromophores that have unique molecular structures and evolved from non-absorbing precursors (Nguyen et al., 2012; Lee et al., 2013).

Photosensitizers in the atmosphere are an important group of BrC that absorb and convert the energy of photons into chemical energy that can facilitate reactions at aerosol surfaces (George et al., 2015). Therefore, photosensitizers can contribute to organic aerosol aging and growth when generating a triplet excited state that is susceptible to hydrocarbon oxidization upon absorbing light. These photosensitized reactions have been shown in the laboratory to induce to an abiotic source of volatile organic compounds (VOCs) and secondary organic aerosols (SOA) in the marine boundary layer (Rossignol et al., 2016; Tinel et al., 2016; Bernard et al., 2016). Traces of photosensitizing species in the aerosol phase, such as imidazoles, quinones and nitrophenols also contribute to SOA formation through their promoting effect with just a few radical reactions (Li et al., 2016; Desyaterik et al., 2013; Pillar and Guzman, 2017).

Imidazole-2-carboxaldehyde (IC) is a kind of BrC (Ackendorf et al., 2017; Arroyo et al., 2018; Rossignol et al., 2014), produced through the aqueous reaction of glyoxal or methylglyoxal with ammonium sulphate (Aiona et al., 2017). Recent works suggest that IC can act as an efficient photosensitizer in autophotocatalytic aerosol growth (Aregahegn et al., 2013; Rossignol et al., 2014; Palacios et al., 2016). For example, aerosol seeds containing IC can induce the reactive uptake
5 of VOCs when exposed to light, leading to SOA formation (Aregahegn et al., 2013). Humic-like substances (HULIS) are ubiquitous in the troposphere. These water-soluble organic materials are termed humic-like substances (HULIS) due to their similar properties to macromolecular humic substances, such as their amphiphilic and polyacidic nature, aromaticity, surface active properties and light absorption ability (Gelencser et al., 2002; Graber and Rudich, 2006; Sannigrahi et al., 2006; Krivacsy et al., 2008). HULIS correspond to 10–35% of fine organic materials in atmospheric aerosols and account for up to
10 72% of WSOC in some ambient aerosol samples (Emmenegger et al., 2007; Feczko et al., 2007). Humic substances (HS) consist of three operationally defined components: humic acids (HA), fulvic acids, and humins. These HS represent a fraction of the molecularly uncharacterized component of dissolved organic matter in the ocean (Zhu et al., 2017b). Humic acids in the ocean are widely believed to derive primarily from the products of marine phytoplankton degradation and less so from terrestrial sources (McCarthy et al., 1996). For primary marine aerosols, WSOC containing HULIS components was
15 suggested to originate from bubble-bursting at the surface of seawater, which transfers organic matter into marine aerosol particles (Cavalli et al., 2004; Yu et al., 2004). HULIS exist primarily in the droplet mode with aerodynamic diameter in the range of 0.7-0.8 μm (Wang and Yu, 2017). Primary sources of HULIS include fine smoke particles that correspond to the emission from motor vehicles, biomass burning and coal combustion (Fan et al., 2018). Both the chemical transformation and polymerization of gas and condensed-phase low-molecular-weight VOCs are the secondary sources of HULIS (Stone et al., 2009; Gelencser et al., 2002). The interfacial photochemistry of a palmitic acid monolayer involving humic acid as a
20 photosensitizer has been recently investigated (Shrestha et al., 2018). Therefore, the photochemistry of such organic films is attracting increasing attention, as the photosensitized reaction initiated by atmospheric samples containing BrC has not been investigated and the associated mechanism is not understood.

Here, we investigated the interfacial photochemical properties of WSOC from three different sources: i.) IC and HA
25 as identified proxies; ii.) SOA samples collected from a simulation chamber (regarded as a half-real atmospheric sample); and iii.) authentic $\text{PM}_{2.5}$ samples. To the best of our knowledge, the photosensitized reaction of organic Langmuir films involving chamber and atmospheric samples has not been previously investigated. Fatty acids and phospholipids such as 1,2-distearoyl-sn-glycero-3-phosphocholine (DSPC), 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC), stearic acid (SA), elaidic acid (EA) and oleic acid (OA) were selected as proxies of low volatile organic compounds of organic aerosols.
30 Langmuir monolayers at the air-aqueous interface were employed to mimic the organic films that coat the aqueous aerosols (Sobanska et al., 2015; Ruehl and Wilson, 2014; King et al., 2009; Sebastiani et al., 2018; Adams et al., 2016). The stability behaviour of these organic films under irradiation and the impact of photosensitizers on processing the aging of the aerosol are presented and discussed.

2 Experimental section

2.1 Materials and solutions

The zwitterionic phospholipids (DSPC and DOPC) were acquired from Avanti Polar Lipids Inc. The fatty acids (SA, EA and OA) were purchased from Sigma-Aldrich. All chemicals used in the experiment did not require further purification. 5
Ultrapure water (18.2 MΩ•cm) provided by a Milli-Q system (Millipore, France) was used to prepare the artificial seawater (ASW), which is a solution of multiple salts: 426 mM NaCl (≥99%, Acros), 55.5 mM MgCl₂ (99.9%, Alfa Aesar), 29.4 mM Na₂SO₄ (99%, Alfa Aesar), 10.8 mM CaCl₂ (99%, Adamas), 9.45 mM KCl (99%, Alfa Aesar), 2.43 mM NaHCO₃ (≥99.7%, Alfa Aesar), 0.86 mM KBr (≥99%, Acros), 0.44 mM H₃BO₃ (99.5%, Innochem), 0.074 mM NaF (≥99%, Acros), and 0.094 mM SrCl₂•6H₂O (≥99%, Alfa Aesar) (Brzowska et al., 2012; Brzowska et al., 2013). The photosensitizers imidazole-2-
10 carboxaldehyde (IC) (97%, Alfa Aesar) or HA (90%, Aladdin) were added into the ASW with concentrations of 2.5 mM and 30 mg/L, representatively. Five different subphases were used for our experiments: pure ASW, ASW with 2.5 mM IC, ASW with 30 mg/L HA, ASW with PM_{2.5} sample, and ASW with SOA sample. The molecular structures of DOPC, DSPC, SA, EA and OA are provided in Fig. 1(a).

2.2 Atmospheric PM_{2.5} sample collection and preparation

15 Atmospheric fine particulate matter samples were collected at the atmospheric observation station (36°40' N, 117°03' E) located in the central campus of Shandong University in January, 2016. A medium-volume PM_{2.5} sampler (TH-150 A, Wuhan Tianhong, China) was used to collect PM_{2.5} samples on Isopore™ membrane filters (90 mm diameter, 0.4 μm pore size; HTTP, Merck Millipore, Germany). The flow rate of sampling was 100 L/min. The filter samples were sealed and stored at -20 °C before the experiment. All the filters were dissolved into 40 mL ultrapure water with ultrasonic agitation.
20 After sonication, the suspension was centrifuged at 1780 g for 40 min. The supernatant, which contains the water soluble fraction including water-soluble organic compounds (WSOC) and inorganic ions, was transferred to the artificial seawater.

2.3 Chamber sample preparation

The laboratory SOA samples were generated from a 1 m³ FEP-Teflon film chamber at room temperature (298 ± 2 K) and atmospheric pressure. The details of the chamber including the experimental setup and the schematic of the smog chamber facility have been previously described (Liu et al., 2019; Wang et al., 2018; Zhu et al., 2017a). To maximize and homogenize the intensity of radiation, stainless steel mirror surfaces were used as the interior wall of the chamber enclosure. The chamber was surrounded by a total of twelve black lamps (Philips TUV 36 W) with a peak intensity at 365 nm to simulate actinic UV irradiation. Purified air produced by a zero air gas generator (111-D3N, Thermo Scientific, USA) was used as background. Prior to each experiment, the chamber was cleaned by zero air for more than 4 h. Liquid droplet
30 ammonium sulphate seed particles were injected into the chamber by nebulizing a 0.6 M ammonium sulphate ((NH₄)₂SO₄) aqueous solution with an aerosol generator (Model 3076, TSI, USA). A custom diffusion dryer was added after aerosol

generator to make sure that the $(\text{NH}_4)_2\text{SO}_4$ aerosols in solid phase in chamber. The total gas volume in the chamber was recorded with mass flow meters (D80-8C/ZM, Beijing Sevenstar, China). Limonene (99%, tci) was injected into the chamber by a micro syringe and was evaporated into a stream of purified air. Then, an aqueous H_2O_2 solution (30 wt %) was injected to the chamber and served as the OH precursor in these experiments. NO was introduced into the chamber by a gas-tight
5 syringe. Typically, 800 ppb limonene and $5 \times 10^4 \text{ cm}^{-3}$ $(\text{NH}_4)_2\text{SO}_4$ seed aerosols were employed. The SOA particles were collected on pieces of aluminium foil with 25 mm diameter by using a 13-stage Dekati low-pressure impactor (DLPI) (DLPI+, Dekati Ltd, Finland). The particle sizes that were collected by DLPI at a sampling flow rate of 10 L min^{-1} ranged from 30 nm to 10 μm . Then, the SOA samples collected on the aluminium foil pieces were dissolved in ultrapure water and added to the artificial seawater.

10 2.4 Langmuir and irradiation experiments

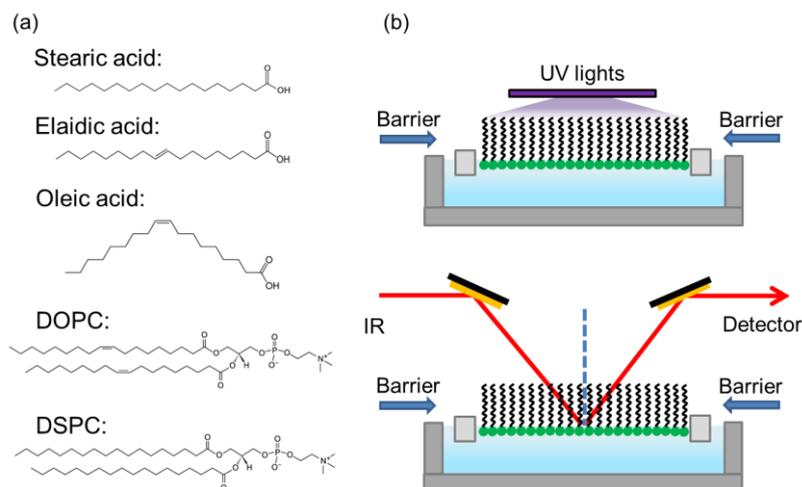

Langmuir and irradiation experiments were performed in a Langmuir trough (Riegler & Kirstein GmbH, Germany). The phospholipid and fatty acid monolayers were prepared by dropping 1 mM chloroform stock solution onto the artificial seawater containing the photosensitizer. After spreading the surfactant solution, ten to fifteen minutes were allowed for the evaporation of solvent before compression and subsequent measurements. Both the surface pressure and molecular area of
15 the Langmuir monolayers were measured with the Wilhelmy plate method during the barrier compression at a constant barrier speed of 3 mm/min. The plate was made of a 3 mm-wide filter paper. A Plexiglass cover was used to guarantee that the experimental condition was relatively sealed. The change of surface pressure at the same molecular area was measured within $\pm 2 \text{ mN/m}$. For area relaxation measurements, the phospholipid monolayers were held at a constant surface pressure of 25 mN/m and the change in molecular area with time was recorded. The irradiation experiments were also conducted at the
20 surface pressure equilibrium of 25 mN/m. The trough was illuminated by three UV lights (Philips TUV 8 W) with wavelengths 365 nm, which does not produce ozone. The irradiation and non-irradiation experiments were conducted with or without the photosensitizers.

2.5 Polarization modulation-infrared reflection absorption spectroscopy measurements

Polarization modulation-infrared reflection absorption spectroscopy (PM-IRRAS) (Bruker, Germany) experiments
25 were conducted to detect the change of organic films at the air–aqueous interface in both dark and irradiation conditions. The incident angle of light beam was set as 40° . The polarization modulation can modulate incident light into p polarization (perpendicular to the reflection plane) and s polarization (parallel to the reflection plane). The difference between the s-polarized and p-polarized spectra can provide information on the organic films at the air–aqueous interface. The spectra were recorded at both polarizations simultaneously due to the high scanning frequency of 42 kHz, thus eliminating the effects of
30 the water vapour and carbon dioxide. When the surface pressure of the organic monolayer reached the set value of 25 mN m^{-1} , the IRRAS spectra were recorded in the range of $400\text{--}4000 \text{ cm}^{-1}$. Each spectrum averaged 2000 scans and had a resolution of 8 cm^{-1} . In the irradiation experiment, first the black lamp was turned on at the surface pressure of 25 mN m^{-1} ,

starting irradiation. IRRAS spectra were measured when 1.5 h irradiation was finished. The experiments in the absence of irradiation were performed to guarantee that the shifts of band position are induced by photochemical oxidation and not related to spectra variability. **Fig. 1(b)** shows a schematic of the IRRAS and irradiation setups.

3 Results and discussion

3.1 Packing and phase behaviour of lipid monolayers

10 Pure water is relatively transparent to the near-infrared and near ultraviolet wavelengths of light. Dissolved salts in seawater have no light absorption under visible light but slight absorption under ultraviolet light (Carpenter and Nightingale, 2015). The surface pressure–area (π -A) isotherms recorded for DOPC and DSPC monolayers on artificial seawater with and without photosensitizers are shown in **Fig. 2(a)** and **(b)**, respectively. Owing to the amphiphilic characteristics of phospholipids, the head groups of DOPC and DSPC molecules prefer to be in the aqueous phase while their chains stretch
15 into the air phase. When the surface area of the DOPC monolayer was larger than $125 \text{ \AA}^2/\text{molecule}$, the distance between the DOPC molecules was quite large and the intermolecular force was quite weak. The surface pressure of a DOPC monolayer on artificial seawater started to increase from $125 \text{ \AA}^2/\text{molecule}$. The DOPC monolayer surface state underwent a transition from the gas to the liquid phase. This caused condensation and ordering at the interface, increasing the surface pressure of the organic monolayer. Finally, the DOPC monolayer collapsed at 46 mN/m (Pereira et al., 2018). The π -A isotherms of the
20 DOPC monolayers were shifted to larger molecular areas upon the introduction of the photosensitizing molecules into the bulk artificial seawater. Due to their high water solubility, pure IC and HA molecules cannot form Langmuir monolayers. The collapse pressure of DOPC monolayer decreased from 46 to 28 mN/m with the addition of IC. The collapse pressure for

the DOPC monolayer on the artificial seawater with HA was even lower. The DOPC monolayers on the artificial seawater containing water-soluble organic species extracted from PM_{2.5} and SOA samples also shifted to larger areas. The collapse pressure for the DOPC monolayer on the artificial seawater with PM_{2.5} sample was 41 mN/m. The π -A isotherm of the DOPC monolayer on artificial seawater mixed with SOA sample coincided with that of the DOPC monolayer on the artificial seawater with IC in both the liquid and condensed phase. Finally, the curve the DOPC monolayer on artificial seawater containing SOA sample showed a collapse pressure similar to that on pure artificial seawater.

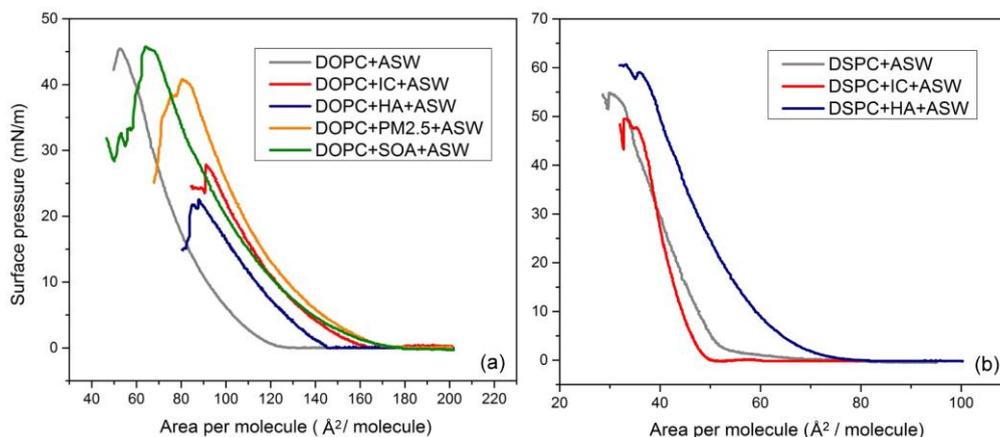

Figure 2: Surface pressure–area (π -A) isotherms of (a) DOPC and (b) DSPC monolayers on artificial seawater (ASW) containing IC, HA, PM_{2.5} and SOA samples.

10

In line with previous studies, DSPC molecules pack closely and form numerous van der Waals bonds to hold the DSPC monolayer together, with a collapse pressure was 55 mN/m (Chou et al., 2002; Yin et al., 2016). Although the structures of DSPC and DOPC are quite similar, the lift-off area for the DSPC monolayer on artificial seawater was smaller than that for the DPPC monolayer in **Fig. 2(b)**. The difference of lift-off areas can be attributed to the unsaturated aliphatic chains in the DOPC molecule, which induce a less ordered structure relative to DSPC with saturated chains. The less tight packing of the hydrocarbon tail in DOPC could create more space for the incorporation of photosensitizer molecules, which is in good agreement to the earlier report (Aoki et al., 2016). The introduction of photosensitizers into the subphase also had a profound effect on the shape of π -A isotherms for DSPC monolayers. At any fixed surface pressure, the molecular area for the DSPC monolayer on artificial seawater with HA was much larger than that for just the DSPC monolayer.

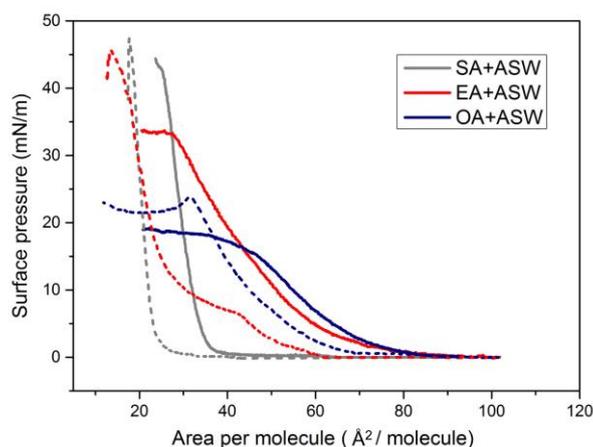

20

As shown in **Fig. 3**, the lift-off area for the SA monolayer is 40 Å²/molecule, which is substantially smaller than the lift-off areas for the EA and OA monolayers. Completely saturated stearic acid has a straight chain which can pack tightly into a solid phase. The surface pressure of EA and OA monolayers began increasing at the same molecular area of 82 Å²/molecule. The unsaturation in the alkyl chains of EA and OA is responsible for the differences in the lift-off areas. Compared to a fully saturated SA with the same number of carbon atoms, elaidic acid and oleic acid molecules possessing a double bond cannot be fully condensed into monolayer. However, the EA monolayer can reach a maximum surface pressure

25

of 34 mN/m, which is higher than that of OA (20 mN/m). Elaidic acid has a double bond at the number 9 carbon. The double bond of alkane chain in elaidic acid is *trans*, therefore elaidic acid molecule remains straight and can still pack well in a monolayer (Kanicky and Shah, 2002). Oleic acid is the *cis*-isomer of elaidic acid. The kink and bend of the alkyl chain at the position of the *cis* double bond induced steric hindrance during the compression of oleic acid molecules. The oleic acid monolayer was less able to pack as tightly as elaidic acid and form a liquid-expanded phase.

10 **Figure 3: Surface pressure–area (π – A) isotherms of SA, EA and OA monolayers on ASW (solid line) and ASW containing IC (short dashed line) solutions.**

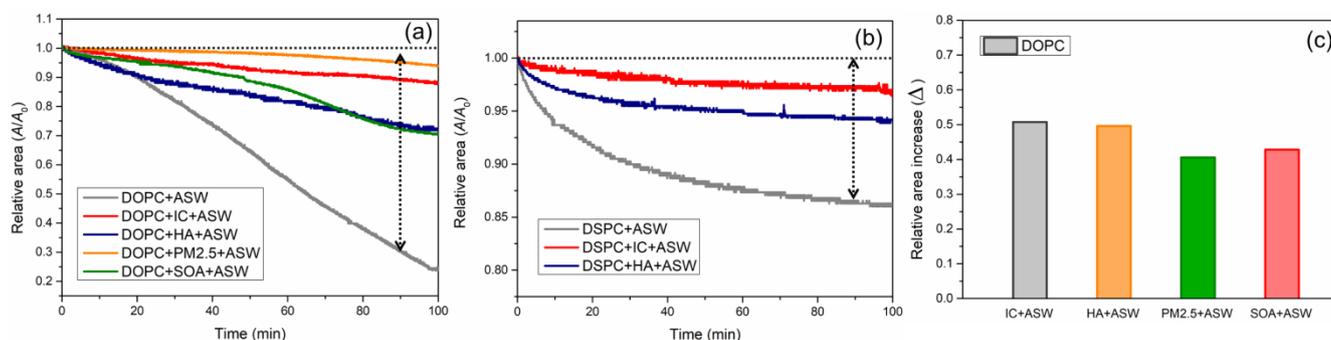

In the presence of IC in the artificial seawater, the fatty acid monolayers shifted to smaller areas and had higher collapse pressures relative to pure artificial seawater. The lift-off area value of 60 $\text{\AA}^2/\text{molecule}$ for EA monolayer on artificial seawater containing IC is larger compared to saturated SA monolayer on the same subphase, reflecting that the *trans*-double bond in the alkyl chain of EA also produces an obstructive effect on molecular packing. In contrast to the OA monolayers, the EA monolayers on the artificial seawater containing IC transitioned from expanded to condensed phases during the monolayer formation. These results indicate that *trans*-double bonds drastically increase more attractive interactions than *cis*-double bonds among the unsaturated hydrocarbon chains. Additionally, the EA monolayer exhibits the liquid-condensed phase transition below 17 $^{\circ}\text{C}$ (Iimura et al., 2001). The behaviour in the condensed phase of the EA monolayer is similar to that of the SA monolayer. The EA monolayer on the artificial seawater containing IC collapsed at the surface pressure of 46 mN/m. As such, there is a remarkable obstructive effect on the ordering of organic film for the film-forming molecule that contain a *cis*-double bond. On the other hand, the OA has a greater tendency to form expanded monolayers. The *cis*-double bond in OA disturbs close packing of the molecules and weakens the chain-chain attractive interaction (Iimura et al., 2001). The collapse of the OA monolayer on the artificial seawater containing IC occurred in the liquid state at a surface pressure of 24 mN/m.

3.2 Stability of lipid monolayers under irradiation

In order to get a better understanding of stability behaviour and relaxation mechanism for lipid monolayers at the air–water interface, we measured area relaxation curves at a fixed surface pressure of 25 mN m^{-1} for both dark and irradiated experiments. The change in relative area (A/A_0) for the lipid monolayer was analysed as a function of time. The irradiated and non-irradiated curves of DOPC and DSPC monolayers are shown in **Fig. S1-S8**. The curve for the DOPC monolayer on pure artificial seawater exposed to the illumination was similar to that without irradiation (**Fig. S1**). There was no photosensitized reaction with only artificial seawater solutions. The decreasing trend of the molecular area for the irradiated DOPC monolayer on artificial seawater was due to the loss of organic molecules in the subphase. The rapid loss of molecular area on pure artificial seawater was related to spontaneous lipid degradation by oxidation, which was induced by reactive oxygen species in the air (Liljeblad et al., 2010). As shown in **Fig. 4(a)**, considerable changes of molecular areas for the DOPC monolayer were observed when the irradiation started in presence of a photosensitizer. The area of the DOPC monolayer on pure artificial seawater was reduced to 30% under the irradiation. There was evidently a much greater change in the decay rate of the DOPC monolayer upon the addition of photosensitizer molecules to the subphase of artificial seawater. The presence of photosensitizing molecules in the subphases decreased the loss of the molecular area for the DOPC monolayer. In the case of artificial seawater containing IC and HA (**Fig. 4(a)**), the molecular area of the DOPC monolayer after 90 minutes of irradiation was reduced to 89% and 74%, respectively. The loss of molecular area for the DOPC monolayer on the artificial seawater containing the SOA sample was similar to that in artificial seawater containing HA. In the presence of artificial seawater mixed with the $\text{PM}_{2.5}$ samples, there was only a 5% loss of the molecular area of the DOPC monolayer after 90 minutes of irradiation.

20

25

Figure 4: (a) Relative area (A/A_0) of the relaxation curves of irradiated DOPC monolayers on artificial seawater containing IC, HA, $\text{PM}_{2.5}$ and SOA samples, respectively. (b) Relative area (A/A_0) of the relaxation curves of irradiated DSPC monolayers on artificial seawater containing IC and HA, respectively. (c) Relative area increase (Δ) of DOPC monolayer after 90 minutes; this value was calculated from the difference between the irradiated and non-irradiated curves (Figures S2-S5). A_0 is the molecular area of monolayer at 25 mN/m .

There were no significant changes of the molecular areas for the DSPC monolayers with and without exposure to light (**Fig. S6-8**). In the irradiation experiments, the decrease of the DSPC monolayer area in artificial seawater with IC and HA is less than 5% after 90 minutes (**Fig. 4(b)**). The loss of the DSPC monolayer area 90 minutes of irradiation is at least 13%, with respect to the subphase of pure artificial seawater without photosensitizers. The area loss observed for lipid monolayers for the different compositions of the subphases, at a constant surface pressure, is indicative of their stability (Avila et al., 1999). Accordingly, DSPC monolayers are typically more stable than DOPC ones, irrespective of irradiation. The smaller loss of molecular area suggested that the presence of photosensitizer molecules in the subphase improved the stability of the lipid monolayer relative to pure artificial seawater.

In the presence of photosensitizers, the relative areas of the irradiated DOPC monolayers became larger than those of the non-irradiated DOPC (**Fig S2-5**). This effect is clearly shown where the effect of the photosensitizer on both the DOPC monolayer in the dark and irradiation is illustrated as a relative increase in area (Δ) (**Fig. 4(c)**). The presence of IC in the subphase yielded a relative area increase (Δ) of 51% for DOPC monolayer. The relative area increase for the DOPC monolayer with the PM_{2.5} sample after 90 minutes of irradiation reached 41%. The relative increases of molecular area for the DOPC monolayer mixed with HA and SOA samples were 50% and 43%, respectively. Pure chemicals (IC and HA) were more efficient in increasing the relative area of unsaturated organic monolayer. Compared to the experiments without irradiation, DOPC monolayers were considerably more stable upon irradiation with a photosensitizer. In irradiation experiments, the relative areas of the DSPC monolayer on the artificial seawater mixed with IC or HA were much closer to those experiments without irradiation. Therefore, the stability of the DSPC monolayer on the artificial seawater containing photosensitizers did not change much between the irradiated and dark experiments. The different results of relative area curve between the DOPC and DSPC monolayers implied that the different reactions were induced by photosensitizers under irradiation.

3.3 Ordering of lipid monolayers at the air-aqueous interface with or without irradiation

The molecular-level interactions of photosensitizers with DOPC and DSPC monolayers can be analysed by surface sensitive PM-IRRAS. The C-H stretching mode of methylene (-CH₂-) and terminal methyl (-CH₃) groups for the aliphatic chains of DOPC monolayer were located in the range of 2820–3050 cm⁻¹. In the dark experiment on pure artificial seawater (**Fig. 5(a)**) the bands at 2922 and 2853 cm⁻¹ were assigned to antisymmetric ($\nu_{as}(\text{CH}_2)$) and symmetric methylene (-CH₂-) stretching ($\nu_s(\text{CH}_2)$) modes, respectively. The antisymmetric ($\nu_{as}(\text{CH}_3)$) and symmetric methyl stretching ($\nu_s(\text{CH}_3)$) vibrations were observed at 2959 and 2882 cm⁻¹, respectively. The observation of the CH₃ bands indicated the *gauche* defects in the alkyl chain (Li et al., 2017). The CH stretching in the HC=CH group at 3023 cm⁻¹ was relatively weak. In the absence of photosensitizers, there were no significant changes of the IRRAS spectra for DOPC monolayer after 90 minutes of irradiation. For the DOPC monolayer on the artificial seawater containing IC molecules, the bands of $\nu_{as}(\text{CH}_2)$ and $\nu_s(\text{CH}_2)$ stretching were observed at 2923 and 2854 cm⁻¹, respectively. After 90 minutes of irradiation, the $\nu_{as}(\text{CH}_2)$ and $\nu_s(\text{CH}_2)$ bands were shifted to lower wavenumbers at 2921 and 2842 cm⁻¹, respectively. The shifts in the CH₂ bands could be

attributed to the changes in chain ordering and the interactions of the photosensitizing molecules with the hydrocarbon chain in the DOPC monolayer. The peak height intensity ratio between the antisymmetric CH_2 stretching (I_{as}) and symmetric CH_2 stretching (I_{s}) is usually used to assess the order of the organic monolayer packing (Aoki et al., 2016; Huang et al., 1982). When IC was added in the subphase, the ratio of peak height intensity between the antisymmetric CH_2 stretching and symmetric CH_2 stretching of the DOPC monolayer increased from 1.61 to 1.82 due to irradiation, indicating an increased order of the monolayer chains. With respect to DOPC mixed with the $\text{PM}_{2.5}$ sample (**Fig. 5(b)**), the ratio between I_{as} and I_{s} increased from 1.48 to 1.73 under irradiation. The band of $\nu(\text{HC}=\text{CH})$ at 3023 cm^{-1} shifted to 3020 cm^{-1} under the irradiation of the DOPC monolayer mixed with IC. The existence of the $\nu(\text{HC}=\text{CH})$ band in the irradiation experiment suggested that the aliphatic chain of DOPC molecules does not break at the initial position of the double bond. The new weak band at 3001 cm^{-1} that occurred after irradiation was also assigned to $\nu(\text{HC}=\text{CH})$ stretching. This band implied the formation of unsaturated products in the photosensitized reaction. The shifts in CH_2 and CH_3 bands to lower wavenumbers (**Fig. 5(e)**) indicate that the conformation order of the aliphatic chains increased in the DOPC monolayer after 90 minutes of irradiation. According to the shifts in these CH_2 and CH_3 bands in dark and irradiation experiments, IC was suggested to be the most efficient photosensitizer among the four samples in the photosensitized reaction of organic aerosol surface.

15

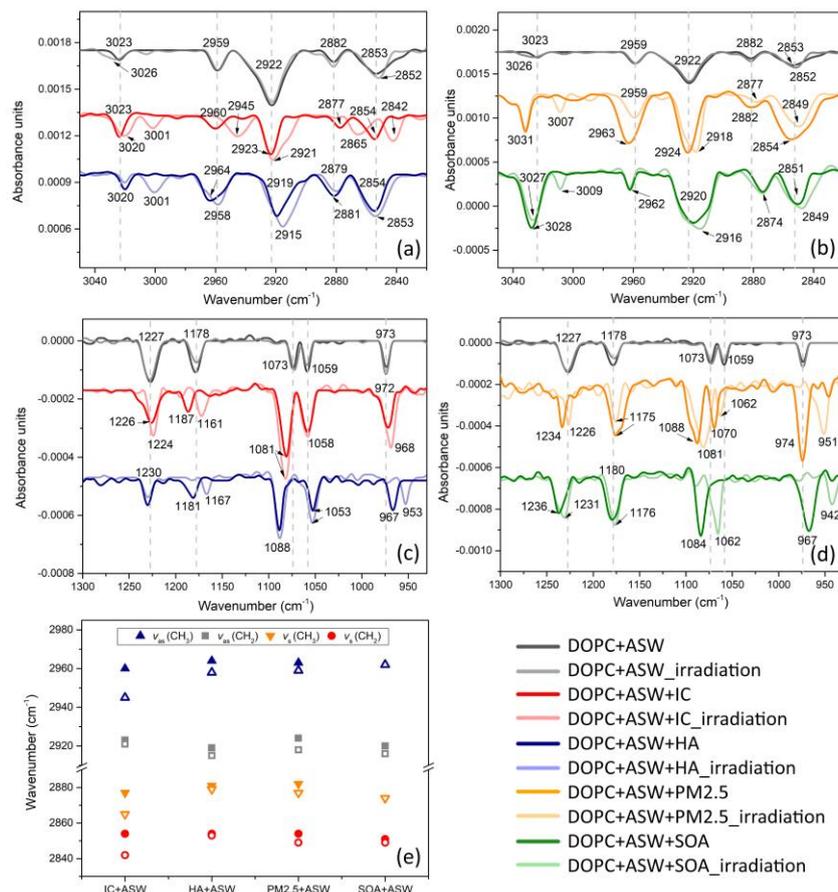

Figure 5: PM-IRRAS spectra of irradiated and non-irradiated DOPC monolayers in the range of (a) 2820-3050 cm⁻¹ and (c) 930-1300 cm⁻¹ on the artificial seawater containing IC or HA. PM-IRRAS spectra of irradiated and non-irradiated DOPC monolayers in the range of (b) 2820-3050 cm⁻¹ and (d) 930-1300 cm⁻¹ on the artificial seawater containing PM_{2.5} or SOA sample. (e) The frequencies of antisymmetric and symmetric stretching methylene (CH₂) and methyl (CH₃) vibrations for DOPC monolayer on the artificial seawater mixed with IC, HA, PM_{2.5} or SOA sample. IRRAS spectra were recorded at 25 mN/m. (Solid shapes: no irradiation exposure; Open shapes: irradiation exposure)

The antisymmetric P=O stretching ($\nu_{as}(\text{PO}_2^-)$) band and the symmetric stretching ($\nu_s(\text{PO}_2^-)$) band for DOPC monolayer on pure artificial seawater (**Fig. 5(c)**) were located at 1227 and 1073 cm⁻¹, respectively. The increase in relative intensity in the $\nu_s(\text{PO}_2^-)$ band at 1081 and 1088 cm⁻¹ suggests that IC and HA induce a strong interaction with a PO_2^- group in the DOPC monolayer. The bands of asymmetric carbonyl ester stretching ($\nu_{as}(\text{CO-O-C})$) at 1187 cm⁻¹ shifted to 1161 and 1167 cm⁻¹ for the DOPC monolayer mixed with IC and HA, respectively. The antisymmetric stretching of the choline group ($\nu_{as}(\text{CN}^+(\text{CH}_3)_3)$) at 973 cm⁻¹ was shifted to 967 cm⁻¹ due to the interaction of HA with the choline and phosphate groups in DOPC. For the DOPC monolayer on the artificial seawater containing SOA sample, the $\nu_{as}(\text{PO}_2^-)$ band at 1236 cm⁻¹ and

$\nu_s(\text{PO}_2^-)$ band at 1084 cm^{-1} (**Fig. 5(d)**) were shifted to 1231 and 1062 cm^{-1} , respectively. The shifts in the P=O stretching vibrations suggested that hydrogen bonding between phosphate groups and surrounding water molecules appeared to be affected by irradiation. The band at 1059 cm^{-1} assigned to $\nu_s(\text{C-O-PO}_2^-)$ vibration was shifted to 1070 cm^{-1} for the DOPC monolayer on the artificial seawater containing $\text{PM}_{2.5}$ sample. In the presence of the SOA sample in the subphase, the $\nu_{\text{as}}(\text{CN}^+(\text{CH}_3)_3)$ band of irradiated DOPC monolayer was shifted from 967 to 942 cm^{-1} , which indicated modifications in the packing of DOPC monolayer affected by irradiation.

The spectral shifts induced by the photosensitizer and irradiation were more drastic for DOPC monolayers than for the DSPC ones. With respect to the DSPC monolayer on the artificial seawater, the antisymmetric CH_2 stretching and symmetric CH_2 stretching (**Fig. 6(a)**) were 2919 cm^{-1} and 2851 cm^{-1} , respectively. The CH_2 bands in the DSPC monolayers were more intense relative to the DOPC monolayer, thus shifting to lower wavenumbers. This can be attributed to the formation of more a compressed and packed DSPC monolayer relative to DOPC. Lower wavenumbers of CH_2 bands are indicative of highly ordered conformation with *all-trans* characteristics (Simon-Kutscher et al., 1996; Christoforou et al., 2012; Snyder et al., 1978). Upon introducing IC into the subphase, the peak height intensity ratio ($I_{\text{as}}/I_{\text{s}}$) between the antisymmetric and symmetric CH_2 stretching vibrations of the DSPC monolayer increased from 1.47 to 1.67. The $I_{\text{as}}/I_{\text{s}}$ value decreased to 1.43 for the DSPC monolayer on the artificial seawater containing HA, indicating a slightly less ordered DSPC monolayer on the HA-containing subphase, as shown in the π -A isotherm. Minimal wavenumber shifts of P=O, C-O- PO_2^- and $\text{CN}^+(\text{CH}_3)_3$ stretching vibrations were observed under irradiation in **Fig. 6(b)**. This result suggests that the positions of choline and phosphate vibrations in the DSPC head groups were not affected by irradiation. According to the comparison with the IRRAS spectra of DSPC monolayer in dark condition, no products were observed during the 90 minute irradiation of the DSPC monolayer by 365 nm UV light.

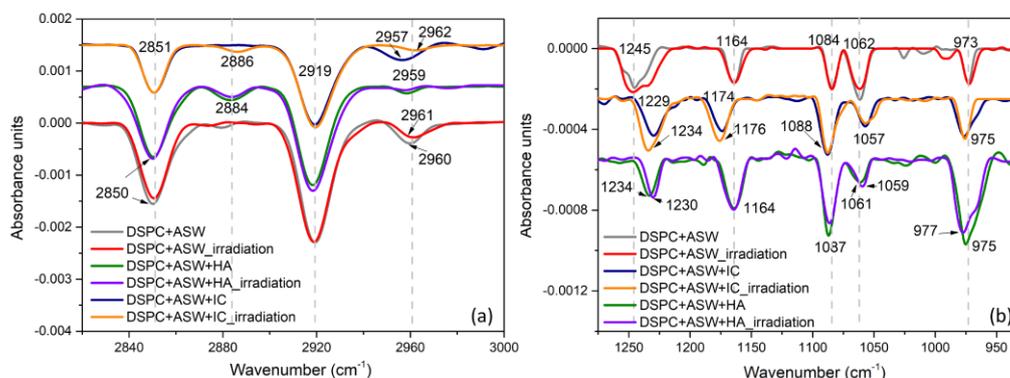

Figure 6: PM-IRRAS spectra of DSPC monolayers in the range of (a) $2820\text{-}3000\text{ cm}^{-1}$ and (b) $930\text{-}1275\text{ cm}^{-1}$ on the subphases of artificial seawater containing IC or HA with and without exposure to irradiation. IRRAS spectra were recorded at 25 mN/m .

3.4 Proposed mechanism for photosensitized reaction of lipid monolayers at the air-aqueous interface

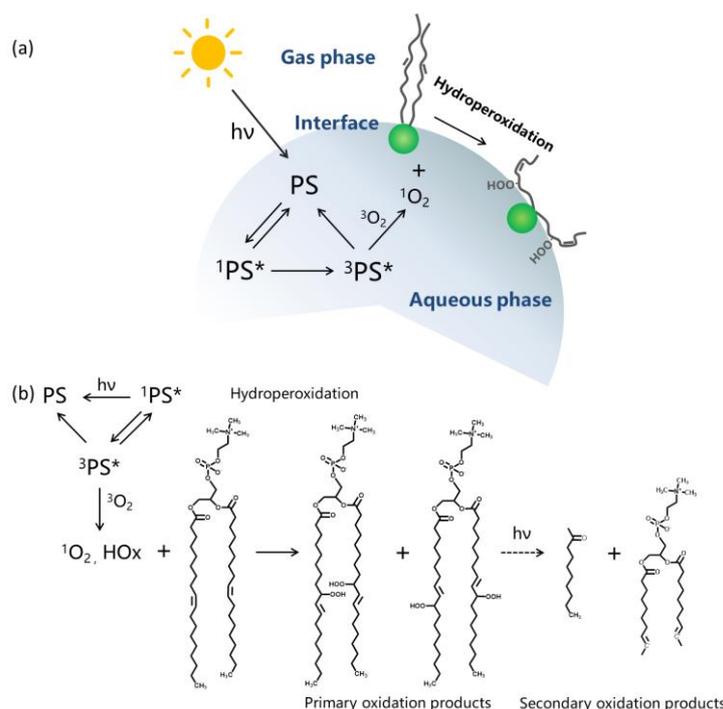

These light-absorbing organic aerosol species can participate in the aging of organic aerosol by acting as photosensitizers. Upon light activation, the excited triplet state of photosensitizer can undergo type I (electron transfer) and/or type II (energy transfer) reactions to generate a variety of highly reactive oxygen species (ROS) (Ding et al., 2011; Aguer et al., 1999). A type I reaction can reduce molecular oxygen (O_2), generating oxidizing radicals and radical anion species (e.g., $O_2^{\bullet-}$, HO^{\bullet}), while a type II reaction can transfer energy to O_2 to produce singlet oxygen (1O_2). The triplet excited state of IC ($^3IC^*$), HA ($^3HA^*$) and HULIS ($^3HULIS^*$) also can directly oxidize other organic material (Tsui et al., 2017; Tsui and McNeill, 2018; Shrestha et al., 2018).

These ROS, along with the triplet excited state of photosensitizers, can react with lipids at the air-aqueous interface, resulting in the photochemical aging of organic film on the aqueous aerosol surface. The slow oxidation of DSPC molecules at the air-sea water interface in the ambient environment does not produce sufficient surface-active molecules, leading to the loss of DSPC molecules from the surface. Previous irradiation studies suggest that green light (530 nm) induced little loss in the surface area of saturated 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) monolayer mixed with photosensitive erythrosine or eosin Y molecules (Pereira et al., 2018; Aoki et al., 2016). When considering the liposomal binary mixture of phospholipids containing 1,2-bis(10,12-tricosadiynoyl)-sn-glycero-3-phosphocholine ($DC_{8,9}PC$) and DPPC, $DC_{8,9}PC$ can produce intermolecular cross-linking following the release of 5,6-carboxyfluorescein dye under UV irradiation. The same photochemical reaction had no effect on DPPC molecules, even when exposed to radiation with a wavelength of 254 nm, which carries relatively greater energy (Kenaan et al., 2018). Both DSPC and DPPC molecules possess the same phosphocholine head and saturated aliphatic chain, which is likely why there rather similar activity of DPPC and DSPC with the photosensitizer under irradiation. We inferred that the photo induced reaction did not occur for DSPC monolayer based on the relative area relaxation curves and IRRAS results of DSPC monolayer.

Unsaturated lipids are more susceptible to the attack of 1O_2 and free radicals. Reactions of 1O_2 with unsaturated bonds in lipid chains can generate hydroperoxide (OOH) groups and then increase molecular area of lipid monolayer due to hydrophilic-hydrophobic balance of the modified chain (Caetano et al., 2007; Riske et al., 2009; Aoki et al., 2016; Pereira et al., 2018). The hydroperoxide group in DOPC is more water soluble than the aliphatic chain of DOPC (**Fig. 7 (a)**). Moreover, DOPC hydroperoxides may further transport toward the hydrophilic region of the monolayer and dissolve into the aqueous phase, leading to a larger surface area of the DOPC monolayer at the air-aqueous interface (Brault et al., 1986). In contrast to pure DOPC monolayer, the formation of hydroperoxides produced by hydroperoxidation reaction between 1O_2 and DOPC can be considered as the reason of the distinct relative area increase (Δ) in **Fig. 4(c)**. Giant unilamellar vesicles containing a large amount of unsaturated lipids exhibited a rapid increase in surface area, resulting in morphological changes under irradiation (Riske et al., 2009). Simulations of molecular dynamics also showed that the hydroperoxide group of lipids has a tendency to reside close to the surface with a concomitant expansion of surface area per molecule (Neto and Cordeiro, 2016; Wong-Ekkabut et al., 2007). The PM-IRRAS technique had no response at the OOH band; therefore, we didn't directly

detect DOPC hydroperoxides by IRRAS. The new bands of $\nu(\text{HC}=\text{CH})$ at 3001, 3007 and 3009 cm^{-1} also support the formation of unsaturated DOPC hydroperoxides present at the air-aqueous interface. The mechanism for the photochemical reaction of the DOPC monolayer by the excited photosensitizer is summarized in **Fig. 7 (b)**. Lipid hydroperoxides are the primary oxidation products and are relatively stable at room temperature. After the initiation phase of hydroperoxide formation, lipid hydroperoxides may further decompose to radicals, leading to the formation of ketones, aldehydes, carboxylic acids, alcohols, esters, and short-chain hydrocarbons (Ghnimi et al., 2017; Choe and Min, 2006). Free radical chain reactions increased the formation of secondary oxidation products. The unsaturated fatty acids also followed this mechanism during the processing of photosensitized oxidation.

10

Figure 7: (a) Proposed model for DOPC-photosensitizer (PS) interaction at the air-aqueous interface. (b) Possible/proposed mechanism for the photo-induced oxidation of DOPC in the presence of photosensitizer (PS).

Past research has proposed the mechanism for the photosensitized degradation of a saturated fatty acid by the excited photosensitizer at the air-water interface (Tinel et al., 2016; Shrestha et al., 2018; Alpert et al., 2017). The radical produced by the initial hydrogen abstraction of the fatty acid can undergo two possible pathways. In the first pathway, the radical-radical reactions were favoured in an oxygen-poor environment. In the second pathway, in an oxygen-rich environment, the reaction between fatty acid radicals and molecular oxygen can produce peroxy radicals which can further decompose to saturated ketones or other oxidized compounds with hydroxyl and carbonyl functional groups. Then, these compounds can

continue to react with molecular oxygen and the excited state of photosensitizer to produce fatty acid radicals and more highly oxidized species.

3.5 Atmospheric implication

Atmospheric aerosol particles are a mixture of a large number of inorganic and organic compounds. The different physico-chemical properties of aerosol components result in inorganic-salt aerosols being coated with a film of surface-active organic materials (Raymond and Pandis, 2003). The structure of the organic coated aqueous aerosol can be simplified as an aqueous core-shell model (Song et al., 2013; Tervahattu et al., 2005; Ellison et al., 1999). The presence of organic film on the aerosol surface can reduce the evaporation rate of water from droplets or particles (Nguyen et al., 2017; Davies et al., 2013). The transport and uptake of chemicals between the gas and liquid phase is affected by organic coating (Donaldson and Valsaraj, 2010). The organic film can reduce the scavenging by larger cloud droplets and affect the lifetime of aerosols (Toossi and Novakov, 1985; Gill et al., 1983). In addition, the optical properties of the droplet can be altered by organic coating (Donaldson and Vaida, 2006).

Atmospheric aerosols may contain light-absorbing BrC in the aqueous core. BrC, which is excited by visible and ultraviolet radiation in the sunlight, can act as photosensitizer to facilitate free radical reactions and contribute to photochemical aging of organic aerosol (Smith et al., 2014; Yu et al., 2014). The photosensitized uptake of limonene was also observed for several SOA materials containing a complex mixture of photosensitive organic compounds collected from the chamber (Malecha and Nizkorodov, 2017). When aerosols containing photosensitizers such as IC and HA were exposed to isoprene, limonene, α -pinene, β -pinene and toluene in the presence of UV light, there was significant SOA formation (Palacios et al., 2016). The gaseous products from interfacial photochemistry of organic film can act as precursors for SOA, while highly oxidized products are likely to be more water-soluble (Bruggemann et al., 2017; Alpert et al., 2017).

In this work, the more water-soluble products like DOPC hydroperoxides appear to dissolve into bulk artificial seawater and partition into the hydrophilic core of organic aqueous aerosols. Subsequently, the processes of hygroscopic growth of aerosol and cloud condensation nuclei activation are impacted. If the organic film on the aerosol surface is either destabilized under irradiation or it is metastable due to the loss of ordering and packing, the organic aerosol will become more permeable to water. As a result, the hygroscopicity of the aerosol particle and the overall size of droplet can increase (Ruehl and Wilson, 2014). Consequently, the atmospheric lifetime of unsaturated species on the aerosol surface can decrease. The photochemical reaction at the air-aqueous interface under the condition of BrC is an efficient and common pathway to remove low volatile organic compounds that are coated on the aqueous aerosols. Moreover, the photosensitized reaction of organic aqueous aerosol likely depends on the film-forming species, given the different reactivities of saturated and unsaturated phospholipids.

4 Conclusions

We have investigated the photosensitized reactions of saturated and unsaturated organic monolayers at the air–water interface as proxies for the photochemical aging of organic-coated aqueous aerosols by BrC. The surfactant molecules SA, EA, OA, DSPC and DOPC were chosen to investigate the effects of degree of unsaturation and conformation on the ordering, packing and stability of organic film. The surface areas of the unsaturated lipids (EA, OA and DOPC) with the double bond in the 9-position were much more expanded than the saturated conformations with the same chain lengths. The type of configurational isomers (*cis* and *trans*) affected the surface properties of the organic monolayer. The π -A isotherms suggested that the EA monolayer had a slightly higher compressibility than the OA monolayer. According to relative area increase curves, the addition of photosensitizers into the subphase increased the stability of DSPC and DOPC monolayers on the aerosol surface, irrespective of irradiation or non-irradiation. The saturated DSPC monolayer has greater photochemical stability than the DOPC monolayer. The formation of the DOPC hydroperoxide increased the relative area of the DOPC monolayer after irradiation. In addition, IC was the most efficient photosensitizer to increase the relative area of the DOPC monolayer, as compared to the laboratory generated SOA sample and field collected PM_{2.5} sample. The changes between the irradiated and dark PM-IRRAS spectra also support the hydroperoxidation of the unsaturated chains in DOPC. DOPC hydroperoxides were considered to be primary oxidation products during the photochemical oxidation of unsaturated lipids via singlet oxygen generation. The photosensitized reaction of DOPC monolayers at the surface of aqueous aerosol can lead to the formation of more oxidized and therefore less reactive species at the surface. Overall, the transformation of hydrophobic organic materials into hydrophilic organic components can alter the hygroscopicity of an organic aerosol particle.
